III-V semiconductors that are epitaxially grown on a GaAs or InP wafer can create thermo-optic interferometer optical switches, carrier-injection interferometer optical switches and SOA optical switches. The waveguide is formed using III-V materials of differing composition. Further, when using III-V semiconductor interferometric optical switches, non-switching SOAs can be monolithically integrated to provide optical gain to compensate for optical losses in the switch circuit. III-V semiconductors are ubiquitous for optical transmitters and receivers, but activity on III-V semiconductor optical switches has declined in the 2010s.

Silicon photonics (SiPh) is fabricated in the silicon layer of a silicon-on-insulator substrate, with silicon dioxide as the waveguide cladding. SiPh can create thermo-optic interferometer optical switches, carrier-injection interferometer optical switches and waveguide-MEMS optical switches. Activity on SiPh semiconductor optical switches has grown in the 2010s as SiPh manufacturing technology becomes more widespread. Silicon is transparent over the optical telecommunication wavelength band (1300 nm–1600 nm). It has high refractive index contrast $n[\text{Si}]/n[\text{SiO}_2] = 3.48/1.45$ which allows very dense circuit layouts. It is cheap and can be manufactured using legacy silicon electronics processes that have exceptionally good process control. The small waveguide size and large index step causes large propagation loss, which can be overcome using very wide waveguides for long-distance routes on the chip.

Interferometric Optical Switch

Mach-Zehnder interferometer optical switch

A Mach-Zehnder interferometer optical switch cell (Fig. 10) comprises a 50/50 input splitter, two internal optical waveguides and a 50/50 output combiner. Commonly used 50/50 couplers are multi-mode interferometers (MMI) and directional couplers. The two internal optical waveguides are nominally the same length. An electrically-controlled phase shifter on one or both arms changes the relative phase of the light on the two arms as it enters the output combiner, which causes the output light to move from one output waveguide to the other. When the phase difference between the arms is $2N\pi$, the switch is in cross state, which means that input 1 is connected to output 2 and input 2 is connected to output 1. When the phase difference between the MZ arms is $(2N+1)\pi$, the switch is in bar state, which means that input 1 is connected to output 1 and input 2 is connected to output 2.

This figure shows only the phase shifter(s) that perform the switching function. However, it is impossible to manufacture the two waveguide arms to have equal optical path length to within a small fraction of a wavelength. Therefore, carrier injection switches also have a static thermo-optic phase shifter to bias the initial phase. If care is not taken, the power consumption of this bias thermo-optic phase shifter dominates the power consumption of the whole switch.

Microring resonator optical switch

Microring optical switches use the thermo-optic effect or the carrier injection effect, and switch a single wavelength of light. They have been proposed for add/drop bus switches, but not to-date been commercially deployed for this purpose.

A microring resonator (MRR) couples light from an input waveguide to an output waveguide when the wavelength of the light resonates with the round-trip of the microring. Microring resonators are usually made in silicon photonics. The diameter of the ring is from several micrometers to tens of micrometers. A single microring has a sharp resonance peak with a Lorentzian lineshape. This lineshape is not compatible with most WDM transmission formats. Multiple microrings can be coupled to produce a flatter-top lineshape that is compatible with a conventional WDM signal.

A significant challenge is that MRR are highly temperature dependent, very sensitive to manufacturing variations, and difficult to maintain alignment with the desired wavelength. In addition, a single-MRR with a sharp Lorentzian transmission is not favorable in a high-speed data transmission system where flat-top response is preferred to minimize the signal waveform distortion and thus the data transmission errors.

Fig. 11 shows a schematic view of an optical add/drop bus, formed using microring optical switch cells. Each microring couples one wavelength from the through waveguide to the add/drop waveguides. Each microring contains a phase shifter. Varying the phase shifter using the thermo-optic effect or the carrier injection effect determines which wavelength is added/dropped.

Microring optical switches have also been used to create switch matrices, such as the crossbar illustrated in Fig. 12. Each microring couples light from a west-to-east input waveguide to a north-to-south output waveguide. The wavelength that is coupled is controlled by the phase shifter in the microring.

Fig. 13 Cross-section of a (a) thermo-optic phase shifter in silicon photonics (b) electro-optic phase shifter in lithium niobate substrate, and (c) carrier-injection phase shifter in silicon photonics or III-V semiconductor.

Optical phase shifters

Cross sections of typical phase shifters are shown in [Fig. 13](#). The phase change induced through the length of the phase shifter is $\Delta\phi = (2\pi\Delta n)/\lambda L$ where Δn is the change in the effective index of refraction of the guided mode due the electrical control, λ is the free-space wavelength of the propagating light, and L is the length of the phase shifter.

A goal of optical switching is to reduce the energy consumed per bit, compared to an electrical switch. However, a simple thermo-optic phase shifter in silicon photonics consumes around 30 mW of electrical power for π -phase shift (P_π), which is much larger than 1 pJ/bit for a complex circuit such as a 32-port matrix at a line rate of 100 Gb/s per port. A thermal undercut technique greatly improves the power consumption of a thermo-optic switch. [Fig. 14](#) demonstrates a thermo-optic switch cell in silicon

Fig. 14 Thermo-optic Mach Zehnder silicon photonic optical switch cell with thermal undercut: (a) schematic layout where a resistive heater (pink) located above one of the waveguide arms (blue) is used to change the index of refraction causing a phase shift in the propagating light wave, (b) microscope image of the fabricated switch.

Fig. 15 32×32 SiPh switch (a) packaged die containing 448 cells with 900 photodiodes, wire-bonded in CBGA and silica waveguide mode adapter couples 64-fiber ribbon to SiPh, and (b) system assembly comprising optical package on breakout board, fiber ribbon, detector A/D boards (on back of breakout board), and thermal test plate. photonics with thermal undercut. Deep trench windows are etched vertically on each side of the thermo-optic phase shifter, followed by anisotropic wet chemical etching of the silicon substrate locally under the heated region. This creates a suspended heater and waveguide, which has low thermal conductivity to the silicon substrate, reducing the power consumption by a factor of 20. In addition, folded waveguide arms under the heater increases the interaction length between the heater and waveguide, thus reducing the power consumption by a factor of the number of folds, which is typically 3. The energy consumption then falls to 100 fJ/bit for the entire optical switch matrix, which is competitive with electrical switches.

A demonstration of a fully-assembled, fully-functional thermo-optic 32×32 silicon photonic optical switch matrix with thermal undercut for reduced power consumption is shown in **Fig. 15**.

A better-isolated heater region consumes less power, but needs more time to tune. **Fig. 16** shows the time-response, when the switch is driven by an electrical square wave with amplitude $P\pi$. The 10%–90% switching time increases from 70 μ s without undercut, to 1.34 ms with undercut. Nonetheless, as described earlier, millisecond response time is appropriate for many applications.

In a carrier injection phase-shifter, the mechanism to actuate the switch is the free-carrier plasma dispersion effect in a lateral p - i - n junction, which is centered on the optical waveguide. A forward-biased current is passed through the junction, which increases the carrier density. The lifetime of the carrier density is 1–2 nanoseconds, and hence the switch time of the phase shifter is several nanoseconds. Therefore, this mechanism is appropriate for optical packet switches. The electrical consumption is typically 1 to 3 mA at about 1 V. The increase in carrier density creates a decrease in refractive index, which saturates as the carrier density increases. However, it also creates an increase in absorption which increases monotonically with carrier density. In silicon photonics, the refractive index change before saturation is large enough to create a push-pull switch with only 0.5 dB absorption loss per switch cell and extinction ratio of 25 dB, which is sufficient for a scalable optical switch. However, a push-only switch has

to be driven too hard into saturation, and the absorption loss is 2 dB per switch cell with extinction ratio of 18 dB or less, and therefore push-only carrier injection switches are not effective for scalable optical switches.

Semiconductor Optical Amplifier Switch

Semiconductor optical amplifiers (SOAs) are used in optical switches as an *ON-OFF* switch by varying the bias voltage. SOAs provide nanosecond switching times and broadband operation, have relatively high gain (15–28 dB) with saturation power in the range of +8 to +15 dBm, are small (100's micrometers to few millimeters in length), and can be integrated with other semiconductor and optical components. The typical architecture of an SOA optical switch is a split-and-block topology, integrating a bank of passive splitters, a bank of SOA, and a bank of passive combiners, as shown in Fig. 17. Larger port counts may use several stages. SOA optical switches demonstrated to date have up to 32×32 ports.

An SOA gate can be switched from a high-gain state to a high-loss state within a nanosecond, by changing the drive current from an electronic driver. The difference between large amplification in the *ON*-state and large absorption in the *OFF*-state provides very high extinction ratio, which is needed for the split-and-select architecture.

SOA optical switches have some performance weaknesses. They have relatively high power consumption, of 10's to 100's mW per SOA in the *ON* state, although the *OFF* state power consumption may be small or zero. Many SOAs are polarization dependent, thus requiring polarization diversity lightpaths or single-polarization networks. SOA are best used to carry a single wavelength, because they have large nonlinearity that causes mixing between signals on different wavelengths.

In an alternative use, SOAs serve as optical power amplifiers to compensate for optical losses in other types of planar lightwave optical switches. III-V semiconductor gain elements can be heterogeneously integrated onto a silicon photonic circuit, with the Si and InP chips independently optimized for high performance, reliability and yield.

Waveguide-MEMS Optical Switch

A waveguide-MEMS switch is a planar lightwave optical switch, using waveguides that are moved by micro-mechanical actuators. Each moving waveguide is one half of an adiabatic waveguide coupler. Each switch cell comprises a pair of adiabatic couplers joined by a 90° bend (Fig. 18(a)). In the *OFF* state, the coupler waveguides are moved away from the bus waveguides, and there is no light coupled between the bus waveguides. Upon application of a voltage to the actuator electrodes, the two movable waveguide couplers are brought in close vicinity of the bus waveguide, creating optical coupling between the fixed and the movable waveguides. In the *ON* state, the optical signal is thus routed from the input port to the desired drop port. The switching time is 10's of microseconds.

A 50×50 optical switch has been demonstrated, using an optical crossbar. The insertion loss compares favorably to other technologies.

Tunable Laser Optical Switch Technologies

A tunable laser optical switch comprises a rapidly-tuned laser at the source, and passive routing using an arrayed waveguide grating routing (AWGR). The switch is illustrated in Fig. 19 and the behavior of the AWGR is illustrated in Fig. 20. To select a destination, the wavelength of a laser is tuned so that the light comes out from the desired output port of the AWGR.

The actuator is in the transmitter – in this manner, the tunable laser optical switch is fundamentally different to all other types of optical switch that are described in this article, as in all other cases the actuator is in the core switch.

An AWGR is similar to the more widely-used optical demultiplexing AWG, where an optical input fiber carries light of multiple wavelengths. The light power is split, passes through an array of curved waveguides of unequal length, and then recombines in a star coupler. The star coupler has multiple output waveguides, and the phase relationship of the curved waveguides is constructed so that light from each wavelength interferes constructively at only one of the output waveguides. An AWGR is similar, except that the input coupler has multiple input fibers, and the geometry is organized so that the mapping of input wavelength at output ports is cyclical. A typical AWGR has -25 dB adjacent channel crosstalk, 7 dB insertion loss, and 3 dB uniformity.

Tunable laser optical circuit switches have been used experimentally for core router growth and for switch core growth (see earlier section for definition of these applications). In both cases, the switching time is limited by the time that it takes to accurately switch the wavelength of the laser. Microsecond switching time is possible, but control is very challenging at nanosecond switch time. Scalability is limited to 40 ports, and AWGRs cannot be cascaded to form large port count systems. Also, AWGRs require DWDM transmitters, which are not commonly used within data centers or high performance computers as they are expensive and consume a large power.

Why Do We Need Photonic Integration?

To overcome fiber transmission impairments at higher modulation rates – and to overcome speed limitations of optical and electrical components – optical transceiver architectures increasingly rely on transmission components with multiple functional elements (lasers, modulators, power splitters/combiners and wavelength multiplexers). For example, 100, 200, and 400 Gb/s optical transceiver architectures for the local area network applications combine 25 Gbaud on-off keying (OOK) or four-level pulse amplitude modulation (PAM4) with multiplexing four or even eight wavelengths into one single-mode fiber (LAN/MAN Standards Committee of the IEEE Computer Society, 2010). In the metro, and long-haul space, demand for increased line-card density and reduced power dissipation is being supported by 10 Gb/s SFP + transceivers, either operating at a fixed wavelength or tunable over the C-band. This application utilizes traditional OOK modulation format and requires an externally modulated laser to meet the requirements for dispersion tolerance. In addition, starting from 40 Gb/s, long-haul and metropolitan area telecom applications adopted advanced modulation formats, including polarization multiplexing and multilevel quadrature amplitude modulation (Winzer, 2012). A polarization-multiplexed advanced-modulation-format transmitter requires a laser and two quadrature modulators, typically realized using a nested Mach-Zehnder (MZ) architecture. Widespread deployment of the coherent technology in the datacenter interconnects and metro space requires development of new photonic components that are able to support cost-effective, compact, high efficiency pluggable coherent transceivers.

The requirements for increased optical transmission speed and complexity combined with stringent constraints on cost, size, and power dissipation can be met only by implementing photonic integration to replace several packaged components with one.

What Is Photonic Integration?

Generally speaking, photonic integration refers to any technology that combines two or more functional optical elements to replace several separately packaged components with one. Photonic integration can be categorized into several types: Monolithic integration combines multiple active and passive optical elements fabricated on a single semiconductor chip to form a Photonic Integrated Circuit (PIC). Heterogeneous integration refers to a technology that uses dissimilar materials to provide full set of optical functions (e.g., heterogeneous integration of InP-based epitaxial material with Si photonics enables optical gain function). Finally, hybrid integration co-packages several active optical components that are optically coupled using micro-optics or planar lightwave circuits. In practice, a combination of hybrid and monolithic integration is frequently used. As the title of this article suggests, we will focus on monolithic PICs technology in InP.

Monolithic integration provides a drastic reduction in system footprint, inter-element optical coupling losses, power dissipation, and assembly and test cost. To illustrate the reduction in size, Fig. 1 compares optical components that are required to realize transmission function using discrete laser and modulator with the same functions integrated on an InP PIC. In addition, monolithic integration frequently results in improved reliability since no relative shifts of different optical elements are possible.

Fig. 1 Optical components required to realize 10 Gb/s C-band tunable transmitter: (a) C-band tunable laser diode module and Lithium Niobate modulator; (b) InP photonic integrated circuit with the same functionality – C-band tunable laser integrated with Semiconductor Optical Amplifier and Mach-Zehnder modulator.

Functional Requirements

The primary functions required to implement high-functionality PICs include (1) light-generation and amplification, (2) high-speed phase and/or amplitude modulation, (3) photodetection, and (4) optical routing. Optical routing functions may include only passive elements such as splitters, combiners, etc. and variety of functional elements that rely on the active refractive index tuning to adjust the optical phase. Fortunately, fundamental material properties of indium phosphide (InP) and related quaternary indium gallium arsenide phosphide (InGaAsP) and indium aluminum gallium arsenide (InAlGaAs) compounds enable all required functionalities.

In most cases, all functional sections of an InP PIC are *p-i-n* heterostructure diodes, with i-waveguide core containing bulk quaternary material or multiquantum well (MQW) layers. In general, different materials have to be employed to optimize the performance for each of the functional elements as schematically illustrated in Fig. 2. Specifically, active regions of a high performance laser typically require several relatively narrow compressively strained QWs with the fundamental transition energy close to the target photon energy. The laser MQW active waveguide is typically surrounded by a separate confinement heterostructure to maximize overlap between the optical mode and injected carriers. The upper and lower InP cladding regions are relatively heavily doped to minimize resistive heating. Electroabsorption (EA) and electro-optic MZ modulators in InP material systems fundamentally rely on the quantum-confined Stark effect, which produces red shift of the MQW absorption edge and change of the refractive index when reverse bias voltage is applied to p-i-n hetero-structure. In contrast to the laser, active regions of high efficiency, high speed EA and MZ modulators are blue shifted relative to the operating wavelength and typically require wider QWs to increase the efficiency of the quantum confined Stark effect. For EA modulators the difference between operating wavelength and modulator absorption edge wavelength, known as detuning, is chosen such that the absorption is negligible in the absence of reverse bias but increases rapidly as reverse bias is applied. MZ modulators are designed with larger detuning to achieve efficient index tuning without introducing excess loss. It is always desirable to be able to select the number of the QWs in a modulator active material for a specific performance targets: modulation bandwidth and drive voltage. The optical routing sections of the PIC require material with a bandgap larger than operating photon energy and low doping to minimize propagation loss. They can employ bulk or MQW material. The refractive index tuning can be accomplished through carrier injection mechanism by forward biasing the p-i-n diodes, voltage induced refractive index change under the reverse bias as outlined above, or thermal index tuning mechanism using local resistive heaters. Finally, light detection components require materials with a bandgap smaller than the photon energy to ensure efficient optical absorption.

To ensure high performance of the PIC based devices an integration technology has to provide flexibility in design optimization for different functional elements, efficient optical coupling between them and absence of parasitic reflections that can detrimentally affect laser wavelength stability, noise, and chirp. It is also desirable to minimize the transition regions between different functional sections. Ideally the spacing between different functional sections is selected based on the required electrical and thermal isolation and not constrained by the dimensions of transitions.

InP Integration Technologies

Active-Passive Axial Waveguide Integration

The compelling advantages and possibility of monolithic photonic integration in InP have been recognized from the early 1980s, and multiple approaches to integrate regions with different absorption/gain properties together along a single waveguide have been developed and are widely used in InP PIC fabrication (Coldren *et al.*, 2013).

Fig. 3 illustrates five most common techniques employed for monolithic integration of regions with different absorption/gain properties together along a single waveguide. For Offset Quantum wells Fig. 3(a) and twin waveguide Fig. 3(b) integration technologies different optical functions are separated into vertically displaced waveguides and the integration is realized by selective removal of the unwanted upper waveguides. Selective Area Growth (SAG) technology Fig. 3(c) relies on variation of the local material growth rates and hence the transition energy of the MQWs by changing the width of the pre-patterned dielectric masks before material growth. Quantum well intermixing technology Fig. 3(d) blue shifts the MQW region absorption edge by

Fig. 2 Schematic band diagrams of the different functional sections of an InP PIC: (a) laser, (b) electro-absorption or Mach-Zehnder modulator, (c) passive waveguide, (d) photodiode.

Fig. 3 Active/passive waveguide integration approaches: (a) Offset Quantum wells, (b) twin waveguide, (c) Selective Area Growth, (d) Quantum well intermixing, (e) Material regrowth, (f) Material regrowth combined with selective area growth.

impurity or point defect assisted atomic inter-diffusion between the wells and barriers at a high annealing temperature. In the Material regrowth technology [Fig. 3\(e\)](#), different optical functions are created by sequential material removal and growth in different regions of the wafer. Several of the integration technologies can be further combined to achieve desired functionality. For example, as illustrated in [Fig. 3\(f\)](#) material regrowth can be combined with SAG by tailoring the dielectric mask shape and thus local waveguide thickness to match laser or modulator waveguide on the left and thin core waveguide for a spot-size converter on the right.

The ‘offset quantum-well’ technology and its variance, the ‘dual-quantum-well’ structure is the most simple integration approach. In this technology the waveguide is subdivided into a wider band-gap section at the bottom and a narrower bandgap MQW stack to be used as a gain section for a laser or an SOA at the top. The bottom section of the waveguide can be made of bulk quaternary alloy or contain a MQW stack embedded in the bulk waveguide. These closely spaced sections are grown in one epitaxial run and form single waveguide that supports only fundamental mode. The gain MQW material is selectively removed in the regions intended for modulators and passive waveguides and, if required, grating is etched into the passive waveguides. A single blanket regrowth of the InP cladding and InGaAs contact layer completes the manufacturing process. Offset quantum-well technology results in relatively low gain confinement factor that limits performance of lasers and SOAs with exception of booster amplifiers where low confinement factor is desirable for achieving high saturation power. However, this technology is very attractive due to its simplicity and manufacturability and has been successfully employed to demonstrate a variety of high performance PICs including widely tunable lasers integrated with SOAs, EA and MZ modulators (see reference [Coldren et al. \(2011\)](#) and references therein).

Another approach for monolithic photonic integration was developed based on twin-guide (TG) technology. As illustrated in [Fig. 3\(b\)](#), a TG structure consists of active and/or passive devices formed in separate, vertically displaced waveguides. In difference from the offset quantum well structures, the waveguide layers in TG structures are spaced further apart. Such waveguide structure can support two optical modes (even and odd). Enhanced version of TG integration technology uses asymmetric twin guides (ATG) structure designed with different effective indexes of the active and passive waveguides. Light is transferred between the waveguides via lateral, adiabatically tapered mode transformers, allowing different optical functions to be realized in the different waveguides. The design of ATG structures and adiabatic tapers were described in details in [Xia et al. \(2005\)](#). The optimum design of the taper (shape and length) depends on the asymmetry of the ATG and the authors’ analysis shows that using the optimal taper shape, a transfer efficiency of 90% can be achieved with the taper length of 290 μm . However, regardless of the fabrication simplicity, AGT technology carries significant drawbacks. These include long tapers, ~ 0.5 dB coupling loss between neighboring sections, and absorption in the gain tapers if left unpumped. Pumping can be extended to include the tapers but even then the gain and saturation power of the SOAs can be significantly compromised in the output taper. Alternative approach is to use QWI to blue-shift the absorption edge of the active material in the taper. Overview of the PICs that have been realized using ATG technology is provided in reference ([Menon et al., 2005](#)). To list a few, these include EMLs, SOA/p-i-n detectors, integrated TG lasers, and integrated arrayed waveguide grating/p-i-n detector.

Quantum well intermixing (QWI) is an effective post-growth technique for increasing the bandgap energy of QWs in the desired locations on the wafer thus integrating laser gain with modulator and passive sections. QWI techniques has been used for

Fig. 4 Schematic representation of a QW potential profile as grown (solid) and after inter-diffusion of atomic species at QW/barrier heterointerfaces (dash).

the fabrication of various PICs in InGaAsP and InAlGaAs MQW materials and relies on inter-diffusion of atomic species at QW/barrier hetero-interfaces at elevated temperatures. Intermixing of the as-grown rectangular wells and barriers results in a graded potential profile and blue shift of the transition energy for the fundamental confined state for electrons and holes as schematically illustrated in Fig. 4. The inter-diffusion process is enhanced dramatically in the presence of point defects or vacancies in the interface region. This enhancement of the intermixing is used to provide spatial selectivity of the band gap shift that is required for monolithic integration. Several intermixing techniques including impurity induced disordering, impurity-free vacancy enhanced intermixing, and ion-implantation enhanced intermixing have been developed.

We will describe the latter two techniques in more details. In the vacancy enhanced QWI process the areas of the wafer that require wider bandgap are capped with a dielectric mask and the wafer is subjected to Rapid Thermal Annealing (RTA) typically at the temperature range of 700–800°C for approximately 30 s. The out-diffusion of group III elements at the semiconductor/dielectric interface create vacancies that rapidly propagate into QW region enhancing the rate of QW intermixing. Vacancy induced QW intermixing has been employed to achieve large bandgap shifts (> 100 nm) in InGaAsP and AlGaAs MQW structures.

The most complex and high performance PICs were realized using implant-enhanced QWI process. This method has been employed for InGaAsP and InAlGaAs materials and produces good spatial resolution and controllable band-gap shifts using anneal time, temperature, and implant dose. Furthermore, any number of QW band edges can be achieved on the same wafer using selective removal of the catalyst.

We will describe implant-enhanced QWI process in more details using widely tunable sampled-grating DBR (SG-DBR) laser-EA modulator PIC reported in Skogen *et al.* (2005) as an example. In the first step, passive and modulator device regions are defined by selectively implanting phosphorous (P+) to introduce point defects into a sacrificial InP implant buffer layer grown above the MQW active region. Next, an RTA step is performed to shift the MQW band edge to that desired in the EAM regions (~ 35 nm). Once the EAM band edge is reached, the point defects are removed in the EAM region by selective removal of the InP implant buffer layer. The annealing is then continued until the desired band gap shift is reached for the tuning sections of the laser (~ 95 nm). Finally, blanket regrowth of the upper cladding and contact layer completes the formation of the waveguide in vertical direction.

Similarly to offset QW integration technology, implementation of PICs based on QWI requires only two epitaxial growth steps. However, QWI technology offers several significant advantages that include ability to place active QWs in the center of the waveguide and therefore maximize gain confinement factor, absence of multiple hetero-barriers and low doped material under the gain sections, ability to use band-gap shifted QWs in the carrier injection tuned phase sections therefor achieving higher index tuning efficiency due to band-filling effect in the step-function density of states. Finally, since QWI does not change the average material composition in the optical waveguide but only slightly changes the compositional profile, the index discontinuity and mode shape miss match at the interface between adjacent sections are small. This results in very low optical coupling loss and eliminates parasitic reflections between adjacent functional sections.

The drawbacks of the QWI techniques include shared number of QWs throughout the PIC and requirement for careful calibration of the intermediate band-gap shifts. The intermixing must also be done in the absence of other rapidly diffusing species in the wafer, such as zinc. Hence, regrowth of the p-doped cladding has to be done after the intermixing step resulting in somewhat poor controllability of the doping profile just above the active regions of the laser and modulator.

SAG has been employed in photonic integration using Metal-Organic Chemical Vapor Deposition (MOCVD) for InGaAsP and AlGaInAs bulk and MQW materials. With SAG technology different band-gap materials can be defined simultaneously using single epitaxial growth with patterned dielectric mask. In the absence of deposition on the mask, extra material is available over the masked zone resulting in the lateral concentration gradient. The gradient leads to extra lateral diffusion of species around the mask and to a local enhancement of the growth rate in the vicinity of the mask. In addition, since the diffusion coefficient in the vapor phase and sticking rate constant to the wafer surface are different for different species, the growth enhancement is accompanied by composition, band-gap, and strain variation as shown schematically in Fig. 5. The region between the mask stripes is used for the laser section and has thicker MQW stack, narrower band-gap, and slight compressive strain. Note, that in the case of MQWs both the composition and QW width are contributing to the red shift of the effective band-gap. Band-gap shifts up to 150 nm for MQW

Fig. 5 Selective area growth: (a) top view of the mask layout and illustration of variation of waveguide thickness (b), material band-gap (c), and strain (d).

material and growth enhancement factor of ~ 2.5 can be achieved with appropriate design of the mask pattern. Examples of PICs fabricated using SAG include DFB-EA, tunable DBR-EA, wavelength selectable DFB arrays, and spot-size converters.

Three dimensional vapor phase diffusion models have been successfully developed and can accurately describe spatial variation of the thickness, composition, bandgap, and biaxial strain of the materials grown with different dielectric mask shapes. The models were validated by employing optical interferometer microscopy, high-resolution micro-photoluminescence, and micro X-ray. The models allow for constructive engineering of the waveguide thickness and composition through the manipulation of dielectric mask shape and also can predict undesired spatial variation that can occur due to neighboring mask cells in the case of high mask density.

The best applications for SAG technology include multi-wavelength laser arrays and spot size converters. Multi-wavelength laser arrays require adjustment of the MQW band-gap of 40 and 60 nm to cover C-band and CWDM O-band grid, respectively. Such band-gap engineering is well within SAG capability. In the case of a spot size converter both waveguide thickness and refractive index can be tapered to produce lossless interface with the rest of the PIC and the desired mode field diameter at the SSC output. In the case of a laser-electroabsorption modulator integration SAG can produce sufficient band-gap shift but limits freedom to optimize the material for each functional section. The design has to rely on the same number of QWs and doping throughout the PIC. In addition, SAG produces wider QWs for the laser and narrower QWs for the modulator imposing severe trade-off between laser and modulator efficiency and adds relatively long ($\sim 100 \mu\text{m}$) transition regions. Such design trade-offs have proven to be acceptable for 2.5 and 10 Gb/s components. However, as the industry moves to 100 and 400 Gb/s transmission, more stringent requirements imposed on the modulation speed and PIC output power will require independent optimization of each functional section and therefore favor regrowth integration.

Among various integration technologies, regrowth integration is the only technology that enables flexibility in the design optimization of each PIC section with minimum transition length. In the regrowth integration technique, the laser gain layer stack is typically grown first on a planar substrate and then protected with a dielectric mask where it is required in the PIC. The exposed gain layers are then etched away, and the layers for the next functional section are grown. This process can be repeated several times to produce optimized layer stack for each PIC section. The primary advantage of the regrowth integration technology is that the layer composition (bulk or MQW) and doping can be changed abruptly, and therefore optimum design can be independently selected for each of the functional sections. The coupling loss between the neighboring sections are primarily determined by vertical alignment of the waveguides which can be controlled to very high accuracy by using selective etch. Even with the perfect vertical waveguide alignment some band-gap engineering is usually required to improve mode overlap and index matching at the transition. Well-designed regrowth transition can consistently produce less than 0.1 dB loss.

InP Waveguides

After the active-passive waveguides are defined along the light propagation direction lateral waveguide geometry has to be chosen based on the desired functionality of the PIC elements. **Fig. 6** illustrates several choices that are available in InP technology. They are arranged from highest to lowest index contrast as indicated in the figure. The deep- and shallow-ridge waveguides are formed by etching after all epitaxial steps are completed. The deep-ridge is fabricated using dry etch technique and due to high index contrast is suitable for bends with small radius of curvature. This type of waveguide is most frequently used as a routing guide for large scale PICs when multiple 90 degree bends, U-turns, and waveguide crossings are required to minimize the chip footprint. The deep-ridge waveguide is also the technology of choice for high-speed Mach-Zehnder modulators since in this geometry the active

Fig. 6 Lateral waveguide cross-sections available in InP technology: (a) deep ridge, (b) buried channel, (c) shallow or surface ridge, (d) buried rib.

Fig. 7 Fabrication flow for planar buried hetero-structure laser.

region capacitance is determined only by the area of the waveguide without parasitic contribution of the electric field fringing effect in the surrounding material.

The shallow ridge waveguide (also called surface ridge) is fabricated through a combination of dry and selective wet etching. Selective wet etch produces very smooth sidewalls with the ridge profile depended on the crystallographic orientation. Due to the selectivity of the wet etch, the depth of the shallow ridge waveguide is controlled precisely. This type of lateral waveguide is a popular choice for many functional section of InP PICs. It is especially well suited for fabrication of CW lasers (FP, DFB, and DBRs), SOAs, and electro-absorption modulators. In contrast to MZ modulators, EAMs are usually short and very high modulation bandwidth can be attained even with larger junction capacitance of the shallow ridge structure.

The buried channel and buried rib waveguides must be defined prior to epitaxial regrowth. If such waveguides are intended for low loss routing they can be capped with thick undoped layer of InP. Buried channel waveguide is also used for manufacturing of high performance CW and directly modulated lasers (DMLs) and laser arrays by using PN or PNIN regrowth to block carrier flow around the active waveguide. **Fig. 7** illustrates the fabrication sequence for a planar buried heterostructure laser. The process starts with the growth of the grating layer followed by the grating etch and regrowth of a spacer and MQW laser active. The lateral waveguide is formed using a combination of dry and wet etch and several layers of InP with different doping are re-grown with the mask still in place. Finally, the mask is removed and the top cladding and contact layers are grown. PN blocking structure is effective for CW lasers but produces very high parasitic capacitance, so Fe-doped InP i-region sandwiched between n-doped InP layers forming PNIN blocking structure is used as an alternative for manufacturing of high-speed DMLs or electro-absorption modulated lasers (EMLs). The advantages of this technology include low threshold current and high differential gain for the lasers due to reduced active region volume and the fact that carriers are confined to the center of the optical mode, relatively symmetric output beam, and good thermal properties. However, this technology adds critical regrowth step with regrowth interfaces positioned along the whole cavity length between MQW active and the blocking. Since the carriers can diffuse rapidly in the QW layers, non-radiative recombination at these interfaces can be detrimental to laser performance and reliability. Excessive parasitic capacitance can limit modulation bandwidth even if PNIN blocking structure is used due to high dielectric constant of InP. Parasitic capacitance can be somewhat reduced by etching trenches to narrow the width of the blocking structure as shown in **Fig. 7**. Finally, it is difficult to engineer low loss, low reflection couplers between a buried heterostructure laser and deep-ridge routing waveguides and high-speed MZ modulators if such laser is used a part of a PIC. This is due to the significant mismatch in the optical mode sizes and effective refractive indexes and the fact that such transitions have to rely on the precise lithography since the mask used to fabricate buried waveguide section is removed prior to the regrowth of the cladding.

Transitions between different waveguide types are essential elements of the integration technology. Transition between deep- and shallow ridge waveguide is the most frequently used transition in large scale PICs that incorporate lasers and SOAs together with high speed MZ modulators and high functionality routing sections. Fortunately, since both types of waveguides are formed after regrowth of the top cladding, this transition can be fabricated using the same dielectric mask to define the waveguide along

the light propagation direction. In this self-aligned process, the coupling efficiency is not impacted by the accuracy of the lithographic alignment and, as described in reference (Coldren *et al.*, 2011), the waveguide mask can be tapered to ensure better overlap between the modes in the shallow and deep ridge sections. Transitions between buried ridge and other ridge types have to rely on an accurate alignment of the surface ridge waveguide mask to the underlying buried waveguide. However, even in this case coupling efficiency in excess of 95% with large manufacturing tolerance ($\pm 0.3 \mu\text{m}$) can be obtained by tapering both waveguides at the junction.

Low loss InP waveguides

Losses in InP photonic waveguides are dominated by scattering loss and absorption provided that the material composition is chosen such that the contribution of the direct band-gap absorption is negligible. Smooth sidewalls are essential for achieving low loss single mode waveguides. As process control improves, the p-doped cladding becomes the most important contribution to loss through inter-valence band absorption. The n-type free carrier absorption is dominated by intra-valley transitions and requires interaction with phonon or ionized impurity scattering to provide conservation of momentum and thus much less significant than p-type absorption. This analysis implies that low loss waveguides on an InP PIC have to be fabricated with undoped cladding or p-doping has to be setback far enough to have negligible overlap with the optical mode. Optical propagation loss below 0.3 dB/cm has been demonstrated for shallow and deep ridge waveguides with doping setback. Excess loss below 0.1 dB per 90 degree turn with 100 μm radius of curvature can be readily achievable in deep ridge waveguides.

Since InP PICs typically include laser and SOA functions, special care has to be taken to suppress parasitic reflections that can occur due to abrupt changes in optical cross-sectional areas or/and effective index of the different components. Such reflections can detrimentally affect noise properties of the laser, introduce adiabatic chirp if reflection occurs after a modulator, and create gain ripples in the SOAs. Tilting the transitions with refractive index discontinuities and introducing tapered features at the transitions from shallow to deep waveguides and between single and multimode regions enables to maintain sufficiently low reflection level without introducing excess loss. Detailed description of splitters, polarization devices, microbends, and de/multiplexers developed for high-functionality InP PICs can be found in Williams *et al.* (2015).

Finally, ion implantation can be employed for electrical isolation between different functional sections of the chip. Hydrogen implant is typically used for passivation of p-doped material. Helium implant can be used for electrical isolation of n-doped material. In both cases the implantation dose and energy need to be tailored to provide the desired isolation without introducing excess optical loss.

We encourage the readers to follow up on the references provided above to learn more about high performance InP PICs developed in various integration platforms. In the last part of this article we will discuss design and performance for several InP PICs fabricated using regrowth integration. However, it is important to understand that the choices that PIC designers have to make are not limited to the integration technology but also include appropriate selection of the architecture (e.g., EA vs. MZ modulator) and additional functional elements that can be included in the PIC to further alleviate design trade-offs and increase fabrication tolerances, enhance functionality, and achieve sufficient margin relative to all performance specifications to enable high manufacturing yield and ultimately low cost. As we describe the PICs, we will point out why certain integration technology, device architecture, and features were adopted for each specific application.

Integrated (C-Band Tunable) Laser Mach-Zehnder Modulator (ILMZ) PIC

Development of ILMZ PIC drastically reduced footprint and power consumption of widely tunable optical transmitters and enabled transition of 10 Gb/s DWDM metro and LH transmission architecture from discrete implementations on a linecard or in 300 pin transponders into the realm of small form factor pluggable modules such as T-XFP and SFP+.

As illustrated in Fig. 8(a), ILMZ PIC consists of a four-section SG-DBR laser, an SOA, and a MZ modulator. The SG-DBR laser is an efficient widely tunable laser source that can be easily integrated with other optical components. This laser was pioneered at UCSB and was used in a variety of high functionality PICs. An SG-DBR laser is a PIC in itself and consists of a MQW gain section

Fig. 8 (a) Schematic cross-section of ILMZ PIC. (b) reflectivity spectra of an SGDBR laser.

Fig. 9 Performance characteristics of ILMZ PIC based transmitter: (a) modulation voltage vs wavelength across C-band, (b) eye diagram at 10.7 Gb/s.

positioned between sampled-grating DBR mirrors. SG-DBR laser utilizes Vernier effect to achieve wavelength tuning in excess of 40 nm with only moderate index tuning in the mirrors. The detailed description of an SG-DBR laser is given in Coldren *et al.* (2004). In brief, by imposing additional periodicity on the holographically defined grating the reflectivity spectra of the mirrors are transformed into combs of reflectivity peaks as shown in Fig. 8(b). The spacing between adjacent peaks is inversely proportional to the grating sampling period. Selecting different sampling periods for the front and back mirrors ensure that only one set of reflectivity peaks can coincide for a particular set of mirror tuning currents resulting in lasing at the specified wavelength. The laser is tuned by adjusting currents in the mirrors to bring the desired reflectivity peaks into alignment. The phase section is used for alignment of the cavity mode to the peak of mirrors' reflectivity. Continuous tuning can be achieved by tuning both mirrors simultaneously. The specific design of SG-DBR laser implemented in ILMZ PIC uses carrier injection index tuning mechanism. Carrier injection is very efficient and fast refractive index tuning mechanism but it introduces cavity losses caused by free carrier absorption. Therefore it is highly desirable to integrate an SOA as an independent power adjustment knob. The integrated SOA compensates modulator loss and cavity losses caused by free carrier absorption in the tuning sections and allows wavelength independent power leveling, beam blanking during wavelength switching, and variable optical attenuator functionality.

Finally, MZ modulator is selected since the device has to operate over full C-band with high extinction ratio and good control of the chirp. Chirp of a differentially driven InP MZ is determined by the build in phase shift and split ratio and thus can be optimized (negative or zero) for the target application.

The PIC is fabricated using regrowth technology for lossless integration of the laser and SOA MQW active regions with the bulk quaternary mirror and phase sections, and independently optimized MQW MZ modulator section. Shallow ridge waveguide is used throughout the PIC. As described above, shallow ridge waveguide is the most simple and robust choice among the possible waveguide structures. From manufacturability point of view, shallow ridge is optimum technology choice for applications that require a single MZ with a moderate bandwidth. Fig. 9 shows some of the key performance characteristics of ILMZ based optical transmitter. Notably, the differentially driven lumped MZ modulator requires less than 1.6 Vpp of modulation voltage per arm. Such low drive voltage is compatible with low power dissipation modulator drivers and is another very important factor that enabled full C-band tunable pluggable modules.

Narrow Linewidth High Power SG-DBR Laser

As described in the introduction, the LH, metro, and datacenter interconnects adopted coherent transmission format and continue to evolve towards higher bit rates by increasing the baud rate and the level of QAM modulation. This trend results in more stringent requirements imposed on the output power of the tunable lasers (> 16 dBm) and, even more importantly, on the laser linewidth (< 100 kHz). As discussed above, performance of widely tunable SG-DBR lasers with carrier injection tuning was adequate to meet full system requirements for 10 Gb/s OOK applications but additional tuning-induced loss is a challenge preventing injection tuned widely-tunable lasers from achieving narrow linewidth across the C-band. To overcome this limitation, Larson *et al.* (2015) developed thermally tuned SG-DBR laser and employed thermal engineering tailoring the impedance of the tuning sections to minimize power consumption and maintain millisecond-timescale tuning speed.

In addition, flexible-grid and colorless/directionless/contention-less network architectures employing power-combined launch require transmission lasers with high spectral purity in order to minimize noise interference on other channels. In particular, side mode suppression ratios (SMSR) greater than 47–50 dB are needed. SMSR of monolithic widely tunable DBR lasers integrated with SOAs is typically limited to 40–45 dB due to gain tilt and amplification of the spontaneous emission generated by the SOA as it is reflected from the back mirror. Addition of the thermally tuned broad-band filter into the PIC enabled to overcome this limitation, thereby simultaneously achieving > 50 dB SMSR and < 70 kHz linewidth at $+ 17$ dBm fiber coupled output power across C-band.

Fig. 10 (a) Schematic layout and cross-section of thermally tuned SG-DBR laser with integrated filter and SOA, (b) Instantaneous linewidth measure for 104 ITU channels at 16.5 and 17.5 dBm fiber coupled power.

The thermally tuned SG-DBR laser PIC comprising of the laser, delay interferometer tunable filter, and SOA is schematically shown in Fig. 10. The device uses regrowth integration technology similar to the injection tuned SG-DBR described above with the micro-heaters deposited above the shallow ridge structure in all tuning sections. The thermal impedance engineering is accomplished by placing sacrificial InGaAs layer underneath the entire PIC. As illustrated in Fig. 10, the sacrificial layer is selectively removed through lateral undercut etching in the thermally tuned sections. These sections become thermally isolated from the substrate and the heat generated in the micro heaters must flow laterally before reaching the substrate through unetched InGaAs. For all other sections the InGaAs remains as a spacer layer through which heat can flow vertically to the substrate/heat sink.

The thermally-tuned SGDBR laser described above is high performance optical source for high bit rate coherent transmitters and local oscillators and is widely adopted in coherent links as a discrete component utilized in combination with stand-alone modulators and coherent receivers. In addition, this all-monolithic laser design lends itself to integration with high-speed IQ modulators to produce high performance fully monolithic dual polarization coherent transmitter PIC.

Dual Polarization IQ Transmitter PIC

A polarization-multiplexed multilevel quadrature amplitude modulation transmitter requires a narrow linewidth laser and two IQ modulators. Compact IQ modulators with nested Mach-Zehnder (MZ) architecture have been successfully demonstrated using InP and Si modulator technologies. Power consumption of such transmitter is directly proportional to the active load (laser and SOA drive currents, modulator photocurrent and termination) and the required modulation voltage. Since the dual-polarization IQ modulator requires four drivers the power efficiency of the transceiver can be significantly improved by lowering modulation voltage.

Electro-optic MZ modulators in InP material systems fundamentally rely on the quantum-confined Stark effect, which produces red shift of the multi-quantum well (MQW) absorption edge and change of the refractive index when reverse bias voltage is applied to p-i-n hetero-structure. The modulation efficiency can be enhanced by optimizing the material band-gap, width of the QWs and using the material with larger conduction band discontinuity such as InAlGaAs. Modulator design optimization also includes the device length, depletion region width and electrode configuration to achieve desired modulation bandwidth. For a 32Gbaud MZ modulator the V_π voltage is typically below 2 V across C-band making InP modulator technology extremely attractive for coherent applications.

Another important consideration for minimizing transmitter power consumption and enabling high optical output power is low loss optical coupling between the laser and modulator. This can be accomplished only by monolithic integration of a narrow linewidth laser with an IQ modulator in a single PIC. Monolithic InP coherent PICs have been developed in multi-channel (Evans *et al.*, 2011) and tunable configurations (Binetti *et al.*, 2012; Akulova, 2016). In this article we will review the design, integration technology, and performance of the PIC reported in Akulova (2016).

The monolithic InP PIC is shown schematically in Fig. 11. The chip integrates C-band thermally tuned narrow linewidth SG-DBR laser with two IQ MZ modulators and three semiconductor optical amplifiers (SOAs). Light exiting the front mirror of the laser is split into three tributaries for X, Y, and Local Oscillator (LO) optical ports. Each optical path integrates an SOA for independent optical power leveling across C-band and variable optical attenuation functionality. The IQ modulators are realized using conventional nested MZ architecture. The signal electrodes of the IQ modulators are implemented using traveling wave design. Differential dc phase tuning sections are integrated into each of the IQ modulators and into individual MZs. The integration of multiple active and passive functional elements in one PIC has been accomplished using regrowth integration technology which is a platform technology for ILMZ and narrow linewidth SG-DBR laser PICs described above. The nested MZ modulator are fabricated using deep ridge waveguides. The performance characteristics of the monolithic DP-IQ transmitter PIC include V_π voltage of less than 2 V and the bandwidth in excess of 38 GHz (Fig. 12).

Fig. 11 Schematic layout of monolithic InP PIC consisting of thermally tuned narrow linewidth C-band tunable SGDBR laser, dual-polarization IQ modulators, and three SOAs.

Fig. 12 Performance characteristics of monolithic widely tunable coherent transmitter PIC: (a) dc transfer function of MZ modulator measured at several wavelengths across C-band; (b) small signal modulation bandwidth.

High-efficiency of InP MZs modulators combined with the capability of lossless monolithic integration with tunable lasers and SOAs positions InP PIC technology as a primary candidate for realization of cost-effective, compact, high-efficiency optical transmitter engines for pluggable coherent modules for 100 and 200 Gb/s and thus enabling wide deployment of coherent transmission in metro and datacenter interconnects links. With the potential for higher bandwidth, high modulation efficiency, and increased scale of photonic integration, the InP PIC technology will continue to scale enabling compact, cost effective solutions for 400 Gb/s and beyond.

Electro-Absorption Modulated Lasers

An EML – the smallest scale InP PIC- consists of a DFB laser and electro-absorption modulator. EMLs have been extensively used in DWDM and ZR metro links 2.5 and 10 Gb/s for decades. They have been commercialized in 100 Gb/s transceivers starting from 2014 and currently being designed into 200 and 400 Gb/s small form factor pluggable transceivers. Wide adoption of the EMLs for these high bit rate application is driven by the transceiver architectures and link budget requirements.

Transmission component architectures adopted by IEEE for the inter-datacenter optical links (500 m to 2 km) and local area networks (up to 40 km) at 100 Gb/s combines 25 Gb/s OOK modulation with multiplexing four wavelengths into one single-mode fiber. These links utilize O-band wavelength range in the minimum fiber dispersion window. Similarly, standards that are currently in development for 200 and 400 Gb/s transmission rely on four and eight wavelengths, respectively, with 50 Gb/s pulsed amplitude modulation (PAM4) format which does not require increase in modulation bandwidth relative to 100 Gb/s architecture. Alternatively, 400 Gb/s transmission can be implemented with only four wavelength using PAM4 modulation at 100 Gb/s per wavelength. In all the cases implementation of components has to fit into power dissipation budget and footprint of small form factor pluggable modules such as QSFP28 and QSFP-DD. These links are un-amplified and have to support 6–18 dB link loss budget (including fiber and connectors loss and transmitter and dispersion penalty) resulting in stringent requirements imposed on transmitter output power and extinction ratio.

Links in the minimum fiber dispersion window relax the requirement on transmitter chirp and can be implemented using directly modulated lasers (DMLs) and EMLs. Several high-performance DMLs and DML array integrated with multiplexer PICs

have been reported (see, e.g., Kanazawa *et al.* (2016) and Matsui *et al.* (2016) and references therein). However, it is advantageous to separate light generation and modulation functions to enable uncooled operation with large margin relative to all performance specifications and therefore high manufacturing yield. EML based transmitters enable independent optimization of the laser for the target output power and low relative intensity noise while EA modulator can easily meet the bandwidth and ER requirements and offers superior dispersion tolerance as compared to DMLs, and therefore can be used up to 40 km applications.

Fig. 13 presents schematic x-section of an integrated DFB laser with a high speed EA modulator. The EML is fabricated using regrowth integration and shallow ridge technology. With exception of the modulator MQW regrowth step, the fabrication process for an EML is similar to the flow for the fabrication of a stand alone DFB laser. Interestingly, the fabrication process for 25 Gb/s DMLs is frequently more complex than for EMLs. In the effort to meet the requirements for modulation bandwidth, DMLs have to be designed with very small active volume and the fabrication might include buried heterostructure process and integration of passive sections to maintain manufacturability as the laser cavity length is reduced to below 150 μm .

EMLs are compact and can be co-packaged or monolithically integrated with multiplexers to realize small form factor transmitter optical sub-assemblies (TOSAs) compatible with QSFP28 transceivers. Fig. 14 shows typical transfer functions of an EA

Fig. 13 Schematic cross-section of an EML chip.

Fig. 14 (a) Transfer function of uncooled EML; (b) Extinction ratio vs insertion loss for fixed modulation voltage ($V_{pp} = 1.2$ V).

Fig. 15 Eye diagrams measured at 28 Gb/s: (a) $ER > 5$ dB, $MM > 40\%$, $V_{pp} = 1.2$ V; (b) $ER > 9$ dB, $MM > 40\%$, $V_{pp} = 1.5$ V.

modulator measured at several temperatures and ER versus insertion loss calculated from the measured transfer function by changing dc bias with fixed modulation voltage. The ER in excess of 10 dB with insertion loss below 2 dB is demonstrated with 1.2 V modulation voltage across wide temperature range. The appropriate bias and modulation voltage is selected based on the target extinction ratio during transceiver calibration. Fig. 15 presents eye diagrams measured at 28 Gb/s. Extinction ratio in excess of 5 and 9 dB is demonstrated with the modulation voltage of 1.2 and 1.5 V, respectively. Such low requirements on the drive voltage ensure compatibility with low power dissipation modulator drivers and improve the power budget of the transceivers.

In summary, we have reviewed available InP integration technologies and discussed how optical link performance requirements drive the selection of PIC functional sections and integration approaches. We presented design, integration technology, and performance for several InP PICs that have been commercialized in Datacom, Metro, and LH transmission systems. InP PICs performance continues to scale to deliver higher transmission capacity at lower cost and power dissipation. In addition, InP technology enables integration of wide range of photonic functions and impacts broad range of market segments including photonic solutions for sensing, imaging, and high-speed signal analysis.

CMOS Transceiver Circuits for Optical Interconnects

Optical Interconnects

Optical interconnects for computing systems use electronic driver circuitry to transmit digitally-modulated light from a source laser over an optical channel, most commonly an optical fiber, to a photodetector where the signal is converted back into the electrical domain with a receiver circuit. Relative to electrical interconnects, these optical communication systems overcome key interconnect bottlenecks and greatly improve data transfer efficiency due to the optical fiber's flat channel loss over a wide frequency range and also relatively small crosstalk and electromagnetic noise. Another important feature of optical interconnects is the ability to combine multiple data channels on a single waveguide via wavelength-division-multiplexing (WDM) and greatly improve bandwidth density. These key features have motivated the application of optical interconnect systems in high-performance computing and data center systems where transmission distances can exceed 1 km.

The dominant optical interconnect transmitter technology for these applications has been directly-modulated multi-mode vertical-cavity surface-emitting lasers (VCSELs) due to these devices being inexpensive and the relaxed alignment tolerances offered by the multi-mode fiber system. However, modal dispersion limits performance as distances reach the km-range and data rates climb above 25 Gb/s. This motivates single-mode solutions that allow for increases in both transmission distances and bandwidth density via WDM. These single-mode systems often utilize external modulation of a continuous-wave (CW) laser operating at a constant power level in order to overcome laser bandwidth limitations and optical spectrum broadening due to modulated laser chirp. Common external modulator devices include electroabsorption modulators (EAMs) and refractive modulators, such as the Mach-Zehnder and ring resonator modulators.

At the receive side, a photodiode is typically utilized to sense the high-speed optical power and produce an input current. This photocurrent is then converted to a voltage and amplified sufficiently for data resolution. In order to support high data rates, sensitive high-bandwidth photodiodes are necessary. High-speed p-i-n photodiodes are typically used in optical receivers due to their high responsivity and low capacitance. In these device structures, the light is absorbed in the intrinsic region and the generated carriers are collected at the reverse bias terminals, thereby causing an effective photocurrent to flow. The amount of current generated for a given input optical power is set by the detector's responsivity. For devices where the light is normally incident, there is an inherent tradeoff between responsivity and bandwidth set by the intrinsic layer width. A wider intrinsic region will result in an increased amount of absorbed photons and higher responsivity, but will also cause increased carrier transit times that results in reduced detector bandwidth. This responsivity-bandwidth tradeoff is broken in waveguide p-i-n structures where the light travels horizontally down the intrinsic region and the electric field is formed orthogonal. These structures allow for both a thin intrinsic region for short carrier transit times and a sufficiently long region for high responsivity.

Energy efficient optical interconnect systems require low-power and area circuits that interface to these optical sources and detectors. This article focuses on CMOS driver and receiver circuits, as this technology allows for low-voltage and low-power operation and the potential to integrate the optical front-ends with the main data processing integrated circuits (ICs). While high-performance silicon-germanium (SiGe) or other compound semiconductor technologies may offer superior performance relative to CMOS implementations, these processes are often more expensive and/or not competitive in terms of energy efficiency for short distance optical interconnect applications.

Transmitter Circuitry

Directly modulated lasers and optical modulators, both electroabsorption and refractive, have been proposed as high bandwidth sources for optical interconnects, with these different sources displaying tradeoffs in both device and circuit driver efficiency. Vertical-cavity surface-emitting lasers are an attractive candidate due to their ability to directly emit light with low threshold currents and reasonable slope efficiencies; however their speed is limited by both electrical parasitics and carrier-photon interactions. A device which doesn't display this carrier speed limitation is the electroabsorption modulator, based on either the quantum-confined Stark effect (QCSE) or the Franz-Keldysh effect, which is capable of achieving acceptable contrast ratios at low drive voltages over tens of nm optical bandwidth. Ring resonator modulators are refractive devices that display very high resonant quality factors and can achieve high contrast ratios with small dimensions and low capacitance, however their optical bandwidth is typically less than 1 nm. Another refractive device capable of wide optical bandwidth (>100 nm) is the Mach-Zehnder modulator, however this comes at the cost of a large device and high voltage swings. All of the optical modulators also require an external source laser and incur additional coupling losses relative to a VCSEL-based link. The following describes CMOS circuitry optimized for these particular optical transmitter devices.

VCSEL Transmitters

A VCSEL, shown in Fig. 1(a), is a semiconductor laser diode which emits light perpendicular from its top surface. These surface emitting lasers offers several manufacturing advantages over conventional edge-emitting lasers, including wafer-scale testing ability and dense 2D array production. The most common VCSELs are GaAs-based operating at 850 nm, with longer wavelength devices manufactured in various material structures also available that operate near 1000, 1310, and 1550 nm. Current-mode drivers are often used to modulate VCSELs due to the device's linear optical power-current relationship. A typical CMOS VCSEL output driver is shown in Fig. 1(b), with a differential stage steering current between the optical device and a dummy load, and an additional static current source used to bias the VCSEL sufficiently above the threshold current, I_{TH} , in order to ensure adequate bandwidth.

Total VCSEL bandwidth is limited by a combination of electrical parasitics and the electron-photon interaction dynamics. The laser diode's dominant electrical time constant comes from the bias-dependent junction RC. In addition to the bias-dependent junction resistance, there is also significant series resistance due to the large number of distributed Bragg reflector (DBR) mirrors used for high reflectivity. VCSEL optical bandwidth is regulated by two coupled differential equations which describe the electron-photon interaction. Derived from these rate equations, the VCSEL relaxation oscillation frequency ω_R , which is proportional to the effective bandwidth, is directly proportional to the square-root of the injected current above the threshold current I_{TH} .

$$\omega_R \propto \sqrt{I - I_{TH}} \quad (1)$$

Output power saturation due to self-heating and also device lifetime concerns restrict excessive increase of VCSEL average current levels to achieve higher bandwidth. VCSEL reliability potentially poses a series impediment to very high speed modulation, as the mean time to failure (MTTF) is inversely proportional to the current density squared. The conflicting dependencies of VCSEL bandwidth and reliability on device current yield a very steep tradeoff.

In order to ease this tradeoff, equalizing output stages have been proposed to extend the data rate for a given average current. As an example, Fig. 2 shows a VCSEL transmitter with a four-tap finite impulse response (FIR) equalizer consisting of one pre-cursor, one main, and two post-cursor taps implemented by summing current sources at the output node. Five parallel data bits, $D[4:0]$, are routed to the taps, where they are shifted one bit time with respect to the clock phases to implement the necessary filter delays. At each tap, a multiplexer serializes the five parallel input bits and drives a differential output stage which steers current between the VCSEL and dummy diode-connected thick-oxide nMOS devices that are connected to a separate 2.8 V LVdd supply. This higher supply is necessary to support the 1.5 V VCSEL knee voltage. Eight-bit current mirror DACs bias the output stages to the desired current value. Because of the smaller current requirements of the pre/post-cursor taps, their muxes and output stages are set to one-fourth the size of the main tap to save power. A static DC current source, I_{DC} , is also used to bias the VCSEL above the threshold current to insure adequate bandwidth. This bias current and the leakage current from the tap driver transistors, I_{leak} , provide sufficient voltage drop across the VCSEL and dummy load to prevent excessive voltage stress on the output stage transistors. While the VCSEL's varying frequency response with current limits the performance of this linear equalizer for large extinction ratio modulation, the frequency response variations diminish with increasing average current due to the square-root relationship and a linear equalizer is effective in canceling intersymbol interference (ISI) for extinction ratios near 3 dB. In order to further improve performance, non-linear equalizers have been proposed with asymmetric current profiles for the different data transitions.

Electroabsorption Modulator Transmitters

An electroabsorption modulator is typically made by placing an absorbing quantum-well region in the intrinsic layer of a reverse-biased p-i-n diode. In order to produce a modulated optical output signal, light originating from a continuous-wave source laser is absorbed in an EA modulator depending on electric field strength through electro-optic effects such as the quantum-confined Stark effect or the Franz-Keldysh effect. These devices are often implemented as a waveguide structure where light is coupled in and

Fig. 1 Vertical-Cavity Surface-Emitting Laser: (a) device cross-section and (b) driver circuit.

Fig. 2 VCSL transmitter with a four-tap FIR equalizer.

Fig. 3 Electroabsorption modulator drivers: (a) simple CMOS inverter and (b) high-swing pulsed-cascode output stage.

travels laterally through the absorbing multiple-quantum-well (MQW) region. Modulation is typically achieved by applying a static positive bias voltage to the n-terminal and driving the p-terminal with the high-speed signal.

Assuming tight integration with the driver circuitry, the EAM can be treated as a lumped-element device consisting of the diode capacitance and a parallel voltage-dependent photocurrent source. While conceptually the high-speed driver could be a simple CMOS inverter (Fig. 3(a)), the sub-1 V swings available in modern CMOS processes limit the achievable extinction ratio for relatively short lumped-element EAMs. Improved extinction ratios are possible with longer EAM device lengths. However, achieving high-speed operation with these longer devices necessitates traveling-wave driver topologies that often require low-impedance termination and a relatively large amount of switching current. Another option is to use a lumped element driver with a higher output swing than the nominal CMOS supply. The ability to drive the smaller devices as an effective lumped-element capacitor offers a huge power advantage when compared to longer controlled-impedance structures, as the CV^2f power is relatively low due to small device capacitance. One circuit which allows for this in a reliable manner is a pulsed-cascode driver, which offers a voltage swing of twice the nominal supply while using only core devices for maximum speed.

Fig. 3(b) shows the pulsed-cascode output stage which accepts both a “low” input IN_{low} that swings between the Gnd and the nominal chip V_{dd} and a “high” input IN_{high} with the same data value that has been level-shifted to swing between V_{dd} and V_{dd2} , where V_{dd2} is nominally twice the voltage of V_{dd} . Static-voltage overstress is eliminated in the output-stage cascode structure by

equally splitting the output voltage across the series transistors. Pulsing the gates of the cascode transistors (MN2 and MP2) during transitions with NAND- and NOR-pulse gates, respectively, allows this driver to eliminate the transient drain-source voltage (V_{DS}) overstress present in static-biased cascode drivers and prevents transistor degradation from hot-carrier injection.

Ring Resonator Modulator Transmitters

As shown in Fig. 4(a), a ring resonator consists of a top waveguide which couples a portion of the incoming continuous wavelength (CW) light into a ring waveguide. At the resonance wavelength, most of the incident light will be trapped due to the interference between the ring and top waveguide. This results in minimal power at the through port, as shown in Fig. 4(b). Adding a second bottom waveguide to the ring allows for the light coupled into the ring from the input port to be coupled out onto the bottom waveguide at the resonance wavelength, implementing a drop filter. By changing the ring waveguide's effective refractive index via the plasma dispersion effect, the resonance wavelength can be shifted to allow for modulation. Fig. 4(c) shows that if the resonance wavelength is aligned with the incident light wavelength, an adequate output extinction ratio is possible. However, if the high-Q device's resonance is off due to temperature sensitivity or manufacturing variations, the performance greatly diminishes (Fig. 4(d)).

The two most common silicon ring resonator modulators, carrier-injection and carrier-depletion devices, are implemented by forming a junction across the ring waveguide. Carrier-injection devices have an intrinsic ring waveguide surrounded by p+ and n+ regions that form the modulator's two electrical terminals. As they operate primarily in forward bias, this allows for significant changes in the intrinsic-region carriers with varying drive signals. While this provides large refractive index changes and high modulation depths, dynamic operation is limited by long minority carrier lifetimes. A pn junction is formed directly in the ring waveguide in carrier-depletion modulators. Higher speeds relative to a carrier-injection ring are generally achievable due to the

Fig. 4 Ring resonator device: (a) schematic, (b) through and drop port power versus wavelength, (c) modulator operation with 0 V bias resonance equal to the incident light wavelength, (d) modulator operation with a 160 pm resonance shift.

Fig. 5 Non-linear pre-emphasis ring modulator driver with $2V_{pp}$ output stage.

ability to rapidly change the depletion width. However, the modulation depth is limited due to the low doping concentration in the waveguide to avoid excessive loss.

The differing characteristics of carrier-injection and carrier-depletion ring modulators necessitate variations in the output stage design to enable high data rate operation. While carrier-injection modulators are capable of high extinction ratios, the operating speed is limited by relatively slow carrier dynamics in forward-bias and parasitic contact resistance in reverse-bias. This necessitates relatively large amounts of non-linear pre-emphasis to compensate for the differing time constants during rising and falling transitions. A single-ended driver optimized for carrier-injection modulators is shown in [Fig. 5](#). This design utilizes a pulsed-cascode output stage for robust high output swing and segments this output stage into main and independent rising/falling edge pre-emphasis drivers. Here the per-edge pre-emphasis strength is set with tunable delay elements that allow optimization of the transient response to be decoupled from the steady-state extinction ratio value. A 65 nm CMOS implementation of this design achieved an output swing of $2V_{pp}$ and a 9.2 dB extinction ratio at 9 Gb/s when driving a carrier-injection ring modulator.

Depletion-mode modulators have shorter carrier lifetimes and can easily achieve data rates >10 Gb/s. However, they typically exhibit low pn junction tunability that necessitates higher modulation voltages, require negative DC-biasing for high-speed operation, and need pre-emphasis optimized for non-linear optical dynamics important at data rates >20 Gb/s. One circuit which can achieve this is a differential version of the [Fig. 5](#) driver with on-die AC-coupling capacitors that allow for a constant negative-bias operation over large-swing dynamic operation. A 65 nm CMOS implementation of this design achieved $4.4V_{pp}$ differential swing and implemented asymmetric 2-tap equalization in the output stage to operate at 25 Gb/s with a 7 dB ER.

In order to ensure reliable operation over temperature and fabrication variations, resonance wavelength tuning can be achieved by adjusting the ring resonator's refractive index thermally, electrically, or by employing both techniques. Thermal tuning with integrated resistor heaters is most commonly employed, as it does not impact ring loss, but the tuning speed is limited by thermal time constants. Alternatively, electrical or bias-based tuning offers the potential for rapid tuning at the cost of some reduction in modulator extinction ratio. This approach has been shown to be effective with carrier-injection modulators, but is generally not considered effective for carrier-depletion modulators due to the reduced tunability.

[Fig. 6](#) shows an average-power-based dynamic thermal tuning loop where a drop-port with a waveguide PD has been added to a ring modulator to monitor the ring's power levels. An FSM automatically locks the ring to the optimal thermal bias point by comparing the average optical power with an on-chip reference voltage to produce error information for the control of a thermal DAC that drives a resistive heater placed close to the modulator. Successful demonstration of this dynamic tuning loop with through-port monitoring was achieved for 25 Gb/s operation of carrier-depletion modulators with integrated $1\text{ k}\Omega$ resistor heaters. This tuning loop was also modified to also tune the drop filters in a 25 Gb/s receiver front-end, with ring power monitoring achieved by adding peak detectors at the TIA output in order to not compete with the receiver's offset correction loop. A similar control loop was used for bias-based tuning of carrier-injection ring modulators, with the thermal DAC replaced by a bias DAC driving the modulator's anode terminal and the high-speed modulation applied to the cathode. This opens the possibility for dual-loop tuning with carrier-injection modulators, which involves a coarse-step thermal DAC and fine tuning with the bias DAC.

Fig. 6 Average-power-based dynamic thermal tuning loop to stabilize the ring resonance wavelength.

Mach-Zehnder Modulator Transmitters

Mach-Zehnder modulators (MZMs) are also refractive modulators which work by splitting the light to travel through two arms where a phase shift is developed that is a function of the applied electric field. The light in the two arms is then recombined either in phase or out of phase at the modulator output to realize the modulation. MZMs which use the free-carrier plasma-dispersion effect in pn diode devices to realize the optical phase shift have been integrated in CMOS processes and have demonstrated operation in excess of 10 Gb/s. The modulator transfer characteristic with half wave voltage V_π is

$$\frac{P_{out}}{P_{in}} = \frac{1}{2} \left(1 + \sin \frac{\pi V_{swing}}{V_\pi} \right) \quad (2)$$

Unlike smaller modulators which are treated as lumped capacitive loads, the relatively low modulation efficiency requires MZM phase shifters that commonly exceed 1 mm in silicon photonic implementations. Thus, the lumped-element drivers that are commonly utilized for ring resonator and electroabsorption modulators are not well suited for MZM operation at high speed. Instead, as shown in Fig. 7(a), traveling-wave drivers are often used with a differential electrical output signal that is distributed along the MZM phase shifter length using a pair of transmission lines terminated with a low impedance. The best high-speed output signal integrity is achieved when the transmission line electrodes are designed such that the propagation velocity of the electrical signal matches that of the optical signal in the MZM waveguides. While conceivably large contrast ratios are possible by simply increasing the MZM phase shifter length, this is limited by high-frequency loss of the long transmission lines and also increased optical insertion loss caused by the long doped waveguides. In order to achieve the required phase shift and reasonable contrast ratio, long devices and large differential swings are required; often necessitating a separate voltage supply MV_{dd} . Thick-oxide cascode transistors are used to avoid stressing driver transistors with the high supply.

A driver which provides more flexibility in electrode design and allows for high-swing lumped element drivers is the multistage topology shown in Fig. 7(b). This design segments the total length of the MZM phase shifters into shorter regions which are driven by high-swing stacked inverter-style drivers. The segment length is chosen to have a self-resonance frequency higher than the signal bandwidth. As the high-frequency loss of these short segments is relatively small, higher contrast ratios are possible with high-swing drivers. A combination of passive wire delay elements and tunable-delay circuitry are employed to match the multistage driver delay with the optical propagation velocity. In this design, the speed and power efficiency is limited by distributing CMOS-level signals across long distances and the power consumed by the tunable delay elements. This driver topology generally achieves better power efficiency at low to moderate data rates due to the dominant CV^2f switching power component. While at the highest data rates, the limited contrast ratio traveling wave design becomes more power efficient.

Receiver Circuitry

Optical receiver front-ends generally determine the overall optical link performance, as their sensitivity sets the maximum data rate and amount of tolerable channel loss. Typical optical receivers use a photodiode to sense the high-speed optical power and produce an input current. This photocurrent is then converted to a voltage and amplified sufficiently for data resolution. In order to achieve increasing data rates, sensitive high-bandwidth receiver front-end circuits are necessary.

Fig. 9 Feedback TIA.

modifying a conventional common-gate input stage to a regulated cascode (RGC) architecture which employs active negative feedback gain to boost the input transconductance. This reduced input resistance pushes the input pole to a higher frequency, relaxing tradeoffs between TIA gain and bandwidth. However, conventional RGC topologies require additional voltage headroom due to the cascode topology. Moreover, extra power is required in the feedback stage in order to avoid excessive TIA frequency peaking and obtain sufficient noise performance. An interesting alternative approach to improve the input bandwidth involves employing a transformer-based RGC input stage which provides passive negative-feedback gain that enhances the effective transconductance of the input common-gate transistor. This allows for considerable bandwidth extension without significant noise degradation or power consumption.

Another wideband receiver frontend is the shunt-feedback TIA shown in **Fig. 9**, which decouples the transimpedance gain and input impedance by the amount of amplifier gain.

$$R_T = R_F \left(\frac{A}{1 + A} \right)$$

Feedback TIA Front-End :

$$\omega_{3dB} \approx \frac{1 + A}{R_F C_{in}}$$

where $A \approx g_{m1} (R_D \parallel r_{o1})$

(5)

The feedback TIA topology has the advantage that only the photodetector signal current flows through R_F , which provides the potential for large transimpedance gain without voltage headroom constraints. This structure allows for potentially both high transimpedance and bandwidth, provided that the amplifier in the TIA has a sufficient gain-bandwidth product, Af_A , to ensure system stability. However, as data rates scale, the TIA's amplifier gain-bandwidth must increase as a quadratic function in order to maintain the same effective TIA gain because of the inherent transimpedance limit.

$$R_T \leq \frac{Af_A}{2\pi C_{in} f_{3dB}^2}$$
(6)

TIA performance scaling is further limited by the lack of gain that is achieved in modern CMOS processes at nominal supply voltages due to both voltage headroom constraints and intrinsic transistor gain. This limits the maximum R_F value, which both reduces the transimpedance gain and increases the input-referred current noise. As data rates increase and less gain is realized in the input transimpedance stage, receiver sensitivity is improved with additional voltage or limiting amplifier (LA) stages that follow the TIA. High-performance optical receivers often use four or more differential amplifier stages in order to achieve adequate sensitivity, which can more than double the total optical receiver power consumption.

Bandwidth-Limited Frontends

The aforementioned optical receiver scaling issues have motivated researchers to investigate bandwidth-limited front-ends in order to improve sensitivity and power consumption. A receiver front-end architecture that eliminates linear high gain elements, and thus is less sensitive to the reduced gain in modern processes, is the integrating and double-sampling front-end shown in **Fig. 10**. The absence of high gain amplifiers allows for savings in both power and area and makes the integrating and double-sampling architecture advantageous for chip-to-chip optical interconnect systems where retiming is also performed at the receiver. The integrating and double-sampling receiver front-end demultiplexes the incoming data stream with parallel segments that include a pair of input samplers, a buffer, and a sense-amplifier. Two current sources at the receiver input node, the photodiode current and a current source that is feedback biased to the average photodiode current, supply and deplete charge from the receiver input capacitance respectively. For data encoded to ensure DC balance, the input voltage will integrate up or down due to the mismatch in these currents. A differential voltage, ΔV_b , that represents the polarity of the received bit is developed by sampling the input voltage at the beginning and end of a bit period defined by the rising edges of the synchronized sampling clocks $\Phi[n]$ and $\Phi[n+1]$ that are spaced a bit-period, T_b , apart. This differential voltage is buffered and applied to the inputs of an offset-corrected sense-amplifier which is used to regenerate the signal to CMOS levels.

Fig. 10 Integrating and double-sampling receiver front-end.

Fig. 11 Low-bandwidth TIA front-end followed by an equalizer: (a) continuous-time linear equalizer and (b) decision feedback equalizer.

One issue with this integrating and double-sampling front-end is that the input node saturates with long runlengths of consecutive bits. A solution to this is to implement a lossy integrator input node by utilizing a relatively large input resistor or low-bandwidth feedback TIA front-end to limit the low-frequency swing to a predictable value. A constant effective differential voltage is achieved by dynamically modulating the sense-amplifier's offset with a discrete-time FIR filter that follows the low-bandwidth input stage.

Fig. 11 shows another receiver front-end architecture which offers sensitivity improvement by utilizing a low-bandwidth feedback TIA followed by an equalizer circuit. At high data rates, the input-referred current noise of wideband feedback TIAs is often dominated by the feedback resistor R_F whose value is limited to achieve sufficient bandwidth. Intentionally increasing R_F results in lower noise which is integrated over a smaller bandwidth. However, significant intersymbol interference (ISI) exists at the

output of this low-bandwidth feedback TIA front-end. This ISI is then compensated by the subsequent equalizer block to achieve adequate voltage and timing margins at the data samplers.

A continuous-time linear amplifier (CTLE) is a simple and low-area equalizer block which implements a high-pass filter transfer function to restore the total receiver front-end bandwidth. While this equalizer doesn't require any additional sampling clocks, it does have to supply gain at frequencies close to the full signal data rate. Also, the CTLE amplifier introduces additional noise. Nonetheless, the ability to reduce the input R_F noise significantly allows for a net sensitivity improvement.

Another equalizer topology is the decision feedback equalizer (DFE). A DFE attempts to directly subtract ISI from the incoming signal by feeding back the resolved data to control the polarity of the equalization taps. Unlike linear equalization, a DFE doesn't directly amplify the input signal noise or cross-talk since it uses the quantized input values. However, there is the potential for error propagation in a DFE if the noise is large enough for a quantized output to be wrong. Also, due to the feedback equalization structure, the DFE cannot cancel pre-cursor ISI. The major challenge in DFE implementation is closing timing on the first tap feedback since this must be done in one bit period or unit interval (UI). Direct feedback implementations require this critical timing path to be highly optimized. Improvements in DFE speed are possible with loop-unrolling architectures which speculative summation with multiple data samplers and additional look-ahead logic to relax the critical timing path.

Introduction

Electromagnetic irradiation of matter generates a coherent superposition of the excited quantum states. The attribute “coherent” relates to the fact that the material excitations originally have a well defined phase dependence which is imposed by the phase of the excitation source, often a laser in the optical regime. Macroscopically, the generated superposition state can be described as an optical polarization which is determined by the transition amplitudes between the participating quantum states.

The optical polarization is a typical non-equilibrium quantity that decays to zero when a system relaxes to its equilibrium state. Coherent effects are therefore only observable in a certain time window after pulsed photoexcitation, or in the presence of a continuous-wave (cw) beam. As *coherent transients* one usually refers to phenomena that can be observed during or shortly after pulsed laser excitation and critically depend on the presence of the induced optical polarization.

Many materials such as atoms, molecules, metals, insulators, semiconductors including bulk crystals, heterostructures, and surfaces, as well as organic and biological structures are studied using coherent optical spectroscopy. Depending on the particular system, the states participating in the optical transitions, the interactions among them, and the resulting time scale for the decay of the induced polarization may be very different. As a result, the time window during which coherent effects are observable can be as long as seconds for certain atomic transitions, or it may be as short as a few femtoseconds (10^{-15} s), e.g., for metals, surfaces, or highly excited semiconductors.

Coherent spectroscopy and the analysis of coherent transients has provided valuable information on the nature and dynamics of the optical excitations. Often it is possible to learn about the interaction processes among the photoexcitations and to follow the temporal evolution of higher-order transitions which are only accessible if the system is in a non-equilibrium state.

The conceptually simplest experiment which one may use to observe coherent transients is to time resolve the transmission or reflection induced by a single laser pulse. However, much richer information can be obtained if one excites the system with several pulses. A pulse sequence with well-controlled delay times makes it possible to study the dynamical evolution of the photoexcitations not only by time resolving the signal but also by varying the delay. Prominent examples of such experiments are pump–probe measurements, which usually are performed with two incident pulses, or four-wave mixing, for which one may use two or three incident pulses.

Besides the microscopic interaction processes, the outcome of an experiment is determined by the quantum mechanical selection rules for the transitions and by the symmetries of the system under investigation. For example, if one wants to investigate coherent optical properties of surface states one often relies on phenomena, such as second-harmonic or sum-frequency generation, which give no signal in perfect systems with inversion symmetry. Due to the broken translational invariance, such experiments are therefore sensitive only to the dynamics of surface and/or interface excitations.

In this article the basic principles of coherent transients are presented and several examples are presented. The basic theoretical description and its generalization for the case of semiconductors are introduced.

Basic Principles

In the absence of free charges and currents, Maxwell’s equations show that the electromagnetic field interacts with matter via the optical polarization. This polarization $\mathbf{P}$, or more precisely its second derivative with respect to time $\frac{\partial^2}{\partial t^2}\mathbf{P}$, appears as a source term in the wave equation for the electric field $\mathbf{E}$. Consequently, if the system is optically thin such that propagation effects within the sample can be ignored and if measurements are performed in the far field region, i.e., at distances that significantly exceed the characteristic optical wavelength λ , the emitted electric field resulting from the polarization is proportional to its second time derivative, $\mathbf{E} \propto \frac{\partial^2}{\partial t^2}\mathbf{P}$. Thus the measurement of the emitted field dynamics yields information about the temporal evolution of the optical material polarization.

Microscopically the polarization is determined by the transition amplitudes between the different states of the system. These may be the discrete states of atoms or molecules, or the microscopic valence and conduction band states in a dielectric medium, such as a semiconductor. In any case, the macroscopic polarization $\mathbf{P}$ is computed by summing over all microscopic transitions p_{cv} via $\mathbf{P} = \sum_{c,v} (\boldsymbol{\mu}_{cv} p_{cv} + c.c.)$, where $\boldsymbol{\mu}_{cv}$ is the dipole matrix element which determines the strength of the transitions between the states v and c , and $c.c.$ denotes the complex conjugate. If ε_c and ε_v are the energies of these states, their dynamic quantum mechanical evolution is described by the phase factors $e^{-i\varepsilon_c t/\hbar}$ and $e^{-i\varepsilon_v t/\hbar}$, respectively. Therefore each p_{cv} is evolving in time according to $e^{-i(\varepsilon_c - \varepsilon_v)t/\hbar}$. Assuming that we start at $t=0$ with $p_{cv}(t=0) = p_{cv,0}$, which may be induced by a short optical pulse, we have for the optical polarization $\mathbf{P}(t) = \Theta(t) \sum_{c,v} (\boldsymbol{\mu}_{cv} p_{cv,0} e^{-i(\varepsilon_c - \varepsilon_v)t/\hbar} + c.c.)$. Thus $\mathbf{P}(t)$ is given by a summation over microscopic transitions which all oscillate with frequencies proportional to the energy differences between the involved states. Hence, the optical

polarization is clearly a coherent quantity which is characterized by amplitude and phase. Furthermore, the microscopic contributions to $\mathbf{P}(t)$ add up coherently. Depending on the phase relationships, one may obtain either constructive superposition, interference phenomena like quantum beats, or destructive interference leading to a decay (dephasing) of the macroscopic polarization.

Optical Bloch Equations

The dynamics of photoexcited systems can be conveniently described by a set of equations, the optical Bloch equations, named after Felix Bloch (1905–1983) who first formulated such equations to analyze the spin dynamics in nuclear magnetic resonance. For the simple case of a two-level model the Bloch equations can be written as

$$i\hbar \frac{\partial}{\partial t} p = \Delta\varepsilon p + \mathbf{E} \cdot \boldsymbol{\mu} I \quad (1)$$

$$i\hbar \frac{\partial}{\partial t} I = 2\mathbf{E} \cdot \boldsymbol{\mu} (p - p^*) \quad (2)$$

Here, $\Delta\varepsilon$ is the energy difference and I the inversion, i.e., the occupation difference between upper and lower state. The field $\mathbf{E}$ couples the polarization to the product of the Rabi energy $\mathbf{E} \cdot \boldsymbol{\mu}$ and the inversion I . In the absence of the driving field, i.e., $\mathbf{E} \equiv 0$, Eq. (1) describes the free oscillation of $p \propto e^{-i\Delta\varepsilon t/\hbar}$ discussed above.

The inversion is determined by the combined action of the Rabi energy and the transition p . The total occupation N , i.e., the sum of the occupations of the lower and the upper states, remains unchanged during the optical excitation since light does not create or destroy electrons, it only transfers them between different states. If N is initially normalized to 1, then I can vary between -1 and 1 . $I = -1$ corresponds to the ground state of the system, where only the lower state is occupied. In the opposite extreme, i.e., for $I = 1$, the occupation of the upper state is 1 and the lower state is completely depleted.

One can show that Eqs. (1) and (2) contain another conservation law. Introducing $\mathcal{P} = p + p^* = 2\text{Re}[p]$ and $\mathcal{J} = i(p - p^*) = -2\text{Im}[p]$, which are real quantities and often named polarization and polarization current, respectively, one finds that the relation

$$\mathcal{P}^2 + \mathcal{J}^2 + I^2 = 1 \quad (3)$$

is fulfilled. Thus the coupled coherent dynamics of the transition and the inversion can be described on a unit sphere, the so-called Bloch sphere. The three terms $\mathcal{P}$, $\mathcal{J}$, and I define the components of the three-dimensional Bloch vector $\mathbf{S} = (\mathcal{P}, \mathcal{J}, I)$. With these definitions, one can reformulate Eqs. (1) and (2) as

$$\frac{\partial}{\partial t} \mathbf{S} = \boldsymbol{\Omega} \times \mathbf{S} \quad (4)$$

with $\boldsymbol{\Omega} = (-2\boldsymbol{\mu} \cdot \mathbf{E}, 0, \Delta\varepsilon)/\hbar$ and $\times$ denoting the vector product.

The structure of Eq. (4) is mathematically identical to the equations describing either the angular momentum dynamics in the presence of a torque or the spin dynamics in a magnetic field. Therefore, the vector $\mathbf{S}$ is often called pseudospin. Moreover, many effects which can be observed in magnetic resonance experiments, e.g., free decay, quantum beats, echoes, etc. have their counterparts in photoexcited optical systems.

The vector product on the right hand side of Eq. (4) shows that $\mathbf{S}$ is changed by $\boldsymbol{\Omega}$ in a direction perpendicular to $\mathbf{S}$ and $\boldsymbol{\Omega}$. For vanishing field the torque $\boldsymbol{\Omega}$ has only a z -component. In this case the z -component of $\mathbf{S}$, i.e., the inversion, remains constant, whereas the x - and y -components, i.e., the polarization and the polarization current, oscillate with the frequency $\Delta\varepsilon/\hbar$ on the Bloch sphere around $\boldsymbol{\Omega}$.

Semiconductor Bloch Equations

If one wants to analyze optical excitations in crystalline solids, i.e., in systems which are characterized by a periodic arrangement of atoms, one has to include the continuous dispersion (bandstructure) into the description. This can be done by including the crystal momentum $\hbar\mathbf{k}$ as an index to the quantities which describe the optical excitation of the material, e.g., p and I in Eqs. (1) and (2). Hence, one has to consider a separate two-level system for each crystal momentum $\hbar\mathbf{k}$. As long as all other interactions are disregarded the bandstructure simply introduces a summation over the uncoupled contributions from the different $\mathbf{k}$ states, leading to inhomogeneous broadening due to the presence of a range of transition frequencies $\Delta\varepsilon(\mathbf{k})/\hbar$.

For any realistic description of optical processes in solids, it is essential to go beyond the simple picture of non-interacting states and to treat the interactions among the elementary material excitations, e.g., the Coulomb interaction between the electrons and the coupling to additional degrees of freedom, such as lattice vibrations (electron-phonon interaction) or other bath-like subsystems. If crystals are not ideally periodic, imperfections, which can often be described as a disorder potential, need to be considered as well.

All these effects can be treated by proper extensions of the optical Bloch equations introduced above. For semiconductors the resulting generalized equations are known as semiconductor Bloch equations, where the microscopic interactions are included at a

certain level of approximation. For a two band model of a semiconductor, these equations can be written schematically as

$$i\hbar \frac{\partial}{\partial t} p_k = \Delta \varepsilon_k p_k + \Omega_k (n_k^c - n_k^v) + i\hbar \frac{\partial}{\partial t} p_k|_{corr} \quad (5)$$

$$i\hbar \frac{\partial}{\partial t} n_k^c = (\Omega_k^* p_k - \Omega_k p_k^*) + i\hbar \frac{\partial}{\partial t} n_k^c|_{corr} \quad (6)$$

$$i\hbar \frac{\partial}{\partial t} n_k^v = -(\Omega_k^* p_k - \Omega_k p_k^*) + i\hbar \frac{\partial}{\partial t} n_k^v|_{corr} \quad (7)$$

Here p_k is the microscopic polarization and n_k^c and n_k^v are the electron populations in the conduction and valence bands (c and v), respectively. Due to the Coulomb interaction and possibly further processes, the transition energy $\Delta \varepsilon_k$ and the Rabi energy Ω_k both depend on the excitation state of the system, i.e., they are functions of the time-dependent polarizations p_k and populations $n_k^{c/v}$. This leads, in particular, to a coupling among the excitations for all different values of the crystals momentum $\hbar \mathbf{k}$. Consequently, in the presence of interactions the optical excitations can no longer be described as independent two-level systems but have to be treated as a coupled many-body system. A prominent and important example in this context is the appearance of strong exciton resonances which, as a consequence of the Coulomb interaction, show up in the absorption spectra of semiconductors energetically below the fundamental band gap.

The interaction effects lead to significant mathematical complications since they induce couplings between all the different quantum states of a system and introduce an infinite hierarchy of equations for the microscopic correlation functions. The terms given explicitly in Eqs. (5)–(7) arise in a treatment of the Coulomb interaction on the Hartree-Fock level. Whereas this level is sufficient to describe excitonic resonances, there are many additional effects, e.g., excitation-induced dephasing due to Coulomb scattering and significant contributions from higher-order correlations like excitonic populations and biexcitonic resonances, which make it necessary to treat many-body correlation effects that are beyond the Hartree-Fock level. These contributions are formally included by the terms denoted as $|_{corr}$ in Eqs. (5)–(7). The systematic truncation of the many-body hierarchy and the analysis of controlled approximations is the basic problem in the microscopic theory of optical processes in condensed matter systems.

Examples

Radiative Decay

The emitted field originating from the non-equilibrium coherent polarization of a photoexcited system can be monitored by measuring the transmission and the reflection as function of time. If only a single isolated transition is excited, the dynamic evolution of the polarization and therefore of the transmission and reflection is governed by radiative decay. This decay is a consequence of the coupling of the optical transition to the light field described by the combination of Maxwell- and Bloch-equations. Radiative decay simply means that the optical polarization is converted into a light field on a characteristic time scale $2T_{rad}$. Here, T_{rad} is the population decay time, often also denoted as T_1 -time. This radiative decay is a fundamental process which limits the time on which coherent effects are observable for any photoexcited system. Due to other mechanisms, however, the non-equilibrium polarization often vanishes considerably faster.

The value of T_{rad} is determined by the dipole matrix element and the frequency of the transition, i.e., $T_{rad}^{-1} \propto |\mu|^2 \Delta \omega$, with $\Delta \omega = \Delta \varepsilon / \hbar$. The temporal evolution of the polarization and the emitted field are proportional to $e^{-i\Delta \omega t - t/(2T_{rad})}$. Usually one measures the intensity of a field, i.e., its squared modulus, which evolves as $e^{-t/T_{rad}}$ and thus simply shows an exponential decay, the so-called *free-induction decay*, see Fig. 1. T_{rad} can be very long for transitions with small matrix elements. For semiconductor quantum wells, however, it is on the order of only 10 ps, as the result of the strong light-matter interaction.

The time constant on which the optical polarization decays is often called T_2 . In the case that this decay is dominated by radiative processes we thus have $T_2 = 2T_{rad}$.

Superradiance

The phenomenon of superradiance can be discussed considering an ensemble of N two-level systems which are localized at certain positions $\mathbf{R}_i$. In this case Maxwell's equations introduce a coupling among all these resonances since the field emitted from any specific resonance interacts with all other resonances and interferes with their emitted fields. As a result, this system is characterized by N eigenmodes originating from the radiatively coupled optical resonances.

A very spectacular situation arises if one considers N identical two-level systems regularly arranged with a spacing that equals an integer multiple of $\lambda/2$, where λ is the wavelength of the system's resonance, i.e., $\lambda = c/\Delta \omega$, where c is the speed of light in the considered material, see Fig. 2(a). In this case all emitted fields interfere constructively and the system behaves effectively like a single two-level system with a matrix element increased by $\sqrt{N}$. Consequently, the radiative decay rate is increased by N and the polarization of the coupled system decays N -times faster than that of an isolated system, see Fig. 2(b). This effect is called superradiance.

It is possible to observe superradiant coupling effects, e.g., in suitably designed semiconductor heterostructures. Fig. 2(c) compares the measured time-resolved reflection from a single quantum well (dashed line) with that of a Bragg structure, i.e., a multiple quantum-well structure which consists of 10 wells that are separated by $\lambda/2$ (solid line), where λ is the wavelength of the

Fig. 1 A two-level system is excited by a short optical pulse at $t=0$. Due to radiative decay (inset) and possibly other dephasing mechanisms, the polarization decays exponentially as function of time with the time constant T_2 , the dephasing time. The intensity of the optical field which is emitted as a result of this decay is proportional to the squared modulus of the polarization, which falls off with the time constant $T_2/2$. The decay of the squared modulus of the polarization is shown in (a) on a linear scale and in (b) on a logarithmic scale. The dephasing time was chosen to be $T_2=10\text{ps}$ which models the radiative decay of the exciton transition of a semiconductor quantum well.

exciton resonance. For times greater than about 2ps the direct reflection of the exciting pulse has decayed sufficiently and one is left with the exponential decay of the remaining signal. **Fig. 2(c)** shows that this decay is much more rapid for the Bragg structure than for the single quantum well due to superradiance introduced by the radiative coupling among the quantum wells.

Destructive Interference

We now consider a distribution of two-level systems which have slightly different transition frequencies characterized by the distribution function $g(\Delta\omega - \bar{\omega})$ of the transition frequencies which is peaked at the mean value $\bar{\omega}$ and has a spectral width of $\delta\omega$, see **Fig. 3(a)**. Ignoring the radiative coupling among the resonances, the optical polarization of the total system evolves after excitation by a short laser pulse at $t=0$ proportional to $\int d\omega g(\Delta\omega - \bar{\omega}) e^{-i\Delta\omega t} \propto \tilde{g}(t) e^{-i\bar{\omega}t}$, where $\tilde{g}(t)$ denotes the Fourier transform of the frequency distribution function $g(\omega)$ and thus the optical polarization decays on a time scale which is inversely proportional to the spectral width of the distribution function $\delta\omega$. Thus the destructive interference of many different transitions frequencies results in a rapid decay of the polarization, see **Fig. 3(b)**.

In the spectral domain this rapid decay shows up as inhomogeneous broadening. Depending on the system under investigation, there are many different sources for such an inhomogeneous broadening. One example is the Doppler broadening in atomic gases or disorder effects such as well-width fluctuations in semiconductor quantum wells or lattice imperfections in crystals.

In the nonlinear optical regime it is under certain circumstances possible to reverse the destructive interference of inhomogeneously broadened coherent polarizations. For example, in four-wave mixing a second pulse may lead to a rephasing of the contributions with different frequencies, which results in the photon echo, see discussion below.

Quantum Beats

The occurrence of quantum beats can be understood most easily in a system where the total optical polarization can be attributed to a finite number of optical transitions. Let us assume for simplicity that all these transitions have the same matrix element. In this case, after excitation with a short laser pulse at $t=0$ the optical polarization of the total system evolves proportional to $\sum_i e^{-i\Delta\omega_i t}$. The finite number of frequencies results in a temporal modulation with time periods $2\pi/(\Delta\omega_i - \Delta\omega_j)$ of the squared modulus of the polarization which is proportional to the emitted field intensity. For the case of two frequencies the squared modulus of the

Fig. 2 (a) N identical two-level systems are depicted which are regularly arranged with a spacing that equals an integer multiple of $\lambda/2$, where λ is the wavelength of the system's resonance. Due to their coupling via Maxwell's equations all fields emitted from the two-level systems interfere constructively and the coupled system behaves effectively like a single two-level system with a optical matrix element increased by $\sqrt{N}$. (b) The temporal decay of the squared modulus of the polarization is shown on a logarithmic scale. The radiative decay rate is proportional to N and thus the polarization of the coupled system decays N -times faster than that of an isolated system. This effect is called superradiance. (c) Measured time-resolved reflection of a semiconductor single quantum well (dashed line) and a $N=10$ Bragg structure, i.e., a multi quantum well where the individual wells are separated by $\lambda/2$ (solid line), on a logarithmic scale. Part (c) is taken from Fig. 5 of Haas, S., Stroucken, T., Hübner, M., *et al.* 1998. Phys. Rev. B 57, 14860.

polarization is proportional to $[1 + \cos((\Delta\omega_1 - \Delta\omega_2)t)]$, i.e., due to the interference of two contributions the polarization varies between a maximum and zero, see Fig. 4(b).

In the linear optical regime it is impossible to distinguish whether the optical transitions are uncoupled or coupled. As shown in Fig. 4, two uncoupled two-level systems give the same linear polarization as a three-level system where the two transitions share a common state. It is, however, possible to decide about the nature of the underlying transitions if one performs nonlinear optical spectroscopy. This is due to the fact that the so-called quantum beats, i.e., the temporal modulations of the polarization of an intrinsically coupled system, show a different temporal evolution as the so-called polarization interferences, i.e., the temporal modulations of the polarization of uncoupled systems. The former ones are also much more stable in the presence of inhomogeneous broadening than the latter ones.

Fig. 3 (a) An ensemble of two-level systems is shown where the resonance frequencies are randomly distributed according to a Gaussian distribution function of width $\delta\omega$ around an average value. (b) The temporal dynamics of the squared modulus of the polarization of ensembles of two-level systems after excitation with a short optical pulse at $t=0$ is shown on a linear scale. Since the dephasing time is set to infinity, i.e., $T_2 \rightarrow \infty$, the polarization of an ensemble of identical two-level system ($\delta\omega=0$) does not decay. However, for a finite width of the distribution, $\delta\omega > 0$, the individual polarizations of the ensemble oscillate with different frequencies and, therefore, due to destructive interference the polarization of the ensemble decays as function of time. Since the Fourier transform of a frequency-domain Gaussian is a Gaussian in the time domain, the dashed, dotted, and dashed dotted line have a Gaussian shape with a temporal width which is inversely proportional to $\delta\omega$.

In semiconductor heterostructures, quantum-beat spectroscopy has been widely used to investigate the temporal dynamics of excitonic resonances. Also the coupling among different optical resonances has been explored in pump-probe and four-wave-mixing measurements.

Coherent Control

In the coherent regime the polarization induced by a first laser pulse can be modified by a second, delayed pulse. For example, the first short laser pulse incident at $t=0$ induces a polarization proportional to $e^{-i\Delta\omega t}$ and a second pulse arriving at $t=\tau > 0$ induces a polarization proportional to $e^{-i(\varphi)} e^{-i\Delta\omega(t-\tau)}$. Thus for $t \geq \tau$ the total polarization is given by $e^{-i\Delta\omega t}(1 + e^{-i\Delta(\varphi)})$ with $\Delta(\varphi) = (\varphi) - \Delta\omega\tau$. If $\Delta(\varphi)$ is an integer multiple of 2π the polarizations of both pulses interfere constructively and the amplitude of the resulting polarization is doubled as compared to a single pulse. If, on the other hand, $\Delta(\varphi)$ is an odd multiple of π , the polarizations of both pulses interfere destructively and the resulting polarization vanishes after the action of both pulses. Thus by varying the phase difference of the two pulses it is possible to coherently enhance or destroy the optical polarization, see Fig. 5(b).

One can easily understand the coherent control in the frequency domain by considering the overlap between the absorption of the system and the pulse spectrum. For excitation with two pulses that are temporally delayed by τ , the spectrum of the excitation shows interference fringes with a spectral oscillation period that is inversely proportional to τ . The positions of the maxima and the minima of the fringes depend on the phase difference between the two pulses. For constructive interference, the excitation spectrum is at a maximum at the resonance of the system, whereas for destructive interference the excitation spectrum vanishes at the resonance of the system, see Fig. 5(a).

Coherent control techniques have been applied to molecules and solids to control the dynamical evolution of electronic wavepackets and also the coupling to nuclear degrees of freedom. In this context, it is sometimes possible to steer certain chemical reactions into a preferred direction by using sequences of laser pulses which can be chirped, i.e., have a time-dependent frequency.

Coherent Photocurrents

Exciting an unbiased inversion symmetric semiconductor with laser light that resonantly above the band gap does not lead to electrical currents. This is due to the fact, that in such a situation one excites the same amount of electrons with positive as with negative (crystal) momentum $\hbar\mathbf{k}$, see Fig. 6(a). Therefore the electrons move with the same average velocity in any direction and

Fig. 4 (a) Two optical resonances with frequency difference $\Delta\omega_1 - \Delta\omega_2$ may be realized by either a three-level system or by two uncoupled two-level systems. After impulsive excitation with an optical pulse the linear polarization of both types of systems show a modulation of the squared modulus of the polarization with the time period $2\pi/(\Delta\omega_1 - \Delta\omega_2)$. For the intrinsically coupled three-level system these modulations are called quantum beats, whereas for an interference of uncoupled systems they are named polarization interferences. Using nonlinear optical techniques, e.g., four-wave mixing and pump probe, it is possible to distinguish quantum beats and polarization interferences since coupled and uncoupled systems have different optical nonlinearities. (b) The temporal dynamics of the squared modulus of the polarization is shown for systems with two resonances and frequency difference $\Delta\omega_1 - \Delta\omega_2$, neglecting dephasing, i.e., setting $T_2 \rightarrow \infty$. After excitation with a short optical pulse at $t=0$ the squared modulus of the polarization is periodically modulated with a time period $2\pi/(\Delta\omega_1 - \Delta\omega_2)$.

consequently no net photocurrent is generated since the currents in opposite directions cancel each other. It is, however, possible to coherently generate photocurrents by nonlinear optical excitation with laser fields that contain two frequencies ω and 2ω which fulfill $\hbar\omega < E_{\text{gap}}$ and $2\hbar\omega > E_{\text{gap}}$ where E_{gap} is the band gap. Such two-color laser fields couple the initial (valence band) and the final (conduction band) states by two quantum-mechanical excitation pathways, i.e., a single-photon transition of the 2ω field and a two-photon transition of the ω field. With this scheme it is possible to coherently control the amount of excitation by the phase difference between the ω and the 2ω fields and to realize asymmetric distributions of electrons and holes in momentum space, see Fig. 6(b), which correspond to the generation of photocurrents.

Such electrical currents generated by two-color laser excitation do not rely on any specific requirements or symmetry of the material and have been observed in several systems. Using the typical selection rules for III-V semiconductors it is possible to show that linearly polarized ω and the 2ω fields generate electrical currents if they are parallel polarized whereas orthogonal polarization directions lead to pure spin currents, i.e., a motion of spin-up and spin-down electrons in opposite directions.

Due to scattering processes, the optically-generated asymmetric momentum-space distributions relax rapidly and consequently the photocurrents decay on short, typically femtosecond, time scales. For the case of a quantum well, see Fig. 6(c), microscopic calculations including Coulomb and electron-phonon scattering predict decay times on the order of 100–200 fs for the charge and spin currents.

Transient Absorption Changes

In a typical pump-probe experiment one excites the system with a pump pulse (E_p) and probes its dynamics with a weak test pulse (E_t), see Fig. 7. With such experiments one often measures the differential absorption $\Delta\alpha(\omega)$ which is defined as the difference between the probe absorption in the presence of the pump $\alpha_{\text{pump on}}(\omega)$ and the probe absorption without the pump $\alpha_{\text{pump off}}(\omega)$.

For resonant pumping and for a situation where the pump precedes the test (positive time delays $\tau > 0$), the absorption change is usually negative in the vicinity of the resonance frequency $\Delta\omega$ indicating the effect of absorption bleaching, see Fig. 8(a) and (b). There may be positive contributions spectrally around the original absorption line due to resonance broadening and, at other spectral positions, due to excited state absorption, i.e., optical transitions to energetically higher states which are only possible if the system is in an excited state. The bleaching and the positive contributions are generally present in coherent and also in incoherent situations, where the polarization vanishes but occupations in excited states are present.

Fig. 5 (a) The interference of two Gaussian laser pulses separated by the time delay τ depends on their phase difference. As shown by the thick solid line in the inset, the spectral intensity of a single pulse is a Gaussian with a maximum at the central frequency of the pulse. The width of this Gaussian is inversely proportional to the duration of the pulse. The spectral intensity of the field consisting of both pulses shows interference fringes, i.e., is modulated with a spectral period that is inversely proportional to τ . As shown by the thin solid and the dotted lines in the inset, the phase of the interference fringes depends on the phase difference $\Delta(\phi)$ between the two pulses. Whereas for $\Delta(\phi)=0$ the spectral intensity has a maximum at the central frequency, it vanishes at this position for $\Delta(\phi)=\pi$. (b) The temporal dynamics of the squared modulus of the polarization is shown for a two-level system excited by a pair of short laser pulses neglecting dephasing, i.e., setting $T_2 \rightarrow \infty$. The first pulse excites at $t=0$ an optical polarization with a squared modulus normalized to 1. The second pulse, which has the same intensity as the first one, also excites an optical polarization at $t=2$ ps. For $t > 2$ ps the total polarization is given by the sum of the polarizations induced by the two pulses. Due to interference, the squared modulus of the total polarization depends sensitively on the phase difference $\Delta(\phi)$ between the two pulses. For constructive interference the squared modulus of the total polarization after the second pulse is four times bigger than that after the first pulse, whereas it vanishes for destructive interference. One may achieve all values in between these extremes by using phase differences $\Delta(\phi)$ which are no multiples of π . It is thus shown that the second pulse can be used to coherently control the polarization induced by the first pulse.

For detuned pumping the resonance may be shifted by the light field, as, e.g., in the optical Stark effect. Depending on the excitation configuration and the system, this transient shift may be to higher (blue shift) or lower energies (red shift), see Fig. 8(a) and (b). With increasing pump–probe time delay the system gradually returns to its unexcited state and the absorption changes disappear.

As an illustration we show in Fig. 8(c) experimentally measured differential absorption spectra of a semiconductor quantum well which is pumped spectrally below the exciton resonance. For a two-level system one would expect a blue shift of the absorption, i.e., a dispersive shape of the differential absorption with positive contributions above and negative contributions below the resonance frequency. This is indeed observed for most polarization directions of the pump and probe pulses. However, if both pulses are oppositely circularly polarized, the experiment shows a resonance shift in the reverse direction, i.e., a red shift. For the explanation of this behavior one has to consider the optical selection rules of the quantum well system. One finds that the signal should actually vanish for oppositely circularly polarized pulses, as long as many-body correlations are neglected. Thus in this case the entire signal is due to many-body correlations and it is their dynamics which gives rise to the appearance of the red shift.

Spectral Oscillations

For negative time delays $\tau < 0$, i.e., if the test pulse precedes the pump, the absorption change $\Delta\alpha(\omega)$ is characterized by spectral oscillations around $\Delta\omega$ which vanish as τ approaches zero, see Fig. 9(a). The spectral period of the oscillations decreases with increasing $|\tau|$. Fig. 9(b) shows measured differential transmission spectra of a multiple quantum-well structure for different negative time delays. As the differential absorption also the differential transmission spectra are dominated by spectral oscillations around the exciton resonance whose period and amplitude decrease with increasing $|\tau|$.

Fig. 6 (a) Schematic illustration of the electron and hole distributions in momentum space that are generated in the conduction and valence band, respectively, by an above band gap optical excitation. Due to the symmetry of the distributions the optical excitation does not lead to a photocurrent. (b) Schematic illustration of the electron and hole distributions in momentum space that are generated by the excitation with a two-color laser field containing the frequencies ω and 2ω . Since the valence and conduction band states are coupled by two quantum-mechanical pathways, i.e., a single and a two-photon transitions, it is possible to coherently control the excitations and to generate asymmetric electron and hole distributions which correspond to the generation of photocurrents. (c) Calculated dynamics of photocurrents that are excited in a GaAs quantum well 150 meV above the band gap by a 20 fs two-color laser field on a logarithmic scale. The simultaneous excitation by the ω and 2ω fields leads to rapid oscillations during the duration of the laser beams. After the excitation, the currents decay approximately exponentially on a 100 – 200 fs time scale. If only electron-LO-phonon scattering is considered, both the charge and spin currents decay with the same time constant, see dashed line. When also electron-electron scattering is included in the analysis, the spin current (dark grey line) decays more rapidly than the charge current (light grey line). Part (c) is taken from Fig. 2(a) of Duc, H.T., Meier, T., Koch, S.W., 2005. Phys. Rev. Lett. 95, 086606.

Fig. 7 Transient optical nonlinearities can be investigated by exciting the system with two time-delayed optical pulses. The pump pulse (E_p) puts the system in an excited state and the test (probe) pulse (E_t) is used to measure its dynamics. The dynamic nonlinear optical response may be measured in the transmitted or reflected directions of the pump and test pulses, i.e., $\pm k_p$ and $\pm k_t$, respectively. In a pump-probe experiment one often investigates the change of the test absorption induced by the pump pulse, by measuring the absorption in the direction k_t with and without E_p . One may also measure the dynamic nonlinear optical response in scattering directions like $2k_p - k_t$ and $2k_t - k_p$ as indicated by the dashed lines. This is what is done in four-wave-mixing and photon-echo experiments.

The physical origin of the coherent oscillations is the pump-induced perturbation of the free-induction decay of the polarization generated by the probe pulse. This perturbation is delayed by the time τ at which the pump arrives. The temporal shift of the induced polarization changes in the time domain leads to oscillations in the spectral domain, since the Fourier transformation translates a delay in one domain into a phase factor in the conjugate domain.

Photon Echo

In the nonlinear optical regime one may (partially) reverse the destructive interference of a coherent, inhomogeneously broadened polarization. For example, in four-wave mixing, which is often performed with two incident pulses, one measures the emitted field in a background-free scattering direction, see Fig. 5. The first short laser pulse excites all transitions at $t=0$. As a result of the inhomogeneous broadening the polarization decays due to destructive interference, see Fig. 3. The second pulse arriving at $t=\tau>0$ is able to conjugate the phases ($e^{i(\varphi)} \rightarrow e^{-i(\varphi)}$) of the individual polarizations of the inhomogeneously broadened system. The subsequent unperturbed dynamical evolution of the polarizations leads to a measurable macroscopic signal at $t=2\tau$. This photon

Fig. 8 (a) Absorption spectra of a two-level system. The solid line shows the linear optical absorption spectrum as measured by a weak test pulse. It corresponds to a Lorentzian line that is centered at the transition frequency $\Delta\omega$, which has been set to zero. The width of the line is inversely proportional to the dephasing time T_2 . In the presence of a pump pulse which resonantly excited the two-level system, the absorption monitored by the test pulse is reduced in amplitude, i.e., bleached, since the pump puts the system in an excited state (dashed line). In the optical Stark effect the frequency of the pump is non-resonant with the transition frequency. If the pump is tuned below (above) the transition frequency, the absorption is shifted to higher (lower) frequencies, i.e., shifted to the blue (red) part of the spectrum, see dotted (dashed-dotted) line. (b) The differential absorption obtained by taking the difference between the absorption in the presence of the pump and the absorption without pump. The dashed line shows the purely negative bleaching obtained using a resonant pump. The dotted and the dashed-dotted lines correspond to the dispersive shape of the blue and red shift obtained when pumping below and above the resonance, respectively. (c) Measured differential absorption spectra of a semiconductor quantum well which is pumped off-resonantly 4.5 meV below the 1s heavy-hole exciton resonance. The four lines correspond to different polarization directions of the pump and probe pulses as indicated. Part (c) is taken from Fig. 1 of Sieh, C., Meier, T., Jahnke, F., *et al.*, 1999. Phys. Rev. Lett. 82, 3112.

Fig. 9 (a) Differential absorption spectra are shown for resonant pumping of a two-level system for various time delays τ between the pump and the test pulse. When the pump precedes the test, i.e., $\tau < 0$, the differential absorption exhibits spectral oscillations with a period which is inversely proportional to the time delay. When τ approaches zero, these spectral oscillations vanish and the differential absorption develops into purely negative bleaching. (b) Measured differential transmission spectra of a multi quantum well for different negative time delays as indicated. Part (b) is taken from Fig. 3 of Sokoloff, J.K., Joffe, M., Fluegel, B., *et al.* 1988. Phys. Rev. B 38, 7615.

Fig. 10 (a) The intensity dynamics as measured in a four-wave-mixing experiment on an ensemble of inhomogeneously broadened two-level systems for various time delays τ of the two incident pulses. The first pulse excites the system at $t=0$. In the time period $0 < t < \tau$ the individual polarizations of the inhomogeneously broadened system oscillate with their respective frequencies and due to destructive interference the total polarization decays, cp. Fig. 3. The second pulse arriving at $t=\tau$ leads to a partial rephasing of the individual polarizations. Due to phase conjugation all individual polarizations are in phase at $t=2\tau$ which results in a macroscopic measurable signal, the photon echo. Due to dephasing processes the magnitude of the photon echo decays with increasing τ , see solid, dashed, dotted and dashed-dotted lines. Describing the dephasing via a T_2 time corresponds to an exponential decay as indicated by the thin dotted line. By measuring the decay of the echo with increasing τ , one thus gets experimental information on the dephasing of the optical polarization. (b) Time-resolved four-wave-mixing signal measured on an inhomogeneously broadened exciton resonance of a semiconductor quantum well structure for different time delays as indicated. The origin of the time axis starts at the arrival of the second pulse, i.e., for a non-interacting system the maximum of the echo is expected at $t=\tau$. The insets show the corresponding time-integrated four-wave-mixing signal and the linear absorption. Part (b) is taken from Fig. 1 of Jahnke, F., Koch, M., Meier, T., *et al.* 1994. Phys. Rev. B 50, 8114.

echo occurs since at this point in time all individual polarizations are in phase and add up constructively, see Fig. 10(a). Since this rephasing process leading to the echo is only possible as long as the individual polarizations remain coherent, one can analyze the loss of coherence (dephasing) by measuring the decay of the photon echo with increasing time delay.

Time-resolved four-wave-mixing signals measured for different time delays on an inhomogeneously broadened exciton resonance of a semiconductor quantum well structure are presented in Fig. 10(b). Compared to Fig. 10(a), the origin of the time axis starts at the arrival of the second pulse, i.e., for a non-interacting system the maximum of the echo is expected at $t=\tau$. Due to the inhomogeneous broadening the maximum of the signal is shifting to longer times with increasing delay. Further details of the experimental results, in particular, the exact position of the maximum and the width of the signal, cannot be explained on the basis of non-interacting two-level systems, but require the analysis of many-body effects in the presence of inhomogeneous broadening.

Multidimensional Fourier Transform Spectroscopy

Exciting a semiconductor with N short laser pulses from different directions may lead to a nonlinear signal that depends on real time and $N-1$ time delays between the incident pulses. The idea of multidimensional Fourier transform spectroscopy is to Fourier transform the time-domain signal with respect to some or all of the time and time delay arguments to the frequency domain.

Fig. 11 Schematic illustration of two-dimensional Fourier-transform spectroscopy signals for a few-level systems. (a) For the case of a single two-level system the absorption and emission take place at the same frequency which leads to a single peak on the diagonal of the two-dimensional signal. (b) Two uncoupled two-level systems absorb and emit at two frequencies and therefore correspond to two peaks on the diagonal. (c) Similarly to case (b), a three-level system can also absorb and emit at two frequencies. However, for a three-level system the coupling among the transitions via the common ground state leads to the appearance of two additional off-diagonal peaks. (d) When the excitation to an energetically higher state is only possible if the system is already excited, this transition frequency appears as an additional off-diagonal peak in the emission. Such a situation can be realized in systems that contain, e.g., exciton and biexciton resonances.

The so-obtained multi-dimensional frequency-domain signal depends on up to N frequencies and contains correlations among the frequency components which arise due to the dynamics in the respective time delays. Such multi-dimensional signals have been shown to provide a transparent way to unravel couplings and interaction processes that determine the complex nonlinear dynamics of several investigated systems.

Fourier transform spectroscopy is frequently performed in four-wave-mixing set-ups where the system is excited by two or three short laser pulses. Fourier transforming with respect to time and time delays provides signals that depend on two or three frequency arguments corresponding to two- or three-dimensional spectroscopy, respectively. A detailed analysis of such signals and theoretical modelling is able to provide valuable information on the nature and the coupling among the optical excitations, their homogeneous and inhomogeneous broadening, many-body effects, etc.

In the most simple example of two-dimensional Fourier transform spectroscopy, one may interpret the two frequencies arguments as excitation and emission frequencies. Optical transitions that can be excited directly from the ground state and contribute to the nonlinear emission appear as peaks on the diagonal corresponding to identical excitation and emission frequencies, see Fig. 11(a) and (b) for the cases of a single and two two-level systems, respectively. Consequently, inhomogeneous broadening, cp. Section 3.3, leads to a broadening of the signal along the diagonal. A coupling of optical transitions, e.g., by sharing a common state as in a three-level system, leads to off-diagonal peaks appearing in Fourier transform spectroscopy, see Fig. 11(c). Also transitions that are only possible in an already excited system lead to off-diagonal peaks that describe emission at frequencies where the system has no linear absorption, see Fig. 11(d).

Nonlinear Optics in Disordered Media: Anderson Localization

Arash Mafi, University of New Mexico, Albuquerque, NM, United States

© 2018 Elsevier Ltd. All rights reserved.

Introduction

Is Anderson localization preserved, enhanced, weakened, or destroyed in the presence of nonlinearity? In this short article, we will learn that there may not be a straightforward answer to this question. A survey of the literature published on this subject reveals that the answer to this rather basic question can best be described as inconclusive at this point. Of course, it should not be a surprise that the potentially chaotic behavior as a result of the nonlinear dynamics is largely behind the present state of debate in the literature on the interplay between disorder and nonlinearity in the context of Anderson localization.

This article presents a survey of some highlights in the literature over the past few years with the hope that an eventual conclusive answer can be found to such a fundamental question in a not so distant future. The question can be cast in a limited form dealing only with the optical Kerr effect, which is of greater interest to the photonics community, or in a more general context to explore and differentiate the impact of various forms of nonlinearity on localization. The interplay between disorder and nonlinearity has been explored over the years in various contexts and different disciplines. Some inevitable overlap remains in the existing literature belonging to different fields of study, primarily due to similarities among the dynamical equations of different physical systems. For example, the Gross–Pitaevskii equation describing the Bose–Einstein condensate is similar to the nonlinear Schrödinger equation describing the propagation of light in a nonlinear optical medium.

Anderson localization in general, and even Anderson localization of light in particular are broad research topics. In the optical domain, the most conclusive results on localization have so far been obtained in the context of transverse Anderson localization of light, where light is transversely localized in a waveguide-like geometry with a disordered transverse profile and propagates freely in a longitudinally uniform medium. Anderson localization is more readily observed in this transverse form as explained in the next section. Moreover, the transversely localized and longitudinally propagating platform allows for a relatively long-distance interaction of light with the optical medium, resulting in an appreciable nonlinear phase shift. As such, we will primarily focus on results that are more relevant to the impact of nonlinearity on transverse Anderson localization. For more details, we refer the interested reader to an excellent review article on this subject by Fishman, Krivolapov, and Soffer and references therein.

Anderson Localization of Light

Anderson localization is the absence of diffusive wave transport in highly disordered scattering media. Its origin dates back to a theoretical study conducted by P. W. Anderson in 1958 who investigated the behavior of spin diffusion and electronic conduction in random lattices. It was soon realized that because the novel localization phenomenon is due to the wave nature of the quantum mechanical electrons scattering in a disordered lattice, it can also be observed in other coherent wave systems, including classical ones.

The fact that Anderson localization was deemed possible in non-electronic systems was encouraging, given that the observation of disorder-induced localization was shown to be inhibited by thermal fluctuations and nonlinear effects in electronic systems. Subsequently, localization was studied in various classical systems including in acoustics, elastics, electromagnetics, and optics. It was also recently investigated in various quantum optical systems, such as atomic lattices and propagating photons.

General studies of Anderson localization have revealed that waves in one-dimensional (1D) and two-dimensional (2D) unbounded disordered systems are always localized. However, in order for a three-dimensional (3D) random wave system to localize, the scattering strength needs to be larger than a threshold value. This statement is often cast in the form of $kl^* \sim 1$, where k is the effective wavevector in the medium, and l^* is the wave scattering transport length. This is referred to as the Ioffe–Regel condition and shows that in order to observe Anderson localization, the disorder must be strong enough such that the wave scattering transport length becomes on the order of the wavelength. The Ioffe–Regel condition is notoriously difficult to satisfy in 3D disordered optical media. For the optical field to localize in 3D, very large refractive index contrasts are required that are not generally available in low-loss optical materials. The fact that Anderson localization is hard to achieve in 3D optical systems may be a blessing in disguise; otherwise, no sunlight would reach the earth on highly cloudy days.

Transverse Anderson Localization of Light

Unlike 3D lightwave systems in which the observation of the localization is prohibitively difficult, observation of Anderson localization in a quasi-2D optical system is readily possible, as was first shown by Abdullaev *et al.* and De Raedt *et al.* In particular, De Raedt *et al.* showed that 2D Anderson localization can be observed in a dielectric with transversely random and longitudinally uniform refractive index profile. An optical field that is launched in the longitudinal direction tends to remain localized in the transverse plane as it propagates in the longitudinal direction in a transversely random dielectric medium. This behavior was dubbed transverse Anderson localization of light.

Fig. 1 (a) Cross section view of the polymer Anderson localization optical fiber developed by Karbasi *et al.* with a nearly square profile and an approximate side width of 250 μm ; (b) zoomed-in scanning electron microscope image of a 24 μm wide region on the tip of the fiber exposed to a solvent to differentiate between PMMA and PS polymer components, where feature sizes are around 0.9 μm and darker regions are PMMA. Adapted with permission from Karbasi, S., Hawkins, T., Ballato, J., Koch, K.W., Mafi, A., 2012a. Transverse Anderson localization in a disordered glass optical fiber. *Opt. Mater. Express* 2, 1496–1503. doi:10.1364/OME.2.001496; Karbasi, S., Mir, C.R., Yarandi, P.G., *et al.* 2012c. Observation of transverse Anderson localization in an optical fiber. *Opt. Lett.* 37, 2304–2306. doi:10.1364/OL.37.002304.

In their pioneering work, Schwartz *et al.* wrote the transversely disordered and longitudinally invariant refractive index profiles in a photorefractive crystal using a laser beam. They used another probe beam to investigate the transverse localization behavior. Their experiment was quite interesting as it allowed them to vary the disorder level by controlling the laser illumination of the photorefractive crystal in a controlled fashion to observe the onset of the transverse localization and the change in the localization radius as a function of the disorder level. The transverse localization of the beam and the free longitudinal propagation due to the longitudinal invariance of the dielectric medium strongly resembled the optical waveguides; therefore, applications of Anderson localization for light propagation in an optical fiber-like medium seemed an appealing extension of these ideas.

In 2012, Karbasi *et al.* reported the first observation of transverse Anderson localization in an optical fiber. In order to obtain large refractive index fluctuations required for a strong transverse localization, they randomly mixed 40,000 pieces of polymethyl methacrylate (PMMA) fiber with refractive index of 1.49, and 40,000 pieces of polystyrene (PS) fiber with refractive index of 1.59, and redrew the random stack to a 250- μm -wide optical fiber with random index fluctuations equal to 0.1 and an approximate transverse random feature size equal to 0.9 μm (see Fig. 1). The large index contrast of 0.1 ensured that both the beam localization radii and the sample-to-sample fluctuations over the ensemble of localized beam radii are sufficiently small to ensure that disordered fiber operates as a genuine optical fiber – they observed that the localized beam radii launched at different transverse positions over the facet of Anderson localizing fiber were all small and were nearly identical. Later, Karbasi *et al.* reported the first observation of Anderson localization in a silica optical fiber as well. The reported glass-air disordered fiber was made from “satin quartz”, which is a porous artisan glass. After drawing the preform, the airholes (bubbles) in the glass were stretched to form the hollow air-rods required for transverse Anderson localization. The large draw ratio sufficiently preserved the longitudinal invariance, without significant disturbance over typical lengths used in the experiments.

Transverse Anderson Localization and Kerr Nonlinearity in Theory and Experiment

Concrete experimental results on the interplay between disorder and nonlinearity are rather sparse. Even in the very few available published work in the literature, one does not get a clear sense on the extent to which Anderson localization is affected by nonlinearity. This is most likely due to the large parameter space and the possibility of many configurations under which the studies can be performed. In this article, we review the results of two pioneering works by Schwartz *et al.* and Lahini *et al.*, involving both experiment and theory, and then examine further theoretical considerations on this issue. The interaction between disorder and other forms of nonlinearity (non-Kerr) will be discussed in the next section.

Earlier, we mentioned the numerical and experimental work of Schwartz *et al.* that resulted in the observation of transverse Anderson localization of light. The authors also investigated the transverse Anderson localization of light in the presence of Kerr nonlinearity, both numerically and experimentally. The defining equation for the nonlinear propagation of light is the nonlinear Schrödinger equation (NLSE) which includes a Kerr nonlinearity term:

$$i \frac{\partial A}{\partial z} + \frac{1}{2n_0 k_0} [\nabla_T^2 A + k_0^2 (n^2 - n_0^2) A] + k_0 n_2 |A|^2 A = 0 \quad (1)$$

where A is slow-varying amplitude of the optical field, k_0 is the vacuum wavevector, z is the propagation distance, T represents the transverse coordinates (x and y here), $n(x,y)$ is the transversely disordered refractive index profile, n_0 is the mean value of the refractive index around which index fluctuation occur, and n_2 is the nonlinear index, which is positive for self-focusing and negative for self-defocusing nonlinearity.

As a case study, the authors considered a disordered lattice where the maximum contribution of the nonlinear term to the index change " $\max(|n_2| \times |A|^2)$ " was assumed to be a maximum of 15% of the index contrast of the underlying periodic waveguide. They also varied the disorder level from 0 to 30%, where the disorder level was defined as the magnitude of random index fluctuations relative to the index contrast of the underlying periodic waveguide. Using numerical simulations, they observed that over this range, the self-defocusing nonlinearity ($n_2 < 0$) results in a moderate (nearly negligible) widening of the average beam profile. They reported that after a short propagation distance, the beam broadens and the remaining propagation is essentially as if the medium were linear, primarily because the intensity is much lower and the nonlinear effects do not play a role anymore. In contrast, the self-focusing nonlinearity ($n_2 > 0$) resulted in a substantial reduction of the average localized beam diameter. The enhancement of localization due to the self-focusing nonlinearity was particularly noticeable when the disorder level was less than 15%. They observed that at high disorder levels, where localization takes place, the difference between linear and nonlinear propagation is reduced, and the behavior is dominated primarily by disorder.

The experiments were performed at different nonlinear strengths. Consider α as the ratio between the peak intensity of the probe beam and the maximum intensity of the lattice-forming beams in the photorefractive crystal. The experiments were carried out for values of $\alpha = 1, 2$, and 3. The statistical analysis of the localized beam radius clearly confirmed the expected reduction in the average beam radius due to the self-focusing nonlinearity. They observed that self-focusing enhances localization, altering the intensity profile from diffusive-like to exponentially decaying. They increased the nonlinearity (increased α) and observed that the intensity profile narrowed down accordingly. At $\alpha = 3$, the output beam profile resembles the input profile, suggesting the formation of a soliton.

Similar results were reported by Lahini *et al.* using disordered 1D waveguide lattices, as shown in Fig. 2. Their experiment consisted of a 1D lattice of $N=99$ coupled optical waveguides patterned on an AlGaAs substrate. The nonlinear Schrödinger equation governing the propagation of light in this coupled lattice system can be expressed as

$$i \frac{\partial U_n}{\partial z} = \beta_n U_n + C(U_{n+1} + U_{n-1}) + \gamma |U_n|^2 U_n \quad (2)$$

where n is the index labeling lattice sites (waveguides), U_n is the optical field amplitude at site n , β_n is the propagation constant associated with the n th waveguide, C is the tunneling rate between adjacent sites, and z is the longitudinal space coordinate. γ characterizes the nonlinear Kerr effect. Disorder was introduced to the lattice by randomly changing the width of each waveguide, resulting in the randomization of the propagation constants over a range of $\beta_0 \pm \Delta$, where β_0 is the propagation constant for a mean value of the waveguide width. Δ/C is defined as the disorder strength, with the implicit assumption that the coupling coefficient between adjacent waveguides is nearly identical.

Light was injected into one or a few waveguides at the input, and light intensity distribution was measured at the output. In the linear regime, Lahini *et al.* identified that highly localized eigenmodes exist near the top edge of the propagation constant band with a flat-phase profile and near the bottom edge of the band with a highly varying-phase profile, having phase flips between adjacent sites. The modes near the middle of the band were not as localized and also showed some phase variations. In the weak nonlinear regime, Lahini *et al.* observed that nonlinearity enhances localization in flat-phased modes and induces delocalization in the staggered modes. This behavior is explained as follows: the presence of the weak nonlinearity perturbatively shifts (increases) the value of the propagation constant of each localized mode. For the flat-phased modes, the nonlinearity shifts the modes outside the original linear spectrum. However, for the staggered, which belong to the bottom edge of the propagation constant band, a perturbative increase in the value of the propagation constant shifts it further inside the original linear spectrum. Therefore, the propagation constant of a staggered mode can cross and resonantly couple with other modes of the lattice, resulting in delocalization.

The effect of nonlinear perturbations on localized eigenmodes was studied by Lahini *et al.* experimentally via exciting a pure localized mode and increasing the input beam power. The intensities were kept far below the self-focusing threshold in the

Fig. 2 Schematic view of the disordered lattice waveguide used in the experiment by Lahini *et al.* Reproduced from Lahini, Y., Avidan, A., Pozzi, F., *et al.* 2008. Anderson localization and nonlinearity in one-dimensional disordered photonic lattices. *Phys. Rev. Lett.* 100, 013906. doi:10.1103/PhysRevLett.100.013906.

periodic lattice. They observed that some of the localized modes exhibited significant response to nonlinearity. The experiments showed that weak positive nonlinearity tends to further localize flat phased localized modes, but tends to delocalize staggered modes, consistent with the theoretical prediction above. The results obtained by Lahini *et al.* do not contradict the general observations of Schwartz *et al.*; rather, they argue that the enhanced localization due to nonlinearity by Schwartz *et al.* is only applicable to certain optical modes.

We would like to point out an early work by Pertsch *et al.* in 2004 who experimentally investigated light propagation in a disordered two-dimensional array of mutually coupled optical fibers. In the linear case they observed that light either spreads in a diffusive manner or localizes at a few sites. The absence of Anderson localization was most likely due to the fact that the disorder was not sufficiently high to localize the field whitening the transverse dimensions of the fiber. However, they reported that for high excitation power diffusive spreading is arrested by the focusing nonlinearity and a discrete soliton is formed.

Further Theoretical Considerations

In 2008, Pikovsky and Shepelyansky presented a somewhat different account of the interaction between disorder and nonlinearity. In their analysis, they considered a discrete nonlinear Schrödinger equation with a third-order diagonal Kerr nonlinear term, isomorphic to Eq. (2), to study the temporal evolution of quantum wavefunction on coupled lattices in the form of

$$i \frac{\partial \psi_n}{\partial t} = E_n \psi_n + \beta |\psi_n|^2 \psi_n + V(\psi_{n+1} + \psi_{n-1}) \quad (3)$$

where β characterizes nonlinearity, V is the hopping matrix element and is deterministic and identical for all terms. The disorder is introduced through the diagonal terms, where they are assumed to be randomly and uniformly distributed in the range $-W/2 < E_n < W/2$, and

$$\sum_n |\psi_n|^2 = 1 \quad (4)$$

is assumed. For optical waveguides, this equation describes the propagation of light in a coupled waveguide lattice, where the coupling strengths among the waveguides are identical but the propagation constants of individual waveguides are randomized by manipulating the geometry or the refractive index of each individual waveguide. Therefore, this conforms well with the problem studied by Lahini *et al.* described earlier. The normalization condition means that the total optical power remains unchanged as the light propagates through the coupled waveguide lattice. The authors verified that in the absence of nonlinearity ($\beta=0$) and in the presence of weak disorder, all eigenstates are exponentially localized as expected from Anderson localization theory with the localization length $l \approx 96(V/W)^2$ at the center of the energy band.

Pikovsky and Shepelyansky considered the spreading of a field that is initially localized at the central lattice point with $|\psi_n(0)|^2 = \delta_{n,0}$. Of course, this problem is fully studied in the limit of no disorder with $W=0$ and a general value of nonlinearity $\beta \neq 0$, e.g., in the context of nonlinear light propagation in discrete lattices, where diffraction and nonlinearity can give rise to interesting physics including diffraction-free propagation and self-localized states or discrete solitons. The opposite limit of no nonlinearity with $\beta=0$ in the presence of disorder $W \neq 0$ is also well studied in the context of Anderson localization. The intermediate regime is the focus of the work presented by Pikovsky and Shepelyansky.

Intuitively speaking, one may think that in a nonlinear disordered coupled waveguide system, the dynamics of the beam is initially influenced by nonlinearity; and as the beam spreads, the effect of nonlinearity becomes weaker and the disorder dynamics takes over. Therefore, one should always expect Anderson localization after a sufficiently long time. The analysis by Pikovsky and Shepelyansky is presented in view of earlier work by Sanchez-Palencia *et al.* who similarly argued for the localization of the field at large time scales, consistent with the intuitive view discussed above. However, Sanchez-Palencia *et al.* argued that the high-momentum cutoff of the Fourier transform of the correlation function for 1D speckle potentials can change localization from exponential to algebraic. Per argument presented in by Pikovsky and Shepelyansky, at first glance, one may think that Kerr nonlinear effects may be favored strongly by localized field configurations because if the field spreads over N lattice sites, the conservation of power implies that the Kerr nonlinearity should scale as $|\psi_n|^2 \sim 1/N$. However, Pikovsky and Shepelyansky argue that the nonlinear frequency shift $\beta |\psi_n|^2 \sim \beta/N$ should be compared with the characteristic distance between the frequencies of the exponentially localized modes, which scales as $1/N$; therefore, the effect of nonlinearity persists and does not quantitatively depend on the width of the field distribution and is omnipresent.

Using a theoretical argument, they suggested that in the presence of non-vanishing nonlinearity, the beam spreading characterized by

$$\sigma^2 = \sum_n (n - \langle n \rangle)^2 |\psi_n|^2 \quad (5)$$

should follow a subdiffusive behavior where $\sigma^2 \propto t^\alpha$ with $\alpha=2/5$. They verified their theoretical argument via numerical integration of Eq. (3) and monitoring the results, up to $t=10^8$. For the numerical simulation they used the boundary condition $\psi_n(t=0) = \delta_{n,0}$, where $n=0$ represents the middle waveguide, and the integration is performed by the operator splitting method. In a sample

set of simulations they chose the nonlinearity strength to be $\beta=V$ for two cases: case 1 with $W=2$; and case 2 with $W=2$. As expected, the initial expansion was ballistic for either case, but after some time t_0 , the expansion became subdiffusive in either case. They fit the subdiffusive expansion to $\sigma \propto t^\alpha$ over the range $t_0 < t < 10^8$ to obtain an estimate for the subdiffusive exponent. In case 1, for different instances of randomness, they obtained $0.32 \leq \alpha \leq 0.39$; and for case 2 they reported $0.28 \leq \alpha \leq 0.41$. Upon averaging over 8 independent realizations, they reported a fit of the form $57.5 \times t^{0.344}$ for case 1 and $8.7 \times t^{0.306}$ for case 2 over the subdiffusive ranges.

Pikovsky and Shepelyansky analyzed the probability distribution $w_n = |\psi_n|^2$ over lattice sites n ; in the absence of nonlinearity they observed an exponential decay with an exponent consistent with the Anderson localization. In the presence of nonlinearity, however, they observed a rather flat distribution in the vicinity of $n=0$ where the width of the flat distribution depended on the value of β . As expected, the (low-intensity) tails of the distribution always followed a decay exponent consistent with the linear theory of Anderson localization. Another important observation reported by Pikovsky and Shepelyansky was the presence of a certain critical strength β_c for nonlinearity, beyond which the reported delocalization behavior happens. The numerical solutions suggested a value of $\beta_c \approx 0.1$ for this threshold value. However, Pikovsky and Shepelyansky argued that the threshold-like behavior might not be perfect and a slow spreading may persist all the way down to very small values of nonlinearity albeit at an extremely slow rate that could not be detected in the numerical integration scheme.

In another study published by Kopidakis *et al.* on the spreading of an initially localized wave packet, the authors confirmed that while there are many initial conditions such that the second moment of the norm in Eq. (5) and energy density distributions diverge with time in agreement with Pikovsky and Shepelyansky, the participation number of a wave packet does not diverge simultaneously. The participation number is defined as

$$P = \frac{(\sum_n |\psi_n|^2)^2}{\sum_n |\psi_n|^4} \quad (6)$$

which is an alternative measure of the wave spreading to Eq. (5). Kopidakis *et al.* prove this result analytically for norm-conserving models that satisfy Eq. (4) with strong enough nonlinearity. They showed that initially localized wave packets with a large enough amplitude cannot spread to arbitrarily small amplitudes. The consequence is that a part of the initial energy must remain well focused at all times.

A later report by Fishman *et al.* provide a somewhat different account of the impact of nonlinearity on Anderson localization in disordered lattices. Fishman *et al.* present a thorough survey of the many subtleties involved regarding the interaction of nonlinearity and disorder. The conclusion is that the situation can best be described as inconclusive at this point. For example, when using the numerical simulations, they caution that Eq. (3) is chaotic with an exponential sensitivity to numerical errors. Because of the possibly chaotic motion due to the presence of nonlinearity, Fishman *et al.* argue that the numerical solutions of Eq. (3) are not actual solutions. In order to draw conclusions similar to those by Pikovsky and Shepelyansky, one must assume that the numerical solutions are statistically similar to the correct solutions with no real theoretical support for this assumption. For long-time (or long-distance) propagation in waveguides, it is not clear that reducing the t step size can control the cumulative numerical error, given that the limit of zero t step may be singular. Details of these arguments can be found in the review article by Fishman *et al.*

Other Forms of Nonlinearity

Other forms of nonlinearity besides Kerr can also interact with the disorder-induced localization. Recently Leonetti *et al.* explored the impact of thermally induced nonlinearity on Anderson localization for a beam of light propagating in the polymer Anderson localizing optical fiber of Fig. 1. They reported the observation of a self-focusing action occurring in the disordered fiber with the binary index distribution which was triggered by a defocusing thermal nonlinearity. The larger light absorption strength in PMMA than PS results in an inhomogeneous temperature distribution. The higher temperature in PMMA translates into a decrease of its refractive index. The result is an increased refractive index mismatch and stronger localization. In effect, they demonstrated that transversely localized modes shrink when the pump intensity is increased despite the fact that $n_2 < 0$ for the polymers, which seems quite counter-intuitive in the first glance.

In a subsequent publication, the authors provided further evidence of this behavior by analyzing the direct relation between the optical intensity and the localization length. In their experiments, they probed the behavior of light by using both a broadband (a femtosecond Ti: Sapphire laser at 800 nm wavelength with 80 nm bandwidth) and a monochromatic laser (solid-state continuous Nd: YAG laser at 1064 nm). They observed that the broadband light beam injected in the fiber is dispersed at the output into a series of peaks corresponding to localized modes. This output spectrum is modified when the input intensity in the system is increased, demonstrating that the nonlinearity also affects the modes structure. Importantly, they found that the spatial extension of the individual modes decreases with fluence due to the thermal nonlinearity. They repeated the experiment using a monochromatic continuous wave (CW) laser, activating only a single spatial mode, and observed similar self-focusing behavior with the optical power. By comparing their observations with standard homogeneous polymer fibers, they proved that the disorder has turned the defocusing medium into a focusing one.

Second-Harmonic Generation in Two-Dimensional Materials

Main Definitions and Background

Two-dimensional (2D) materials are structures in which atoms are arranged periodically in two of the three spatial directions and which have (sub-)nanometric dimension in the third direction. Furthermore, when more than one layer is present, the chemical bonding between atoms in the periodic directions are much stronger (covalent or ionic) than those between layers (van der Waals). 2D materials are synthesized mostly by mechanical exfoliation of three-dimensional van der Waals layered materials. Some of the more common materials, such as monolayers of graphene, h-BN, Gallium chalcogenides (e.g. GaTe, GaSe) and transition metal dichalcogenides (e.g. MoS₂, WSe₂) have been obtained as well by chemical vapour deposition (CVD) or by van der Waals epitaxy (VDWE) (see e.g. [Butler et al. \(2013\)](#)). These processes produce polycrystalline structures with crystal flakes that have one to few layers thickness and with dimensions of 10 μm to 70–80 μm. The flakes which have typically a triangular shape – reflecting the crystal symmetry – are oriented in different directions and separated by grain boundaries. A variety of spectroscopic techniques are in place to characterize the crystal orientation, layers number and stacking, grain boundaries of these polycrystalline structures (see e.g. [Butler et al. \(2013\)](#)).

Second-harmonic generation (SHG) is a nonlinear optical process in which a crystal irradiated with laser light of a given frequency ω generates radiation at the second-harmonic frequency 2ω (see [Boyd \(2008\)](#)). In the context of 2D materials, SHG is relevant as it is the basis of spectroscopic techniques to structurally characterize the samples obtained e.g. by exfoliation or CVD. In addition, there is a general interest in optical properties of 2D materials which are expected to be characterized by strong excitonic effects because of the geometrical confinement and poor dielectric screening. Finally technologically there is an interest in the possibility of employing 2D materials with strong SHG as on-chip optical frequency converters.

We recall here some key relations for the SHG which are needed in the discussion that follows. The electric polarization field $\mathbf{P}$ can be expanded in powers of the total electric field $\mathbf{E}$ as (we assume the dipole approximation, if not otherwise stated, see [Shen \(2003\)](#)):

$$\mathbf{P}(\omega) = \epsilon_0 [\chi^{(1)}(\omega)\mathbf{E}(\omega) + \chi^{(2)}(\omega; \omega_1, \omega_2)\mathbf{E}(\omega_1)\mathbf{E}(\omega_2) + \dots + \chi^{(n)}(\omega; \omega_1, \dots, \omega_n)\mathbf{E}(\omega_1)\dots\mathbf{E}(\omega_n) + \dots] \quad (1)$$

where the coefficients $\chi^{(n)}$ are the (non)linear optical susceptibilities and ϵ_0 is the permittivity of vacuum. The SHG corresponds to the second order term when $\omega_1 = \omega_2$ and thus $\omega = \omega_1 + \omega_2 = 2\omega_1$. Since $\mathbf{P}$ and $\mathbf{E}$ are vector, $\chi^{(2)}$ is a third-rank tensor, $\chi_{ijk}^{(2)}$, with the first index i referring to the direction of the polarization field and the remaining indexes, jk to the direction of the electric field:

$$P_i^{(2)}(2\omega) = \epsilon_0 \chi_{ijk}^{(2)} E_j(\omega) E_k(\omega) \quad (2)$$

In [Eq. \(2\)](#), $P_i^{(2)}$ is the second order contribution to the polarization field. Symmetry properties of the crystal are reflected in the structure of the second order susceptibility tensor. For example in centrosymmetric crystals, i.e. with an inversion center, all elements of the tensor are identically zero (this implies that the SHG from the electric dipole is identically zero. The measured SHG in centrosymmetric crystals is very small, but not identically zero, because of higher order multipole contributions).

The most commonly studied 2D crystals belongs to the D_{3h} symmetry point-group: the crystal structure is invariant under rotation of 120° around an axis perpendicular to the plane of the 2D crystal (an example is given in [Fig. 1](#)). The D_{3h} symmetry point-group does not comprise the inversion operation, so crystals belonging to this point-group have a nonzero SHG. The second order susceptibility tensor in this case has only the $\gamma\gamma\gamma = -\gamma\chi\chi = -\chi\chi\gamma = -\chi\gamma\chi$ components different from zero where we labeled with x and y the armchair and the zig-zag directions (see [Fig. 1](#)). Note that graphene belongs to the D_{6h} symmetry point-group which includes the inversion operation and therefore does not have a dipole-allowed SHG.

Fig. 1 Symmetry of 2D materials belonging to the D_{3h} symmetry point-group. As an example we consider a hexagonal structure with two atoms of different species. Only few units of the infinite periodic structure are drawn. The red dot represents the 3-fold rotation axis perpendicular to the plane of the 2D crystal. A rotation of 120° around this axis does not change the crystal structure. The three in-plane two-fold rotation axes are also represented as red lines with origin at the dot. The x axis is chosen parallel to one of the armchair directions (dotted green line) and the y parallel to one of the zig-zag directions (dotted magenta line).

SHG for Characterization of 2D Materials

SHG experiments on 2D materials are realized by shining laser light onto the sample on a substrate. The second-harmonic power (either reflected or transmitted) is then measured. Most of the SHG experiments on 2D materials are performed in the reflection geometry which is schematically shown in Fig. 2. The substrate is typically dielectric coated, e.g. SiO_2/Si . The substrate can be chosen to be transparent to both the fundamental and SH frequency so that the transmitted SH signal can be measured as well. Normally the sample can be both mechanically rotated around the out-of-plane direction and shifted in the two in-plane directions. Rotation allows to study dependence on the light polarization. Scans in the in-plane directions allows to take a SHG image of the sample. Because of the similarity of the problem, many of the concepts and techniques are reminiscent of concepts and techniques applied in SHG measurements of surfaces, films and interfaces.

Polarization Dependent Measurements

To illustrate the basic principle behind polarization dependent measurements we consider here a linearly polarized laser light with propagation direction perpendicular to the 2D crystal and the associated electric field forming an angle θ_0 with the armchair direction of the crystal which we assume to belong to the D_{3h} symmetry-point group. This is schematically depicted in Fig. 3. Because of the symmetry with respect the three-fold rotation axis, varying the field polarization of 120° leaves the SHG unchanged. That means that the parallel (along x') and perpendicular (along y') components of the SHG electric field E_{SH} vary as $\sin(3\theta + \theta_0)$ and $\cos(3\theta + \theta_0)$ when the sample is rotated by θ . The components of the SH power then, which is proportional to E_{SH}^2 , vary as $\sin^2(3\theta + \theta_0)$ and $\cos^2(3\theta + \theta_0)$. Plotting the reflected SH power as a function of the polarization angle on a polar grid results in a plot similar to that in Fig. 3 (see e.g. Kumar *et al.* (2013)). A fit of the measured data against the expected behaviour for the SH power gives the SH intensity and the initial direction of the electric field with respect to the crystal armchair direction θ_0 .

Then from polarization dependent measurements one can extract two important structural information on the 2D crystal: (1) whether it has a given/expected symmetry, (2) its orientation. Furthermore from the reflected power one can in principle deduce an absolute measure of the SHG, though this is not straightforward as discussed in Section "Absolute Measure of SHG."

Fig. 2 Schematic set up of a SHG experiment in reflection geometry. The light pumped by the source is focus onto the sample by an objective which also collects the reflected light. Before being detected and analyzed from the detector, the fundamental and frequencies other than the SH frequency are blocked by a (set of) filter(s).

Fig. 3 Direction of electric field with respect to the 2D crystal sample. Initially, the electric field, polarized along the x axis, forms an angle θ_0 with the armchair direction of the crystal (x axis). Later the crystal is rotated, and forms an angle θ with the initial direction.

SHG Imaging

By scanning the SH power in the two in-plane directions of an sample illuminated with polarized (quasi-)monochromatic light, the SH can be rendered in a false-color image, where a scale of colors is associated to the (relative) SH intensity in either the x or y directions. If the substrate is chosen such that it has a negligible SHG, then high contrast images can be obtained. These images provide several information on the sample.

First, as the SH intensity does not change within a crystal, domains of the same color can be identified as crystal flakes. Second, because of the dependence on the electric field polarization discussed previously, crystals with a different orientation show a different SH intensity. Then those crystals can be distinguished from each other and their relative orientation can be estimated. However as it is evident from Fig. 4, crystals which form an angle of 60° with each other have the same color. Nevertheless it is still possible to distinguish them because the edges have a different electronic structure with respect to the rest of the crystal and, due to the sensitivity of the SHG to the electronic structure, have a different color (see e.g. Yin *et al.* (2014), Kumar *et al.* (2013)).

When compared with optical imaging, SHG imaging offers several advantages: stronger contrast with respect to the substrate, possibility of distinguish crystals with different orientation and of detecting edges. As discussed in the following section it also allows one to distinguish between different stacking geometries.

Dependence on Stacking and Number of Layers

The SHG is sensitive to the number of layers and to the stacking geometry. The most evident dependence on the number of layers occurs for 2D materials obtained from centrosymmetric 3D crystals (this is the case of several commonly studied crystals such as the transition metal dichalcogenides or the hexagonal-BN). For these 2D crystals a clear pattern is observed in the SHG of even and odd layers samples, with negligible SHG when the number of layers is even (Kim *et al.*, 2013; Li *et al.*, 2013). In fact, samples with an even number of layers have an inversion center and as discussed in Section “Main Definitions and Background” this is reflected in a zero dipole-allowed SHG. Multipole contributions to SHG are in fact several orders of magnitude smaller than the dipole one.

A simple interference model gives an alternative way to understand the even-odd dependence. Let's consider the SH electric field (that is the electric field driven by the SH polarization) of each crystal plane independently. Then for example the SH electric field parallel and perpendicular to the armchair direction in the i th layer are $E_{2\omega}^{\parallel} \propto \cos(3\theta_i)$ and $E_{2\omega}^{\perp} \propto \sin(3\theta_i)$ where θ_i is the angle between the applied electric field and the armchair direction. If we consider two layers, the total SH electric field is then given by the sum of the fields. The intensity – related to the square of the total electric field – then is given by:

$$I_{1+2} = I_1 + I_2 + 2\sqrt{I_1 I_2} \cos(3(\theta_1 - \theta_2)) \quad (3)$$

For identical layers $I_1 = I_2$, then when $\theta_1 - \theta_2 = 60^\circ$, I_{1+2} vanishes. The AB stacking, which gives a centrosymmetric crystal when the number of layers is even, corresponds indeed to an angle of 60° between the armchair directions of two successive layers (see Fig. 5). Instead, for crystals with an AA stacking $\theta_1 - \theta_2 = 0^\circ$ and I_{1+2} has its maximum value. The AA stacking occurs for example in GaSe and GaTe. Moreover it is possible to synthesize layered materials with a stacking different from that of the corresponding bulk layered material (Hsu *et al.*, 2014). Note that the interference model can be refined by considering the SH electric fields as a radiation fields which is equivalent to account for multipole contributions. Then also for an even number of layers in the AB stacking one obtains a small, but nonzero SHG.

Fig. 4 Polar plot of the SH power versus the direction of the incident electric field, θ in Fig. 3. Reflecting the D_{3h} symmetry the parallel (magenta continuous line) and perpendicular (teal continuous line) components of the SH power are proportional to $\sin^2(3\theta + \theta_0)$ and $\cos^2(3\theta + \theta_0)$ respectively. By fitting the experimental data (dots) to the ideal behaviour the initial direction of the field θ_0 and absolute SH power are obtained. This plot is illustrative of typical plots obtained from experiments, but the data is from a real experiment. Dots have been obtained by adding a small random number to the sinusoidal curves.

Fig. 5 Two possible stacking arrangements for two layers represented by equilateral triangles (magenta: bottom layer, blue: top layer). Equilateral triangles have been chosen because they are invariant under the same symmetry operations as 2D crystals belonging D_{3h} symmetry point-group. Top: angle between the two armchair directions of the layer is 0° , this is the so called *aa* stacking, side view on the left and top view on the right. When considering each layer independently, the radiated SH electric fields have the same direction, thus they sum up. Bottom: angle between the two armchair directions of the layer is 60° , this is the so called *AB* stacking (or Bernal stacking), side view on the left and top view on the right. When considering each layer independently, the radiated SH electric fields have opposite direction, thus they cancel. This is consistent with the system being centrosymmetric, i.e. invariant under the inversion operation (the inversion center is along the main rotation axis, at the midpoint between the two layers) and thus having no dipole allowed SHG.

Eq. (3) can be used to extract the stacking geometry of bilayers from polarization dependent measures. On the other hand by adding more layers (and knowing the stacking), one can predict the dependence of the SH intensity on the number of layers. As detailed above, from calculations based on the interference model (or modifications) one expects that in case of *AB* stacking samples with an even number of layers have negligible SHG, while samples with an odd number of layers have all similar SHG. Instead in the case of few layers non-centrosymmetric crystals, e.g. with *AA* stacking, the SH intensity is expected to grow quadratically. However the interference model— even when perfectioned by accounting for absorption and multiple reflections— captures the dependence on the number of layers only partially as it neglects the effects of interlayer interactions on the electronic structure. In particular for very few layers (typically < 10), confinement effects are stronger and the screening less effective. These effects can change both the absorption and SHG spectral shape and onset and ultimately can be captured only by electronic structure calculations. Indeed in experimental studies it is generally observed that a quadratic dependence hold for 10–100 layers, but for < 10 layers the behaviour changes (see e.g. Tang *et al.* (2016)).

Absolute Measure of SHG

A measure of the absolute SHG intensity is not straightforward. From Eq. (1) the SH susceptibility is extracted from the change in the polarization field P of the sample as a function of the total electric field E .

In practice what is measured is the SH radiation intensity (or power) and what is known the intensity (or power) of the applied field. The relation between the two quantities is derived from the wave equation for the electric field driven by the second order polarization field and using Eq. (2) to introduce the SH susceptibility and the total electric field. Then the SH radiation intensity is calculated from the corresponding field as (Boyd (2008)). Because of the quadratic dependence of the polarization on the electric field (Eq. (2)), the SH radiation intensity (power) depends quadratically on the intensity (power) of the applied field. The coefficient of proportionality contains the square of the SH susceptibility and other factors depending on the sample i.e. the thickness, the presence of a substrate, etc. The model assumed to describe the sample influences the experimental estimate for the SH susceptibility as discussed in Section “Models for the Sample.”

Furthermore, as it is the case for the SHG in bulk materials, the intensity of the applied field requires the detailed knowledge of the spatial and temporal dependence of the laser beam. Commonly the dependence on the intensity of the applied field is thus eliminated by measuring the SH power of the sample relatively to a reference material for which the SH susceptibility is accurately known (as e.g. quartz or beta barium borate).

Table 1 collects results from recent experimental measures of the SHG in 2D materials and reports parameters and characteristics that may influence the estimate, which are discussed below (Sections “Models for the Sample, Role of Substrate and Role of Excitonic Resonances”). The out-of-resonance values are usually comparable with those of nonlinear crystals, such as the beta barium borate and potassium titanyl phosphate, commonly used as frequency converters. At resonance, strong to very strong (one to three order of magnitude larger than conventional nonlinear crystal) is reported. In the subsection below aspects that may influence significantly the SHG experimental estimate are detailed.

Table 1 Measure of the SH for 2D materials [monolayer (ML), bilayer (BL), trilayer (TL) and few layers (FL)] from recent experiments. For each material beside the SH is reported how the material was synthesized, the substrate (thickness in parenthesis), excitation wavelength, whether excitonic resonances are excited, which model has been assumed to extract the SH from the measurements and the publication. Considering the number of parameters on which the estimates depend, those should be consider as order of magnitude estimates

Models for the Sample

For 2D materials two models are commonly used (see e.g. [Clark et al. \(2014\)](#)):

- One model assumes that the 2D material sample behaves as bulk and uses the same formula for the SH radiation electric field with the only difference that the phase mismatch is neglected since the thickness of the material is much smaller than the coherence length. With this assumption the relation between the intensity I^{SH} of the SH radiation and the intensity I of the applied electric field at frequency ω to extract the magnitude of the SH susceptibility $|\chi^{(2)}|$ reads:

$$I^{\text{SH}}(2\omega) = \frac{\omega^2 |\chi^{(2)}|^2 \Delta h^2 I^2(\omega)}{2n_{2D}^2(\omega) n_{2D}(2\omega) \epsilon_0 c^3} \quad (4)$$

where Δh is the sample thickness, n_{2D} is the refractive index of the 2D material and c is the speed of light.

- Another model instead considers the 2D material on a dielectric substrate with refractive index n_{sub} as a dipole sheet screened by the substrate and thus considers the electric field driven by the SH sheet polarization. With this assumption the relation between the applied and measured intensities reads:

$$I^{\text{SH}}(2\omega) = \frac{512\omega^2 \pi^2 |\chi_{\text{surf}}^{(2)}|^2 I^2(\omega)}{(n_{\text{sub}}(\omega) + 1)^6 \epsilon_0 c^3} \quad (5)$$

Here $|\chi_{\text{surf}}^{(2)}|$ is the surface second order nonlinear susceptibility ([Shen, 2003](#)) which is relate to the usual (volume) second order nonlinear susceptibility by:

$$\chi_{\text{surf}}^{(2)} = \int dz \chi^{(2)}$$

where the integral runs across the 2D material along the normal to the surface. If we neglect the dependence on z of the nonlinear susceptibility, $\chi_{\text{surf}}^{(2)} = \chi^{(2)} \Delta h$.

One important difference between the two models is that at the denominator of the sheet model (Eq. (5)) the refractive index of the dielectric substrate appears instead of that of the material (Eq. (4)). As the latter is typically much smaller than the former it has been argued that a difference up to three order of magnitude in the estimate of the SH susceptibility may arise.

Role of Substrate

Characteristics of the substrate plays a role in the measured intensity. Typically a dielectric coated substrate is chosen for which the bulk SHG is negligible. However even if the bulk SHG of the substrate is negligible, surface SHG can still be noticeable. In addition atoms may be trapped at the interface between the sample and the substrate. Those defects can modify the SHG of the sample. In particular charge-transfer defects can induce strong local fields and locally enhance the SHG signal.

Furthermore it has been reported that the measured SHG changes when changing the thickness of dielectric coating. This effect has been explained as an enhancement of the measured SHG due to the interference of multiple reflections from the substrate (Miyachi *et al.*, 2016), similar to the enhancement observed in a Fabry-Perot resonator discussed in Section “Optical Devices.”

Finally, while for measurements of the SHG of the sample, substrate effects are a disturbance, in applications one may want to actually enhance the SHG from the sample by choosing an appropriate substrate. In this context few experiments have explored effects of metal substrates as it is expected that strong local fields from surface plasmons could significantly enhance the SH intensity (Zeng *et al.*, 2015).

Role of Excitonic Resonances

Excitations are commonly interpreted in terms of electron-hole pairs. Pictorially, considering the electronic structure of a finite-gap material, an electron-hole pair is formed when an electron is excited from the valence to the conduction energy band. Within this picture the excited system then has an extra electron in the conduction, and a missing electron (or hole) in the valence. The electron and the hole can be considered as particles with opposite charge interacting through the Coulomb interaction and forming a bound state, the exciton. The physics of these bound states resembles that of the hydrogen atom in which the radius and the energies are modified by the electric screening from the surrounding electrons. The largest the screening, the largest the radius of the exciton (i.e. the more delocalized) and the smallest the binding energy. In the case of 2D materials one needs to account for the geometrical confinement that modifies the equations for the radius and binding energy: the binding energy of the ground state exciton is 4 times larger than that of the bulk counterpart and the radius smaller by a factor 2 (Haug and Koch, 1990). Then typically excitons in 2D materials are expected to be more localized and more bound than in their bulk counterpart. Because of the resemblance with the hydrogen atoms excitons are commonly addressed as $1s$, $2p$, etc. even though it should be noted that the symmetry properties of these excitations are different from those of the hydrogenic atomic orbitals and depends on the crystal symmetry.

When the laser frequency ω is such that 2ω matches the energy of one of these excitations the SHG is expected to be enhanced. Indeed experimentally enhancements up to three order of magnitude have been observed for transition metal dichalcogenides (Wang *et al.*, 2015) resulting in very strong SHG at excitonic resonances as can be seen in Table 1.

Electronic Structure Calculations

The SHG can be computed from the electronic structure of the material as (Shen, 2003):

$$\chi_{ijk}^{(2)}(\omega; \omega_1, \omega_2) = \int dk \sum_{v,c,c'} f_v(k) \left\{ \frac{\langle v k | \xi_i | c k \rangle \langle c k | \xi_j | c' k \rangle \langle c' k | \xi_k | v k \rangle}{[\omega - \omega_{cv}(k)][\omega_1 - \omega_{c'v}(k)]} + \frac{\langle v k | \xi_i | c k \rangle \langle c k | \xi_k | c' k \rangle \langle c' k | \xi_j | v k \rangle}{[\omega - \omega_{cv}(k)][\omega_2 - \omega_{c'v}(k)]} + \frac{\langle v k | \xi_k | c k \rangle \langle c k | \xi_j | c' k \rangle \langle c' k | \xi_i | v k \rangle}{[\omega + \omega_{c'v}(k)][\omega_2 + \omega_{cv}(k)]} \right. \\ \left. + \frac{\langle v k | \xi_j | c k \rangle \langle c k | \xi_k | c' k \rangle \langle c' k | \xi_i | v k \rangle}{[\omega + \omega_{c'v}(k)][\omega_1 + \omega_{cv}(k)]} + \frac{\langle v k | \xi_j | c k \rangle \langle c k | \xi_i | c' k \rangle \langle c' k | \xi_k | v k \rangle}{[\omega_1 - \omega_{cv}(k)][\omega_2 + \omega_{c'v}(k)]} + \frac{\langle v k | \xi_k | c k \rangle \langle c k | \xi_i | c' k \rangle \langle c' k | \xi_j | v k \rangle}{[\omega_1 + \omega_{c'v}(k)][\omega_2 - \omega_{cv}(k)]} \right\} \quad (6)$$

The main quantities in Eq. (6) are the single particles wavefunctions $|ak\rangle$ where $a=v$ corresponds to valence and $a=c$ to conduction states, and k is the crystal momentum. ω_{cv} is the difference between the energies of the conduction and valence states. ξ_i is the dipole operator in the i direction, defined consistently with periodic boundary conditions.

Single particle wavefunctions and energies can be obtained from any electronic structure approach. In practice most of nowadays calculations are based on single-particle energies and wavefunctions from a density-functional theory calculations. The main advantages of this approach is computational ease, availability of computer codes while not relying on ad-hoc or experimental parameters. On the other hand, regarding the latter point it has to be noted that due to the underestimation of band gap inherent to this approach, often in calculations the knowledge of the material experimental band-gap is used (as well the band gap obtained from other approaches, such as the GW approximation can be used).

The role of electronic structure calculations of SHG is mainly (1) to connect features in the SHG spectrum to the electronic structure of the material and (2) to provide estimates for the absolute SHG. In the context of 2D materials connecting spectral features to the electronic structure can be important for instance to understand and interpret changes of the SHG with the number

of layers. On the other hand, an estimate of SHG is relevant considering the experimental difficulties in measuring the SHG. Comparison with the theory can provide a more firmly ground for the assumptions made in extracting the experimental SHG.

Eq. (6) is derived considering non-interacting electrons, in what is commonly addressed as independent particle model. More precisely, electron correlation is included in the ground-state calculations from which the electronic structure is extracted, but neglected in the response of the system to external perturbation.

Descriptions beyond the independent particle model include local fields and excitonic effects. The former effect is due to the microscopic electric fields from crystal inhomogeneity which locally counteract the applied electric field. The latter effect is due to the electron-hole long range interaction as discussed in Section “Role of Excitonic Resonances.” Modifications of Eq. (6) so to introduce these effects are nontrivial.

At present very few calculations of the SHG of 2D material exists including local fields and excitonic effects (see e.g. Grüning and Attacalite (2014), Trolle *et al.* (2014)). For transition metal dichalcogenides available calculations confirm the enhancement of the SHG at excitonic resonances and the strong SHG of these materials. As a side result of these works, calculations at the independent particle level are typically underestimating the SHG at excitonic resonances by a factor 2–3. Considering the experimental uncertainties in the determination of the SHG, calculations at the independent particle level can then be considered in general sufficient to provide a reasonable estimate of the SHG.

Optical Devices

As seen in Section “Absolute Measure of SHG” transition metal dichalcogenides have a significant SHG in the frequency range of Ti: Sapphire laser and Gallium chalcogenides have a significant SHG for wavelengths near 1560 nm relevant for telecommunications. This strong SHG can potentially be exploited for on-chip optical devices (e.g. frequency converter). One problem in the realization of such devices is that in spite of the intrinsically strong SHG the length scale available for light-matter interaction is subnanometric, so that the resulting signal is weak. One proposed solution is to embed the 2D material in a resonant optical micro Fabry-Perot cavity. Prototypes of devices built on this principle showed enhancement of the SHG from one to three order of magnitude (Day *et al.*, 2016; Yi *et al.*, 2016).

Furthermore, a prototype of optical data storage has been proposed (Zeng *et al.*, 2015) which exploits the dependence of the SHG intensity on the number of layers in MoS₂. In particular for a coated metallic substrate the SHG is found to increase with number of layers up to a certain thickness (17 nm for gold) and then to decrease again. Then, by choosing the number of layers exhibiting the strongest SHG, information can be stored by locally reducing the number of layers and can be read out by detecting the SHG intensity.

Introduction

Refractive index, gain and loss play a pivotal role in light propagation. Modulating the refractive index as a means to mold the flow of light dates back to antiquity when rock crystals like the “Loupe of Sargon” were used to produce fire by focusing sun rays. Since then, index crafting has reached such level of sophistication that artificial structures as diverse as optical fibers, photonic crystals, and meta-materials became possible. Optical amplification or gain was realized much later, followed by the discovery of the laser, and has enabled numerous applications in many areas of science and technology. However, this is not the case for attenuation. Loss, unlike the other two processes, is still perceived to be a foe, an undesirable attribute that should be avoided or compensated at all costs. It is perhaps for this particular reason that up until recently the simultaneous use of index, gain, and loss as a viable route to achieve new optical behavior has been generally overlooked.

At a first glance, deliberately intermixing gain with loss may appear counterintuitive and perhaps pointless. Recently, however, there has been a growing evidence within the field of non-Hermitian optics, indicating that the presence of *exceptional points* (phase transition points) arising in judiciously designed parity-time symmetric systems can be utilized to build structures with customized properties and functionalities- previously thought to be unattainable. In what follows, we first provide a mathematical description of parity-time symmetry both in the context of quantum mechanics and optics, and then continue by overviewing some of the current developments concerning the use of PT-symmetry for laser mode management and sensing, while also looking into their anomalous scattering properties for designing invisibility cloaks.

Spontaneous Symmetry Breaking and Exceptional Points

The field of parity-time (PT) symmetry began in 1998 following the discovery by Bender and Boettcher, who first indicated that a wide class of non-Hermitian Hamiltonians can exhibit entirely real spectra, provided that they commute with the parity-time ($\hat{P}\hat{T}$) operator (Bender and Boettcher, 1998). While the use of non-Hermitian operators has been suggested in the past as a means to incorporate loss in quantum mechanics, Bender and Boettcher’s work has been largely perceived as counterintuitive, since it went against the commonly held view that real eigenvalues are only associated with Hermitian observables. Starting from the aforementioned premise, one can directly show that a necessary (but not sufficient) condition for PT symmetry to hold is that the complex potential involved in such a Hamiltonian should satisfy $V(x) = V^*(-x)$. In other words, the real part of the complex potential must be an even function of position, while its imaginary component should be anti-symmetric. In such pseudo-Hermitian configurations, the eigenfunctions are no longer orthogonal, i.e., $\langle m|n \rangle \neq \delta_{mn}$, and hence the vector space is skewed. Even more intriguing is the possibility for a sharp symmetry-breaking transition – once a non-Hermiticity parameter exceeds a certain critical value. In this latter regime, the Hamiltonian and the $\hat{P}\hat{T}$ operator no longer display the same set of eigenfunctions (even though they commute) and as a result, the eigenvalues of the system become partially, or entirely, complex. This broken PT-symmetry phase is associated with a so-called exceptional point (EP) or a non-Hermitian degeneracy.

While the implications of these mathematical theories in quantum mechanics are still a matter of debate (since the realization of complex potentials in quantum mechanics is inherently out-of-reach), later it has been recognized that photonics can provide a fertile ground where PT symmetry concepts can be experimentally investigated (Makris *et al.*, 2008). The transition from quantum mechanics to optics can be formally justified by considering the isomorphism between the Schrödinger equation and the paraxial wave equation (see Table 1). In this regard, the complex refractive index profile plays the role of an optical potential: $k_0(n_R(x) + in_I(x))$. In optical systems, PT symmetry demands that the spatial distribution of the refractive index is an even function ($n_R(x) = n_R(-x)$), whereas the imaginary component (representing gain or loss) is an odd function of position ($n_I(x) = -n_I(-x)$). One can also show that in high contrast settings, where the electrodynamic problem must be treated fully vectorially, the condition for PT symmetry is expressed through the complex permittivity, e.g., $\epsilon(r) = \epsilon^*(-r)$. Nonetheless, since in most systems the imaginary part of the complex refractive index function is considerably smaller than its real counterpart, the PT symmetry condition in these two scenarios is almost equivalent.

To elucidate some the physics of exceptional points, here we provide a simple example of a two-level non-Hermitian PT symmetric system. In optics, this may be realized by two coupled resonators or waveguides, one exhibiting gain, while the other one experiencing an equal amount of loss. In the case of two cavities, energy exchange occurs in time, while for waveguides it takes place in space. Schematics of these configurations are depicted in Fig. 1.

Here we consider the case of two identical evanescently coupled cavities as depicted in Fig. 1(b). In order to simplify our analysis, we assume both resonators are single moded. For this system, the field evolution dynamics are described by the following

Table 1 Isomorphic relations between the Schrödinger equation in quantum mechanics and the paraxial wave equation in optics

	Quantum mechanics	Optics
Governing Equation	Schrödinger equation $i\hbar \frac{\partial \psi}{\partial t} = -\frac{\hbar^2}{2m} \frac{\partial^2 \psi}{\partial x^2} + V(x)\psi$	Paraxial wave equation $-i \frac{\partial E}{\partial z} = \frac{1}{2k} \frac{\partial^2 E}{\partial x^2} + k_0 n(x)E$
Wave function	$\psi(x, t)$	$E(x, z)$
Eigenvalues	Energy states	Propagation constants
Potential energy	Potential $V(x) = V_R(x) + iV_I(x)$	Refractive index $K_0 n(x) = K_0 n_R(x) + iK_0 n_I(x)$
PT-symmetry necessary condition	$V_R(x) = V_R(-x)$ $V_I(x) = -V_I(-x)$	$n_R(x) = n_R(-x)$ $n_I(x) = -n_I(-x)$

**Fig. 1** Two realizations of two-level parity-time symmetric optical systems, (a) a pair of coupled waveguides, one subjected to gain and the other to loss, trade energy along the direction of propagation at a rate of κ , (b) a pair of cavities, one experiencing gain and the other loss, exchange energy in time at a rate of κ .

set of equations:

$$\begin{cases} i \frac{da}{dt} - i \frac{g}{2} a + \kappa b = 0 \\ i \frac{db}{dt} + i \frac{g}{2} b + \kappa a = 0 \end{cases} \quad (1)$$

Here a and b represent the modal field amplitudes in the gain and loss cavities, respectively, g stands for the gain/loss coefficient, and κ is the coupling strength. This system supports two supermodes with distinct characteristics that depend entirely on the ratio between gain/loss (g) and coupling (κ). When $g/2\kappa < 1$, the two eigenvalues are real and are given by $\lambda_{1,2} = \pm \cos(\theta)$ where $\theta = \sin^{-1}(g/2\kappa)$ and the corresponding eigenvectors are $|1\rangle = [1 e^{i\theta}]^T$ and $|2\rangle = [1 - e^{-i\theta}]^T$. Note that these eigenvectors are not orthogonal in spite of the fact that the spectrum is real. In this case, none of the two modes experiences a net gain or loss, instead they oscillate, i.e., they remain neutral.

The spectral response of this PT-symmetric two-level system drastically changes as soon the gain-loss contrast exceeds the coupling strength ($g/2\kappa > 1$). In this regime, the eigenvalues are expressed by $\lambda_{1,2} = \pm \sinh(\theta)$ where $\theta = \cosh^{-1}(g/2\kappa)$, and their corresponding non-orthogonal eigenvectors turn out to be $|1\rangle = [1 i e^{\theta}]^T$ and $|2\rangle = [1 - i e^{-\theta}]^T$, indicating that the symmetry of each mode is broken in the sense that one of them resides mostly in the gain cavity while the other one in the lossy resonator. As a result, one of the eigenmodes enjoys amplification while the other experiences attenuation. Obviously, the supermode that mostly occupies the gain/loss region is amplified/attenuated. Fig. 2 displays the complex component of the eigenvalues as a function of $g/2\kappa$. The transition point $g/2\kappa = 1$ between these two different regimes is called the *exceptional point*. At this crossing, something quite remarkable happens. The dimensionality of the vector space is abruptly reduced from 2 to 1. This is evident from the fact that the two eigenvectors become entirely identical $[1 i]^T$ and neither oscillate nor exponentially varying. Instead the modal amplitudes depend algebraically on time ($\sim C_0 + C_1 t$).

Initial theoretical and experimental work carried out by several groups indicates that light propagating through non-Hermitian or PT-synthetic media can exhibit surprisingly unusual behavior. Among the numerous properties that such systems can display are: absorption enhanced transmittivity (Guo *et al.*, 2009; Rüter *et al.*, 2010), unidirectional invisibility (Lin *et al.*, 2011),

Fig. 2 The imaginary part of the eigenvalue vs. the change in the imaginary part of refractive index (gain-loss contrast) is depicted for a PT two-level system. At the exceptional point the symmetry of the modes breaks and two supermodes emerge, one amplifying and the other one attenuating.

unidirectional light transport (Peng *et al.*, 2014), topological chirality (Doppler *et al.*, 2016; Xu *et al.*, 2016), single mode lasing (Hodaie *et al.*, 2014; Feng *et al.*, 2014), and enhanced sensitivity at the exceptional point (Wiersig, 2014). In most cases, one may design the system close to the exceptional point such that one desired attribute can be extracted whereas other undesired properties remain below the threshold breaking. In what follows we provide an overview of the current developments in this field. In particular, we explain how the selective breaking of parity-time symmetry in multimode laser cavities can result in single mode operation. We will then look into the sensitivity of a system that is biased at an exceptional point and the anomalous scattering properties of PT-symmetric arrangements.

Mode Management in PT-Symmetric Lasers

Since the invention of diode lasers in 1962, there has been an ongoing effort to design optical cavities that funnel the maximum output power into a single spatiotemporal mode. Ultimately, a cavity becomes intrinsically single-moded only when its dimension is comparable to the wavelength of light. Most of the time, this criterion severely limits the amount of coherent emission that can be generated by a laser. On the other hand, when the active region is enlarged beyond this limit, most semiconductor lasers, because of their inhomogeneous lineshape, become susceptible to multimode operation something that eventually leads to output power fluctuations, instabilities, and lower beam quality. This explains why developing a compact, single mode laser has been the subject of numerous research activities over the past few decades. Such efforts have since resulted in several ingenious laser designs. For example, single transverse mode operation can be achieved using broad area slab coupled waveguide lasers (SCOWL). On the hand, distributed feedback (DFB), distributed Bragg reflector (DBR), and vertical cavity surface emitting lasers (VCSEL) have been designed to operate in a single longitudinal mode.

In recent years, the stringent requirements in photonic integrated circuits, have set new challenges for on-chip light sources. Not only such lasers must occupy a small size and exhibit a low threshold, they should also couple easily to the rest of the photonic network, preferably through a bus waveguide. In addition, cavity designs that rely on multi-step growth processes must be avoided. One family of lasers that can address these challenges are micro-ring lasers. Microring resonators have small footprint and as lasers they expected to show low thresholds because of their high quality factors. However, even a microring with a radius on the order of few tens of micrometer, tends to support several longitudinal modes across the gain bandwidth of most III-V active gain materials. Up until recently, the only systematic way to enforce single mode operation in such arrangements was through the incorporation of dispersive vertical gratings. Such a technique, however, seriously deteriorates the quality factor of the ring; hence increasing the threshold and reducing the slope efficiency. In what follows we will describe how selective PT symmetry breaking can be used to enforce single mode operation in microring lasers. This technique was first proposed by Miri *et al.* (2012) in the context of broad area lasers and amplifiers. In 2014, the use of PT symmetry for controlling the longitudinal mode contents of microring resonators

has been proposed by two independent groups. In one approach, the ring is patterned by a parity-time-symmetric grating structure (Feng *et al.*, 2014). In the other work, the active ring is paired with a lossy cavity to establish parity-time symmetry (Hodaie *et al.*, 2014). In what follows we will focus on the latter technique because of its simplicity in terms of avoiding additional gratings.

Single Longitudinal Mode Lasing

PT symmetry breaking can be elegantly exploited to establish single longitudinal mode operation in inherently multi-moded microring lasers. One way to do so, is by utilizing a coupled arrangement of two structurally identical ring resonators; one experiencing gain, and the other one an equal amount of loss. In general, when two fully identical resonators (both subjected to gain, loss, or neither) are placed next to one another, the degeneracy between their respective modes will be broken. The frequency splitting $\Delta\omega$ of the resulting supermode doublets $\omega_n^{(1,2)}$ is directly proportional to the coupling coefficient, i.e., $\Delta\omega = 2\kappa$ (Fig. 3(b)). On the other hand, in a PT-symmetric arrangement (like that depicted in Fig. 3(c)), the relationship between eigenfrequencies and coupling is by nature different, as indicated in the following expression:

$$\omega_n^{(1,2)} = \omega_n \pm \sqrt{\kappa_n^2 - g_n^2} \quad (2)$$

Consequently, any pair of modes, whose gain/loss contrast (g_n) remains below the coupling coefficient (κ_n), undergoes bounded neutral oscillations. However, as soon as g_n exceeds κ_n , a conjugate pair of lasing/decaying modes emerges. Consequently, the judicious placement of this PT threshold will allow a complete suppression of all non-broken mode pairs in favor of a single amplified mode associated with the aforementioned conjugate pair (Fig. 3(c)). As the imaginary parts of the eigenvalues diverge, degeneracy between their real parts is restored.

Even in the absence of PT-symmetry, any resonator with a spectrally non-uniform gain distribution $g(\omega)$ can in principle exhibit single-mode operation, provided that the loss exceeds the gain for all but one resonance. However, in this regime, the amplification cannot surpass the gain contrast $g_{\max} = g_0 - g_1$, where g_0 refers to the gain of the principal mode and g_1 to that of the next-strongest competing resonance. Obviously, this approach will impose severe constraints on the operating parameters, especially in the case of cavities having wide gain linewidths and/or closely spaced resonator modes, where $g_{\max}$ is very small. On the other hand, in a PT-symmetric setting, the coupling κ now plays the role of a virtual loss, and all undesirable modes must fall below its corresponding threshold. According to Eq. (2) we find that in this case the maximum achievable differential gain is:

$$g_{\max,PT} = \sqrt{g_0^2 - g_1^2} = g_{\max} \cdot \sqrt{\frac{g_0/g_1 + 1}{g_0/g_1 - 1}} \quad (3)$$

Given that $g_0 \geq g_1$, a selective breaking of PT symmetry can therefore systematically increase the available amplification for single-mode operation. As a matter of fact, the square-root behavior of this enhancement (a direct outcome of PT symmetry breaking), as characterized by the enhancement factor $G = g_{\max,PT}/g_{\max}$, is capable of providing substantially higher selectivity, especially when the initial contrast between adjacent modes is small ($g_1 \rightarrow g_0$). Consequently, this approach naturally exhibits a type of broadband self-adaptive single mode selection that is, in principle, applicable to any active resonator configuration. It should be stressed that this type of mode discrimination is resilient and remains valid even when PT symmetry does not exactly hold for all modes involved. On a fundamental level, the mechanism is related to the presence of an exceptional point in the system.

To experimentally verify these findings, active ring resonators based on InGaAsP quantum wells were defined using electron beam lithography and reactive ion etching (RIE). The gain and loss regions were determined by selective optical pumping at 1064 nm. The resonators were tested by placing them within a circularly symmetric Gaussian pump beam to implement three pumping configurations (single ring, evenly pumped double ring, and PT-symmetric ring arrangement). Accordingly, the effective pump powers were calculated from the geometric overlap between the active medium and the pump profile. Fig. 4(a,b) illustrate the behavior of a single ring (radius 10 μm , ring width 500 nm, height 210 nm) when exposed to an effective peak pump power of 2.5 mW (15 ns pulses with a repetition rate of 290 kHz). Under these conditions, at least four modes contribute significantly to lasing in the isolated ring. When two such rings are both placed at a distance of 200 nm from one another and exposed to the same pump power, one can clearly see the coupling-induced mode splitting (Fig. 4(c,d)), which occurs symmetrically around the resonance wavelengths of each ring in isolation. In this coupled regime, both structures are contributing equally. Once PT-symmetry is established, by withholding the pump from one of the resonators (Fig. 4(e,f)), lasing occurs exclusively in the active ring, where single-mode operation is now achieved. The presence of the lossy ring serves to suppress the unwanted longitudinal modes with a contrast exceeding 20 dB.

Comparing the light-light curves of these three lasing arrangements reveals that the slope efficiency in all scenarios remains virtually the same- indicating that the presence of lossy cavity in the PT-symmetric arrangement has no effect on the efficiency and output power. Moreover, the spectrally resolved light-light curves that compare the power in the fundamental mode of the single and the PT double ring resonators show that the PT system indeed offers superior performance, since the emission from the single ring includes contributions from several modes. This mechanism of mode selectivity using parity-time symmetry is robust in terms of fabrication inaccuracies and can accommodate active media with wide gain spectra. Moreover, as the occurrence of PT symmetry breaking is exclusively determined by the relation between net gain and coupling, the proposed arrangement is by nature self-adapting.

Fig. 3 Schematic principle of mode suppression in PT-symmetric microring lasers. (a), (b) In a coupled arrangement of two identical and evenly pumped rings, mode pairs emerge. (c), (d) PT-symmetry can be exploited to enforce stable single mode operation in otherwise multi-moded cavities. Fig. 4 Experimental observation of mode suppression by PT-symmetry breaking. (a) Emission spectrum of a single resonator. (b) Corresponding intensity pattern within the ring as observed from scattered light. (c) Spectrum obtained from an evenly pumped pair of such rings. (d) The intensity pattern shows that both resonators equally contribute. (e) Single-moded spectrum under PT-symmetric conditions. The mode suppression ratio exceeds 20 dB. (f) Lasing exclusively occurs in the active resonator. Reproduced from Hodaei, H., Miri, M.A., Heinrich, M., Christodoulides, D.N., Khajavikhan, M., 2014. Parity-time-symmetric microring lasers. *Science* 346, 975–978.

Laser Transverse Mode Filtering

PT-symmetry can also be utilized in promoting the fundamental transverse mode in broad-area and multi-moded microring lasers (Hodaei *et al.*, 2016). In fact, as shown in Eq. (2), the virtual threshold at the exceptional point $g/\kappa=1$ introduces an additional degree of freedom: the coupling constant κ between the active and the lossy cavity mediated by the evanescent overlap of their respective modes. As it is well known, higher-order spatial modes systematically exhibit stronger coupling coefficients due to their lower degree of confinement. Consequently, in a PT symmetric arrangement, as the gain increases (when $g>\kappa$), the fundamental mode is the first in line to break its symmetry, thus experiencing a net amplification. On the other hand, for this same gain level, the rest of the modes retain an unbroken symmetry and therefore remain entirely neutral.

Fig. 5 (a)–(c) Intensity distributions in a microring resonator with a cross section $0.21 \mu\text{m} \times 1.5 \mu\text{m}$ and a radius of $R=6 \mu\text{m}$ as obtained by finite element simulations for the first three transverse modes, (d)–(f) intensity distribution of these same modes within the PT symmetric ring resonators. While the TE_0 mode operates in the broken PT symmetry regime and lases, all other modes remain in their exact PT phase and therefore they stay neutral, and (g) Exponential decay of the temporal coupling coefficients κ with cavity separation d . Higher order modes exhibit a much larger coupling coefficient than their lower-order counterparts. Reproduced from Hodaei, H., Miri, M.A., Hassan, A.U., *et al.*, 2016. Single mode lasing in transversely multi-moded PT-symmetric microring resonators. *Laser & Photonics Reviews* 10 (3), 494–499.

Fig. 5(a)–(c) depicts the transverse intensity profiles of different spatial modes supported by a single microring resonator with a radius of $R=6 \mu\text{m}$ and waveguide dimensions of $0.21 \mu\text{m} \times 1.5 \mu\text{m}$. The curvature of the ring imposes a radial potential gradient, which deforms the mode fields into whispering-gallery-like distributions. Whereas the centroid of all modes shift towards the ring center, the exponential decay outside the ring still grows strongly with the mode order. As shown in **Fig. 5(d)–(f)**, for a certain coupling coefficient, set by the distance between the two rings, the transverse TE_0 field is the only mode to break its PT symmetry while all the higher order modes (TE_1 , TE_2) are still in the exact PT phase and hence occupy both rings equally. This behavior is also evident in **Fig. 5(g)** where the coupling strength between different transverse modes is depicted as a function of the separation between the two rings. For a fixed distance, the coupling coefficient increases with the order of the transverse mode, since the effective indices of higher order modes lie closer to that of the surrounding medium, allowing for stronger evanescent interactions across the cladding region. This trend persists for all wavelengths, and in conjunction with the difference in confinement enables PT symmetry breaking to be employed as a mode-selective virtual loss.

Fig. 6(a) and **(b)** illustrate the transition from multimode behavior in a broad area microring laser to single mode operation in a twin-ring configuration as enabled by preferential PT symmetry breaking. These experiments were conducted in high-contrast active ring resonators based on quaternary InGaAsP (Indium-Gallium-Arsenide-Phosphide) multiple quantum wells embedded in SiO_2 (silicon dioxide). The gain bandwidth of the active medium spans the spectral region between 1260 and 1590 nm. Whereas the quantum wells are present in all wave-guiding sections, gain and loss is provided by selectively pumping the respective rings (pump wavelength: 1064 nm). **Fig. 6(a)** shows the spectrum obtained from a single microring laser. As expected from the differences in confinement between mode sets, only the TE_0 and TE_1 and TE_2 modes undergo lasing. In an isolated ring, a decrease of the overall pump power does not yield single mode operation. On the other hand, when the active ring of the PT-symmetric double-ring arrangement is supplied with the same pump power as in **Fig. 6(a)**, the TE_1 and TE_2 modes are readily eliminated (see **Fig. 6(b)**) as they fall below the PT breaking threshold and therefore experience zero net gain. The corresponding resonances are suppressed with a fidelity of over 30 dB down to the noise floor of the measurement.

The PT transverse mode filtering mechanism described above is fundamentally different from the standard spatial mode filtering techniques that are typically used in lasers. For example, intra-cavity apertures or spatial filters have long been used to

Fig. 6 (a) A single microring resonator lases in various TE₀, TE₁ and TE₂ resonances, (b) in contrast, a PT-symmetric double ring arrangement reliably suppresses all the TE₁ and TE₂ modes with a contrast exceeding 30 dB. Reproduced from Hodaei, H., Miri, M.A., Hassan, A.U., *et al.*, 2016. Single mode lasing in transversely multi-moded PT-symmetric microring resonators. *Laser & Photonics Reviews* 10 (3), 494–499.

limit the presence of higher order transverse modes by introducing differential loss between modes. However, in such schemes, all modes including the fundamental one, experience loss, though to a varying degree. Therefore, the resulting mode suppression obtained by such techniques is often incremental and comes at the expense of undesirable losses in the fundamental mode. In contrast, the abrupt onset of PT symmetry breaking at the exceptional point relocates the selected mode to the active region, whereas all higher order modes remain equally distributed between loss and gain regions. Consequently, this method offers a high degree of mode discrimination, without any detrimental impact on the overall lasing efficiency or output power.

Another advantage of PT-symmetric laser cavities is their robustness with respect to nonlinearity-induced instabilities. Conventional broad-area weakly-guiding single-mode lasers often are subject to severe filamentation even at moderate intensities. In contrast, the influence of such effects on the above system remains negligible. The observed robustness against nonlinear perturbations can be intuitively understood by keeping in mind that in the microring systems examined here, the index contrast between the core and cladding regions is significant and hence for all practical purposes is not affected by nonlinearity-induced index changes. For example, for circulating powers in the range of tens of mW, the resulting change in the refractive index due to self-focusing properties of the semiconductor gain material is estimated to be at most on the order of 10^{-3} . This level of nonlinearity will be an issue only for much more densely packed sets of transverse modes, e.g., when the width of the waveguides involved is substantially increased.

In conclusion, single spatial mode operation can be effectively enforced in parity-time symmetric broad area coupled cavities. Unlike most other schemes for laser transverse mode control, this method establishes mode selectivity through coupling to a lossy cavity without compromising the optical power extracted from the fundamental mode. Following the initial experiments, more recently, this approach has been tested in the context of two coupled waveguide lasers. This technique is versatile, scalable and can be applied to a wide range of broad area laser systems.

Sensing at Exceptional Points

Degeneracy occurs ubiquitously in nature. Within the context of eigenvalue problems, this property is encountered in a broad range of physical disciplines and is behind some of the most intriguing phenomena observed in both classical and quantum

physics. In terms of applications, through lifting an existing degeneracy, a small perturbation can lead to a detectable splitting between the corresponding eigenvalues. This principle has been utilized as a measurement tool in many and diverse settings. Similarly, in optics, breaking the degeneracy of resonant frequencies can be used as a means to detect small changes in the refractive index and/or loss. Along these lines, ultrahigh Q microcavities have been developed that nowadays are regarded as one of the most promising photonic arrangements for a variety of extreme sensing applications, ranging from single molecule detection to recording minute rotation rates.

The action of a perturbation on the degeneracy of a conservative (Hermitian) system is well understood. A point in parameter space at which such a degeneracy occurs is called a diabolic point (DP). At such points, a disturbance of strength ε leads to energy shifts and splittings that are at most on the order of ε . In non-Hermitian settings, however, another type of degeneracy is possible: that associated with an exceptional point. At this point, the dimensionality of the arrangement is abruptly reduced and as a result, the reaction of a system to perturbations around an EP is more drastic as compared to that at a DP. In fact, a perturbation of strength ε acting on a second-order EP (when only two eigenvalues and eigenvectors merge) so happens to result to an energy splitting that is proportional to $\varepsilon^{1/2}$. This implies that the sensitivity of a sensing set-up can be enhanced by several orders of magnitude (since $\varepsilon^{1/2} \gg \varepsilon$ for small perturbations) by exploiting the physics of EPs. Furthermore, one can show that the enhanced sensing of non-Hermitian systems is not limited to that offered by $\varepsilon^{1/2}$. By using even higher-order exceptional points (EP-Ns), it is possible to further boost the sensitivity up to $\varepsilon^{1/N}$. For example, an EP system of order $N=5$ can “amplify” a disturbance on the order of 10^{-10} up to 10^{-2} , an eight order improvement over that expected from a Hermitian sensor.

Exceptional points appear in various non-Hermitian settings, where there is coupling between resonances of the system while they are subjected to a spatially non-uniform gain and/or loss distribution. As of today, however, perhaps one of the most elegant ways to systematically generate them is through PT symmetry. In applications pertaining to sensing, a key advantage of PT-symmetric systems is their high sensitivity to external perturbations. Such a response not only facilitates the experimental observation of the square-root behavior as suggested above, but it can also provide a practical route to increase the sensitivity of microcavity sensors. Fig. 7 depicts schematics of such non-Hermitian sensor arrangements comprising of coupled resonators. The cavities are identical in shape and size, but are subject to different levels of gain and/or loss. The contrast between the amplification levels experienced by the cavities can be introduced, for example, through preferential pumping. Although strictly speaking, such systems may not be invariant under the simultaneous action of parity (P) and time (T) operators, they can nevertheless be transformed into becoming PT symmetric once they are gauged through a constant gain/loss bias. Fig. 7(d) shows how the sensitivity in such arrangements can be enhanced depending on the order of the exceptional point involved.

The mathematical explanation behind the enhanced sensitivity expected from a PT symmetric coupled cavity configuration (when biased at an exceptional point) can be obtained, for example, by considering the modal behavior of the structure depicted in Fig. 1(b). In general, each ring, when uncoupled, can support a number of longitudinal modes both in the clockwise and counterclockwise directions. Without loss of generality, here we limit our analysis to a single longitudinal mode in one direction. We also assume that the cross-section of the rings are designed so as to support only the fundamental TE mode. In order to analyze the sensitivity response, we assume that a small perturbation is applied to the ring resonator subjected to gain. In this respect, the interplay between the electric modal fields in the two identical rings can be effectively described through a set of

Fig. 7 A schematic of three photonic PT molecules exhibiting (a) 2nd, (b) 3rd, and (c) 4th order exceptional points. Red cavities exhibit gain, blue loss, and gray are neutral. (d) The dependence of sensitivity to perturbation strength.

time dependent coupled equations:

$$\begin{cases} \frac{da}{dt} = -i(\omega_0 + \epsilon)a + \kappa b + g_1 a \\ \frac{db}{dt} = -i\omega_0 b + \kappa a + g_2 b \end{cases} \quad (4)$$

Here, the cavities are treated as lumped resonators, a and b are modal amplitudes for a particular longitudinal resonance, κ and $g_{1,2}$ represent the coupling factor between the resonators and their associated gain/loss values, respectively, and ϵ is an intentionally induced perturbation. The two eigenvalues associated with this set of equations are given by the following expression:

$$\omega_{1,2} = \omega_0 + \epsilon/2 \pm \sqrt{\kappa^2 - (\Delta g/2 + i\epsilon/2)^2} \quad (5)$$

where $\Delta g = |g_1 - g_2|$ represents the gain-loss contrast between the resonators. If $\kappa = \Delta g/2$, the system is known to be at the exceptional point. Under this condition, Eq. (2) can be rewritten as:

$$\omega_{1,2} = \omega_0 + \epsilon/2 \pm i\sqrt{\epsilon\kappa/2} \quad (6)$$

In the absence of any perturbation ($\epsilon = 0$), the two frequencies are expected to be exactly equal to ω_0 . This is a large departure from a standard Hermitian system in which the two resonances are expected to split by 2κ . Furthermore, when operating at the exceptional point ($\kappa = \Delta g/2$), an induced perturbation ϵ leads to a $\Delta\omega_{PT} = \sqrt{2\kappa\epsilon}$ splitting in the real part of the eigen-frequencies. Therefore, by monitoring the splitting between the two resonances in the spectral domain, one can effectively determine the magnitude of the applied perturbation. Clearly, in this two-level system, the corresponding wavelengths diverge according to a square-root function of the perturbation ($\Delta\lambda \sim \epsilon^{1/2}$). Compared to a Hermitian or Hermitian-like single cavity configuration, the aforementioned square root behavior can substantially amplify the response of the system to a small perturbation (Chen *et al.*, 2017; Hodaei *et al.*, 2017). This approach has been recently suggested as a means to devise ultrasensitive microscale gyroscopes (Ren *et al.*, 2017).

Anomalous Scattering Properties of PT-Symmetric Arrangements

At a first sight, it may seem that balanced regions of gain and loss in a PT-symmetric system cannot affect the propagation of light in such settings, as the net amplification/attenuation in such systems is zero. However, as shown in several recent studies, the inter-mixing of gain and loss can significantly alter the dynamics of light in PT systems and can lead to a host of intriguing phenomena (Miri *et al.*, 2016). In order to shed light on anomalous scattering properties of PT-symmetric arrangements, here we focus on a PT-symmetric grating defined as follows (Lin *et al.*, 2011; Regensburger *et al.*, 2012):

$$n(z) = n_0 + n_R \cos(k_B z) + i n_I \sin(k_B z) \quad (7)$$

where, $k_B = 2\pi/\lambda_B$ and λ_B is the grating period. Clearly, this refractive index profile satisfies the necessary condition of PT symmetry, i.e., $n^*(-z) = n(z)$. Under weak refractive index and gain/loss modulations, i.e., $n_R, n_I \ll n_0$, this system is analytically solvable and its dynamics is governed by the coupling between the forward and backward propagating waves, as well as the gain/loss contrast. To show this, we consider a solution of the form $E(x, t) = E_f(x, t)e^{-i(\omega_0 t - k_0 n_0 z)} + E_b(x, t)e^{-i(\omega_0 t + k_0 n_0 z)}$, where E_f and E_b represent the slowly varying envelopes of the forward and backward propagating waves, ω_0 is a central frequency and $k_0 = \omega_0/c$ is the free space wavenumber. It is straightforward to show that this ansatz leads to the following simple coupled mode equations:

$$\left(\frac{\partial E_f}{\partial z} - \frac{1}{v} \frac{\partial E_f}{\partial t} \right) = +i(\kappa + g)e^{-i2\delta z} E_b \quad (8a)$$

$$\left(\frac{\partial E_b}{\partial z} + \frac{1}{v} \frac{\partial E_b}{\partial t} \right) = -i(\kappa - g)e^{+i2\delta z} E_f \quad (8b)$$

where, in these relations, $v = c/n_0$ represents the phase velocity in the background medium, $\delta = k_0 n_0 - k_B/2$ shows the detuning in the grating-assisted phase matching of the forward and backward propagating waves, and finally $\kappa = k_0 n_R/2$ and $g = k_0 n_I/2$ are two coupling coefficients associated with the real and imaginary parts of the complex grating. An interesting property of the coupled mode Eq. (8) is an asymmetry in the coupling between the forward and backward waves; according to these relations, the forward wave is coupled to the backward wave at rate $\kappa + g$, while the reverse process occurs at rate $\kappa - g$. Quite interestingly, for $\kappa = g$, the backward wave becomes completely independent from the forward. As a result, the complex grating will not have any influence on a wave propagating toward the left.

Under the ansatz of $(E_f, E_b) = (F_0 e^{-i\delta z}, B_0 e^{i\delta z}) e^{i\Omega t} e^{i(Kz - \Omega t)}$, the band structure of the PT grating is found to be:

$$\Omega^2/v^2 = K^2 + \kappa^2 - g^2 \quad (9)$$

This dispersion diagram is shown in Fig. 8 for different ratios of g/κ . According to this figure, for $\kappa > g$ there is a finite band gap $\Delta\omega = 2v\sqrt{\kappa^2 - g^2}$. By increasing the gain/loss, the band gap reduces such that for $\kappa = g$ the dispersion relation becomes the same as a the background medium, i.e., $\Omega/v = \pm K$. Finally, for $\kappa < g$, the dispersion diagram flips and regions with complex eigen-frequencies, associated with amplification and attenuation, emerge.

Fig. 8 The dispersion diagram of a PT-symmetric grating for (a) $g=0.8\kappa$, (b) $g=\kappa$, and (c) $g=1.2\kappa$. The dashed line in part (c) shows the imaginary part of Ω .

Such periodic PT-symmetric structures can exhibit surprising behavior such as unidirectional invisibility and unusual reflection characteristics. More specifically, light propagating in such a system can experience reduced or enhanced reflections (with a coefficient that can even exceed unity) depending on the direction of light propagation. This can be understood by considering that the left–right symmetry is now broken in this PT configuration and propagation is no longer the same when the sequence of the gain and loss regions is exchanged. Even more interesting is what happens at the PT threshold: light waves entering the structure from one side do not experience any reflection and can fully traverse the grating with complete transmission. Given that this occurs without acquiring any phase imprint from the PT grating, the periodic structure is essentially invisible. The situation is very different when light is incident from the other side.

Laser-Induced Damage in Optical Materials

Wolfgang Rudolph and Luke A Emmert, University of New Mexico, Albuquerque, NM, United States

© 2018 Elsevier Ltd. All rights reserved.

Introduction

Shortly after the invention of the laser, in the early 1960s, it became apparent that the ability of optical materials to withstand high laser intensity and fluences was of utmost importance for advances in laser development and nonlinear optics. Despite considerable progress in the past decades (Wood, 2003; Ristau, 2015) the physics and materials science of the interaction of high-intensity lasers with optical materials is still a very active and challenging research area. Laser-induced damage (LID) and laser ablation rest on similar physical foundations and describe the phenomena of irreversible material modification. Laser induced damage of surfaces and films is often associated with the removal of material.

The defining parameter is the laser-induced damage threshold (LIDT). Its value is often published as a fluence (J cm^{-2}) for pulsed laser systems and as an intensity (W cm^{-1}) for continuous wave (CW) lasers. The CW LIDT is valid for exposures long enough to reach steady-state temperatures. Typical time scales range from microseconds to seconds depending on the spot size. Solutions to the thermal diffusion equation reveal that the maximum temperature reached is proportional to the incident power divided by the beam radius (Ristau, 2015, see Chapter 2) for uniform bulk and surface absorption. Pulse LID is the subject of this article. LIDT values depend on material type (metals, semiconductor, insulators), topology (bulk, surface, thin film, multilayer), preparation (surface polishing, film deposition method, annealing, etc.), as well as laser parameters (wavelength, pulse duration, spot size, repetition rate, etc.). They also depend on how the damage test is performed. For example, if each test pulse illuminates a new sample site (1-on-1 test) or if several (S) pulses illuminate the same sample spot (S-on-1) (ISO 11254-2, 2011). Being transparent dielectrics have the highest LIDTs of all materials for lasers from the near infrared to the near ultraviolet spectral region.

Fig. 1 illustrates the material response of a dielectric sample as a function of the incident fluence. Often the LIDT behavior of a material is characterized by the probability that damage is observed when a pulse of certain fluence is incident, $P(F)$. There is a fluence range that separates catastrophic damage (for instance a surface crater) from reversible material modifications such as refractive index changes. The width of this transition region ΔF is narrow for fs pulses and becomes increasingly broader for ps, ns, and longer pulses. Different physical origins of damage are responsible – deterministic damage initiation for short pulses governed by intrinsic material properties and probabilistic, extrinsic-defect controlled damage for longer pulses. It should be noted that the physical mechanisms responsible for optical damage also enable laser machining and material processing.

The LIDT F_{th} is defined as the minimum fluence for damage to occur, i.e., $P(F \leq F_{th}) = 0$ (Porteus and Seitel, 1984). An optic will remain undamaged provided the incident fluence $F < F_{th}$. Because of the statistical nature of laser-induced damage there are practical difficulties in determining F_{th} so a damage fluence F_d , where $P(F = F_d) = 0.5$, is often used in the scientific literature. For short pulse LID, where the transition region ΔF is narrow, F_{th} and F_d are nearly the same. LIDT can be different for 1-on-1 and S-on-1 tests. Typically, the multiple pulse LIDT is smaller. There are also cases where the damage threshold increases when the sample is illuminated with a laser. This laser conditioning is used in high-power laser systems by gradually ramping up the laser power. Annealing of defects is a possible mechanism enabling laser conditioning (Bercegol, 1998).

Table 1 lists LIDTs for representative materials and pulse durations. Scaling laws (for dielectrics in particular) are known to extrapolate to other materials and pulse durations (Ristau, 2015, see chapter 5).

To discuss issues related to LIDT we refer to the schematic diagram of the morphology of an optical surface (or film) shown in Fig. 2.

Fig. 1 Response of a dielectric material as a function of incident pulse fluence. The graph on the right shows a typical damage probability as a function of incident pulse fluence measured with femtosecond pulses that probe intrinsic material properties (F_{th} , F_d , and ΔF are defined in the text.).

Table 1 Representative 1-on-1 LIDTs for selected optical components, pulse durations and wavelengths

Optics	Pulse duration	Wavelength	LIDT (J cm^{-2})	References
Fused silica (bulk)	100 fs	800 nm	~ 4	Lenzner <i>et al.</i> (1998)
	10 ns	1064 nm	5000	Smith and Do (2008)
Dielectric HR mirror	100 fs	800 nm	0.2–1.0	Stolz <i>et al.</i> (2009)

Metal (Al) film	100 fs	800 nm	0.3	Sun <i>et al.</i> (2015)

Fig. 2 Schematic diagram of the morphology of an optical wide-gap material. In high-quality materials, the density of defects of type 1 is low. Defects of type 2 and 3 are considered intrinsic. They determine macroscopic material properties probed by an incident laser. Additional defects (type 4) can be created during sub-threshold laser irradiation, for example, by a train of pulses. Defects can introduce states within the bandgap of the host material, which makes optical excitation more efficient, lowering the LIDT.

A laser excitation spot will typically contain several defects of type 1. Controlled by such statistically distributed defects, long-pulse LIDTs are stochastic and depend on spot size (DeShazer *et al.*, 1973). For sufficiently small spot sizes LIDTs representing intrinsic material properties are more likely to be observed. When measuring LIDTs of bulk materials care has to be taken to avoid or properly take into account propagation effects like self-focusing and dispersive effects in particular for short pulses. Characterization of damage controlling defects remains a challenge. Nondestructive techniques often lack sensitivity when the defect density is low.

Because of their importance for high power optical components dielectrics have received a lot of attention and are the focus of this encyclopedia entry. The physical processes leading to visible damage depend on the material and illumination conditions. In all cases a sufficiently large energy density has to be deposited first, which then triggers the material response that leads to the damage signature. This is illustrated in Fig. 3.

Fundamental Processes of Laser-Induced Damage

The intrinsic laser-induced damage mechanism of wide bandgap dielectrics is rather well understood (Emmert and Rudolph, 2015 and references therein). From the femtosecond to the nanosecond pulse regime, LIDT is reached when the excitation pulse has created an electron plasma of sufficient energy density in the conduction band. The processes leading to this electron plasma involve multiphoton ionization (interplay of multiphoton absorption and tunneling) of valence band electrons and impact ionization. The relative importance of these two processes has long been a question (Jones *et al.*, 1989) and remains an active research topic even today (Rajeev *et al.*, 2009; Karras *et al.*, 2011; Mouskeftaras *et al.*, 2013).

Damage will occur if the density of energy deposited into the conduction band plasma reaches some critical value. Its exact value is not *a priori* clear and depends, among other things, on the pulse duration. If damage were purely thermal, the critical energy would be related to the evaporation enthalpy. This, however, is rarely the case. A large enough density of conduction band electrons (electron plasma) can destabilize the lattice – similar to the excitation of a molecule to a non-binding state.

Dielectric breakdown used in modeling LID provides a useful proxy for the critical energy as a damage criterion (Bloembergen, 1974). The electron plasma can linearly absorb light through “free” carrier absorption also known as inverse Bremsstrahlung. With increasing absorption, the skin depth in which energy is deposited becomes smaller amplifying the rate of the energy deposition even more. Dielectric breakdown occurs at the plasma density (i.e., critical electron density) at which the plasma frequency

Fig. 3 Laser-induced damage in optical materials. Energy deposition is followed by an initial material response leading to visible, irreversible changes.

coincides with the laser frequency. The success of this criterion also stems from the fact that because of the exponential increase in plasma density during the incident pulse, the predicted threshold pulse fluence depends only logarithmically on the numerical value of the critical electron density.

Rate equations that model the electron density in the conduction have been quite successful in explaining the main features of intrinsic LIDT in particular in the short pulse regime. The principal structure of such a rate equation is of the form

$$\frac{d}{dt}n_e = K(I) + A(I, n_e) - L(n_e) \quad (1)$$

where n_e is the conduction band electron density and I is the laser intensity. The first term, $K(I)$, is the multiphoton ionization rate. It represents a combination of multiphoton absorption and tunneling described by Keldysh (1965). The second term, $A(I, n_e)$, describes impact (avalanche) ionization. This is the process where a highly excited electron in the conduction band (CB) transfers its energy to a valence band electron through collision, promoting it to the CB. This collision results in two electrons near the bottom of the CB. Repeating this process leads to exponential growth of n_e (avalanche ionization). This term is often approximated by an_e (from the flux-doubling model, which assumes that impact ionization takes place as soon as a CB electron has acquired sufficient energy (Stuart *et al.*, 1996)), where a is the avalanche ionization coefficient. This coefficient is usually taken as constant, but attempts have been made to measure an intensity dependence (Rajeev *et al.*, 2009; Karras *et al.*, 2011). The last term in Eq. (1) accounts for relaxation of electrons out of the conduction band. This term can represent either uni- or bi-molecular recombination with holes or existing trap states.

Using the concept of dielectric breakdown when a critical electron density n_{crit} is reached for LID, this rate equation predicts the observed subpicosecond pulse duration and bandgap scaling (Mero *et al.*, 2005) for subps pulses. Refinements to the rate equations are (1) multiple rate equations/multiple levels in the conduction band (Rethfeld, 2004); (2) effect of plasma on the local field in a film (Gallais *et al.*, 2010); and (3) estimation of energy deposition (Gallais *et al.*, 2015). Measurements and solutions to Eq. (1) for dielectric films and surfaces suggest that in the subps regime the LIDT scales approximately linearly with the material bandgap and as a power law with respect to pulse duration, τ^κ with $\kappa \approx 0.3 \dots 0.4$, for 1-on-1 damage (Mero *et al.*, 2005).

Multiple pulse, S-on-1, LIDTs need to take into account accumulating laser-induced material changes. This material *incubation* is apparent in the dependence of LIDT on the number of pulses in the test that illuminate each sample site. As the number of pulses increases, the damage threshold decreases. Possible underlying mechanisms are that (1) during the pulse train laser-induced defects and other material modifications increase the absorption and/or (2) the critical energy for damage decreases due, for example, to defect caused weakening of bonds. The latter can be expressed as a decrease in a critical enthalpy G , for example, evaporation enthalpy that leads to damage. In a simple model, the threshold fluence for pulse number S is determined by the absorption (coefficient) of the sample and the critical enthalpy after the previous pulse, $\alpha(S-1)$ and $G(S-1)$, respectively (Sun *et al.*, 2015):

$$F_{th}(S) \approx \frac{G(S-1)}{\alpha(S-1)} \quad (2)$$

Fig. 4 shows a typical incubation curve $F_{th}(S)$.

To explain incubation on a microscopic level we refer to the energy level diagram in Fig. 5. At fluences just below the LIDT a subcritical electron density is generated in the conduction band. Between pulses most of these electrons relax to the valence band, but some remain trapped in midgap native and laser-induced states. The electrons can be re-excited by subsequent laser pulses and enhance the generation of the conduction band plasma. The process repeats with each pulse until the midgap states become

Fig. 4 Measured LIDT of a HfO_2 film as a function of the number of 50-fs pulses illuminating one and the same sample spot, normalized to the single-pulse LIDT F_1 . The first ($S-1$) pulses modify (incubate) the material leading to a reduction of F_{th} for the last pulse (number S) that triggers catastrophic damage. The optic can be used as long as the laser fluence $F < F_\infty$, i.e., the multiple pulse LIDT. Reproduced from Nguyen, D.N., Emmert, L., Mero, M., *et al.*, 2008. The effect of annealing on the subpicosecond breakdown behavior of hafnia films. In: Proc. of SPIE, vol. 7132, p. 71320N.

Fig. 5 Energy diagram of optical excitation and relaxation of dielectric materials. It is assumed here that the laser probes intrinsic material properties. The bandgap E_g exceeds the single photon energy. Optical excitation of electrons from valence band (VB) to conduction band (CB) is therefore possible only through a multi-photon process. The left group of processes is important for 1-on-1 events and short pulses; the right group plays a role for long pulses and pulse trains. Relaxation out of the CB can occur on a subps time scale. There is a certain probability that defects like self-trapped excitons and color centers are created (laser induced defects) during a long pulse or train of pulses.

saturated or damage occurs. This phenomenon can be modeled by adding additional rate equations (Emmert *et al.*, 2010) to include the various electronic states and transitions (see Fig. 5). In the case of fused silica, the microscopic states responsible for incubation are well known. Electrons in the conduction band combine with valance band holes to form self-trapped excitons (STEs). In most cases these relax through a non-radiative mechanism, but sometimes the STE will relax into an E' center and a non-bridging oxygen. The generation of these defects has been exploited to create a variety of optical structures in bulk glass (Beresna *et al.*, 2014). In many oxide films, the trap states have not yet been identified, but oxygen vacancies are predicted (Cavartin *et al.*, 2006).

Defect-Induced Damage

At pulse durations on the order of picoseconds and longer, a second class of extrinsic defects often controls the optical performance limits even in high-quality materials (Papernov, 2015). Defects in dielectric oxides can be, for example, clusters of partially

Fig. 6 (a) Schematic of an optical sample with randomly distributed extrinsic defects (dots) and incident laser beams of spot size A and B (dashed circles). The large spot (A) is likely to contain one or more defects and measure LIDT controlled by defects. A smaller beam (B) will often probe the intrinsic material that has a higher damage threshold. (b) $P(F_0)$ as a function of F_0/F_{th} for different values of the product $\pi w^2 \rho / 2$. The defect density and/or beam radius increases from bottom to top.

oxidized material with metal-like properties, impurities, or residues from surface polishing, cf. defects of type 1 in Fig. 2. Metal-like defects, for example, lack a bandgap and thus single photon absorption of long pulse and CW lasers can be efficient. One damage mechanism here can be the creation of a localized, hot, high-pressure plasma that eventually explodes, ejecting material. The fact that damage is controlled by defects is the main cause for the wide range of reported LIDT values.

As pointed out previously, the presence of such defects leads to an excitation spot size dependent LIDT. A large beam spot is more likely to illuminate defects that determine the damage threshold. A sufficiently small spot is likely to probe the intrinsic, defect-free material. This behavior is illustrated in Fig. 6(a). In general, a material is described by a defect distribution $\bar{\rho}(F)$. The product $\bar{\rho}(F)dF$ gives the density (areal or volume) of defects whose damage threshold is in the range from F to $F + dF$. This distribution also depends on the wavelength of the excitation laser (Jensen *et al.*, 2009).

A consequence of defect-initiated damage is that LIDT is probabilistic rather than deterministic. For fluences below the intrinsic LIDT, the probability of damage is equivalent to the probability that a defect is located in a region of the beam where the fluence is sufficiently large to initiate damage. Given a defect distribution and a beam profile, the probability of damage can be predicted. An example that is often used is an ensemble of identical defects described by a damage threshold F_{th} and density ρ illuminated by a Gaussian beam of radius w ($1/e^2$ intensity) and peak fluence F_0 . In this case, the damage probability is of the form

$$P(F_0) = 1 - (F_{th}/F_0)^{-\pi w^2 \rho / 2} \quad (3)$$

Note that the product in the exponent ($\pi w^2 \rho$) is the average number of defects within a circle of radius w . The shape of the function $P(F_0)$ for different values of $\pi w^2 \rho$ is illustrated in Fig. 6(b).

A variety of nano- and microstructures can be responsible for defect-initiated damage. Subsurface cracks can result from the cutting and polishing of optical surfaces. Cracks have sharp edges that can lead to local field enhancements or act as local absorbers due to surface states. An important defect in multilayers, which are typical for optical mirrors and beam splitters, are nodules (Tench *et al.*, 1994). These are particles embedded in the multilayer stack during deposition. Large nodules can disrupt the multilayer leading to mechanically weak interfaces and local intensification of the electric field. Laser conditioning has proved particularly successful in mediating the performance limiting effect of nodules (Bercegol, 1998).

Finally, defect-initiated damage even occurs in material that appears free of structural defects. This observation is attributed to nanoabsorbers that may result from local substoichiometric or metal-like regions. These nanometer-scale absorbers trigger an expansion of the absorption volume at intensities above the LIDT which leads to micron-scale craters (Lange *et al.*, 1987; Papernov and Schmid, 2002; Demos *et al.*, 2013).

Measuring LIDT

The LIDT of materials and optical components is measured by destructive damage tests. A variety of tests have been developed to address both engineering and scientific goals. On the one hand LIDT measurements are used to determine the operational limits of commercial products and/or for qualifying an optic for use in a system. In this case a witness sample is often used. But also, as a scientific tool, damage testing is used for characterizing materials. Examples of scientific interest include pulse duration scaling discussed earlier, bandgap scaling, incubation, and the distribution and characterization of defects. LIDT tests reveal material imperfections that are often not detected by other (non-destructive) diagnostic measurements.

Traditional damage tests are based on the evaluation of whether damage occurred following illumination of the sample with a train of pulses. This evaluation can be done either immediately by observation of damage with a scatter probe or an in-situ microscope or later using post mortem microscopy. Alternatively, measuring the ablation crater diameter as a function of fluence

has also been applied successfully for LIDT tests. Extrapolation to the fluence where the crater diameter is zero gives the LIDT for 1-on-1 (Liu, 1982) and S-on-1 experiments (Sun *et al.*, 2015). The following are few common examples of LIDT measurements methods.

Fig. 7 Illustration of the ISO standard for LIDT tests. The damage probability versus fluence is measured. A tested optic (left) is divided into a number of tests sites and tested at various fluences F_i . The result of each test is either damage (red) or no damage (green). For each fluence F_i , the number of damage events m_i is counted. The probability is estimated by dividing the number of damage events by the number of tests at the given fluence. The probability vs. fluence (right) is plotted and LIDT is determined by extrapolating the curve to zero probability.

Fig. 8 Experimental setup for a nanosecond (or longer) pulse STEREO-LID test. The onset of damage and the location of damage initiation within the excitation spot are monitored for each event. Defect controlled damage leads to the ejection of a material jet as seen in the inset. Reproduced from Xu, Y., Emmert, L.A., Rudolph, W., 2015. Spatio-Temporally REsolved Optical Laser Induced Damage (STEREO LID) technique for material characterization. Opt. Express 23, 21607–21614.

An early and intuitive methodology is the R-on-1 test. In this test, each site is tested repeatedly with increasing fluence until damage occurs. While still used occasionally, the R-on-1 method does not account for laser conditioning and incubation discussed previously and therefore the test depends on the details of how the fluence is increased.

The ISO LIDT standard (ISO 11254-2, 2011) is based on a measurement of damage probability (Porteus and Seitel, 1984). The method is illustrated in Fig. 7. The damage probability is plotted as a function of the incident fluence and the damage threshold F_{th} is determined by extrapolating the curve to zero probability. Strictly speaking, this extrapolation requires knowledge of the defect density distribution function. Since this distribution is rarely known, it is done typically with a linear fit. It is important that a site is tested just once even if no damage occurred, because the material might have changed. The shape of the damage probability curve provides qualitative information about the optic. For small beam sizes, a narrow fluence range between the 0% and 100% damage probability is an indication of intrinsic damage.

The ISO protocol provides a balance between practical aspects of component testing and obtaining material data for scientific studies. It is poor at quantifying sparse fluence limiting defects. This issue, however, is especially important for large area optics. For such applications, raster scan methods using large spots have been developed (Borden *et al.*, 2005). At the National Ignition Facility a 1-mm test beam is scanned over a 1-cm² area. The tests are overlapping in order to illuminate the entire square. The scans are repeated with increasing fluence, like the R-on-1 method, but this is considered to mimic the laser conditioning that would occur for the optic under realistic operation conditions. Finally, to reduce the effect of outliers, the LIDT is defined as the fluence at which 10 or more damage events are observed.

The previous methods all share the common feature that they test for damage or no damage and therefore set an upper bound on the true damage threshold. A method that measures the damage fluence/intensity during a pulse is Spatio-Temporally REsolved Optical Laser-Induced Damage (STEREO-LID (Xu *et al.*, 2015a)) so named because it measures both the time during the pulse and the location within the beam spot where damage is initiated. Using the spatial/temporal intensity profile of the pulse, the critical fluence/intensity for each test event can be determined (Fig. 8).

Using STEREO-LID an optic is tested at multiple sites, like the ISO test, but all at an incident fluence sufficient to ensure a damage event. Each test event (one pulse at one sample site) determines where within the beam profile the damage initiating defect was located and when during the pulse “damage” occurred.

From these data one can derive the following: (1) the LIDT of performance-limiting defects: These are simply the lowest LIDT observed in the data set; (2) the defect distribution function $\bar{p}(F)$: this function can be retrieved without *a priori* assumptions by relating it to a histogram of the damage fluences of the data set (Xu *et al.*, 2015b); (3) the damage probability $P(F)$: This is done by a straightforward simulation of the ISO test using $\bar{p}(F)$. It should be noted that the same number of test sites provide not only new information about the sample compared to the ISO test, but also produce the ISO data with much greater accuracy.

Four-Wave Mixing

L Canioni and L Sarger, University of Bordeaux, Talence, France

Introduction

Light waves propagate along straight lines in a vacuum and in materials. However, their amplitude and phase can only be affected by the intrinsic properties of the sample, such as absorption and refraction index. Experimental work from the early 1960s, has deviated from this simple approach, mainly through propagating intense light beams in crystals and glasses. Among many puzzling new effects, frequency conversion and beam coupling have triggered intense studies and opened a whole new field, theoretically and experimentally. These various phenomena have been classified according to the order of their optical non-linearity. The second order mainly occurs in frequency generation and has already been discussed in previous articles of this encyclopedia. Therefore, this article will be devoted to the higher order, in which self focusing, coupling, and mixing of light beams will be explained. We will illustrate some simple ideas with a convenient model before describing a few applications.

The framework of electromagnetic wave interaction with matter is embedded in the Lorentz force. The oscillating electric field drives the components, ions, and electrons, but due to the large mass differences, only the electron movement is strongly perturbed. In dielectric media, these carriers are connected with static bonds such that the applied electric field modulates the spatial position of equilibrium of the charges. As a result, a dipolar moment is created and oscillates quasi-adiabatically at very high frequencies (between 10^{14} and 10^{17} Hz) for an applied optical wave. These collective oscillations of the induced dipoles compose the so-called matter polarization, proportional to the driving electric field amplitude. Magnetic field interaction is usually much weaker and so can be neglected in nonmagnetic media.

As an electromagnetic wave, lasers are a coherent source of very high intensity, i.e., large electric fields. For example, in standard pulsed lasers focused on a target, the light intensity can easily reach 10 Tw/cm^2 , corresponding to an electric field of the order of magnitude of the internal bonding field (10^{10} V/m). At this level of interaction, dipolar moments are no longer strictly proportional to the applied electric field, as depicted in Fig. 1. In the weak field regime, the simple perturbation approach displaces the carriers in a power series of the applied electric field. The polarization is thus developed in series, in respect to this electric field.

Formalism

Relation Between Field and Polarization: The Response Function

Although numerous works have been published with a frequency description of the material polarization, we will discuss here the study of nonlinearity in the time domain in order to follow the physical reality. In most processes, both spaces are equal and can be selected at will, as long as the entire requirements are fully understood; the electromagnetic field is classically described.

In the time domain, the polarization can be developed as

$$P(r, t) = P_{\text{Linear}}(r, t) + P_{\text{Nonlinear}}(r, t) \quad (1)$$

where the linear part of the polarization can be written as

$$P_{\text{Linear}}(r, t) = \epsilon_0 \int_{R^3} \int_{-\infty}^{\infty} R^{(1)}(r_1, t_1) E(r - r_1, t - t_1) dt_1 dr_1 \quad (2)$$

Fig. 1 Polarization for various field amplitude: (a) Weak field case, linear response. (A) Strong field, distortion and nonlinearity.

Fig. 2 Three incoming beams E_1 , E_2 , E_3 create a polarization (nonlinear). The sample responds while radiating a fourth field E_4 .

This general expression is rather complex but shows that the polarization, due to collective movement of carriers in a macroscopic volume (thousands of dipoles) centered at position r , always depends on the applied electric field. This expression is also nonlocal as dipoles–dipoles interactions play an important role.

In general, for the nonlinear (NL) part of the polarization, an approximation of the local interaction is described for simplicity. For a second-order interaction, one can write:

$$P_{\text{NL}}^{(2)}(r, t) = \epsilon_0 \int_{-\infty}^{+\infty} \int_{-\infty}^{+\infty} R^{(2)}(t_1, t_2) E(r, t - t_2) E(r, t - t_2 - t_1) dt_1 dt_2 \quad (3)$$

For the other series expansion – at third order, one obtains

$$P_{\text{NL}}^{(3)}(r, t) = \epsilon_0 \int_{-\infty}^{+\infty} \int_{-\infty}^{+\infty} \int_{-\infty}^{+\infty} R^{(3)}(t_1, t_2, t_3) E(r, t - t_3) E(r, t - t_3 - t_2) E(r, t - t_3 - t_2 - t_1) dt_1 dt_2 dt_3 \quad (4)$$

This third-order polarization already combines three electric fields. This nonlinear polarization also radiates a fourth wave and is therefore the adopted framework for describing four-wave mixing experiments (Fig. 2).

As the physical properties of materials depend only on time intervals between the different pulse interactions, Eq. (4) can be rearranged as

$$P_{\text{NL}}^{(3)}(r, t) = \epsilon_0 \int_{-\infty}^{+\infty} \int_{-\infty}^{+\infty} \int_{-\infty}^{+\infty} R^{(3)}(t - \tau_1, t - \tau_2, t - \tau_3) E(r, \tau_1) E(r, \tau_2) E(r, \tau_3) d\tau_1 d\tau_2 d\tau_3 \quad (5)$$

If the sample response time is much shorter than pulse duration, the so-called adiabatic limit (as for electronic cloud deformation excited distant from resonance) the polarization is written as

$$P_{\text{NL}}^{(3)}(r, t) = \epsilon_0 \sigma^{(3)} E(r, t) E(r, t) E(r, t) \quad (6)$$

We will see later how this expression is useful for third-harmonic generation and optical Kerr effects, etc. This expression is accurate for materials excited at a distance from resonances and care must be taken to reserve such a model for corresponding processes. In this case, the frequency approach is quite simple too and both spaces, time or Fourier, can be chosen at will.

For very long response time, such as orientational or structural molecular reorganization, one can use the Born–Oppenheimer approximation and present the nonlinear polarization as

$$P_{\text{NL}}^{(3)}(r, t) = \epsilon_0 E(r, t) R'(t) \quad (7)$$

Similar is linear polarization, where the response function takes into account the changes of the molecular structure under the light intensity stress:

$$R'(t) = \int_{-\infty}^{+\infty} d^{(3)}(t - t_1) E(r, t_1) E(r, t_1) dt_1 \quad (8)$$

The material response will then be mostly driven by the field amplitude rather than the frequency.

Properties of Nonlinear Susceptibilities

The third-order nonlinear susceptibility $\chi^{(3)}$ is the Fourier transform of the response function R and has proved to be a most practical tool in optical nonlinear theory. The symmetry properties of the material lead to simplification on the tensor of rank 4 (fourth rank tensor), involved in four-wave mixing:

$$P_i^{(3)}(\omega_m) = \epsilon_0 \sum_{n_1, \dots, n_p} \sum_{i_1, \dots, i_p} \chi_{i i_1, \dots, i_p}^{(3)}(\omega_m; \omega_{n_1}, \dots, \omega_{n_p}) E_{i_1}(\omega_{n_1}) \dots E_{i_p}(\omega_{n_p}) \quad (9)$$

The nonlinear susceptibility tensor must account for all the spatial and symmetrical order of the sample. This will eventually reduce the number of independent elements from a possible 81.

Wave Equation in Nonlinear Regime

From Maxwell's equations, with a sample without free carriers and current, one can deduce the wave equation in the time domain, as:

$$\Delta E - \frac{1}{c^2} \frac{\partial^2 E}{\partial t^2} - \frac{1}{c^2} \frac{\partial^2 P_L}{\partial t^2} = \frac{1}{c^2} \frac{\partial^2 P_{NL}}{\partial t^2} \quad (10)$$

In the frequency domain, this equation reduces to

$$\Delta \tilde{E}(r, \omega) + k(\omega)^2 \tilde{E}(r, \omega) = -\mu_0 \omega^2 \tilde{P}_{NL}(r, \omega) \quad (11)$$

In order to solve these (coupled) wave equations in relation to four-wave mixing, we must develop the electric field and the polarization in a slowly varying envelope approximation, using the following conventions:

$$E_i(r, t) = \frac{1}{2} \left(A_i(r, t) e^{i(\omega_i t - k(\omega_i) z)} + \bar{A}_i(r, t) e^{-i(\omega_i t - k(\omega_i) z)} \right) \quad (12)$$

$$P_{NL}(r, t) = \frac{1}{2} \left(p_{nl}(r, t) e^{i(\omega t - k(\omega) z)} + \bar{p}_{nl}(r, t) e^{-i(\omega t - k(\omega) z)} \right) \quad (13)$$

Within the framework of small perturbations, diffraction can be neglected and the wave equation can be easily reduced to one dimension:

$$\frac{\partial A}{\partial z} = \frac{i\omega}{2n(\omega)\epsilon_0 c} p^{NL}(z, \omega) \exp(-ik(\omega)z) \quad (14)$$

where ω represents the sum or difference permutations over all the frequencies ω_i , thus reflecting the law of energy conservation.

In the case of four-wave mixing, one has to solve four coupled equations for the four interacting waves. Using the polarization [Eq. \(13\)](#), one gets:

$$\frac{\partial A_j}{\partial z} = \frac{i\omega_j}{2n(\omega_j)c} \chi^3 A_1^{(*)} A_2^{(*)} A_3^{(*)} \exp\left(\sum_{i=1,2,3} \exp(\pm ik_i(\omega_i)z)\right) \exp(-ik(\omega_j)z) \quad (15)$$

This set of generic equations respectively represent indifferently, either the three incoming beams ($j = 1, 2, 3$), or the radiated field E_4 at ω . The algebra used here associates at each complex conjugate field (*) with the counter propagating wave ($-k$). The amplitude variation of the j field at frequency ω_j is due to the coupling of the three other fields within the sample. The accumulated field is nevertheless always strongly dependent of the phase term and will vanish except when this phase term is zero. This is known as the phase matching condition which has to be fulfilled to ensure an efficient energy conversion. A more general approach of this condition can be found in the corresponding article of this encyclopedia.

Example and Selected Applications

When inserting the full material polarization (linear and nonlinear) into the propagation equation, even restricted at third order, a whole set of processes must be considered. All of them are described by the generic equation already presented, but only a few very important processes – with increasing complexity – will be described here.

Optical Kerr Effect

We consider one single beam incident at frequency ω on a sample. The non-linear polarization is given by

$$P_{NL}^{(3)}(r, t) = \frac{\epsilon_0}{8} \chi^{(3)} (E(r, t)^3 + E^*(r, t)^3 + 3E(r, t)^2 E^*(r, t) + 3E(r, t) E^*(r, t)^2) \quad (16)$$

The polarization at frequency ω reduces to

$$P_{NL}^{(3)}(r, t) = \frac{3\epsilon_0}{4} \chi^{(3)} |E(r, t)|^2 E(r, t) \quad (17)$$

This term has the same phase as the incident beam and, therefore, the phase matching is automatic. Using [Eqs. \(12\)](#) and [\(13\)](#), one can rewrite the wave equation for the optical Kerr effect in the thin sample approximation:

$$\frac{\partial A}{\partial z} = \frac{3i\omega}{8nc} \chi^{(3)} |A|^2 A \quad (18)$$

The solution of this equation is

$$A(z) = A(0) \exp\left(\frac{3i}{8nc} \chi^{(3)} |A(0)|^2 z\right) \quad (19)$$

Along the beam, the amplitude of the input pulse stays constant for this process but its phase is affected by a nonlinear shift proportional to power density I .

In literature, one can find the concept of n_2 , the sample nonlinear index, in the following formula:

$$\psi_{NL}(z) = \frac{\omega}{c} n_2 I z \quad (20)$$

In this way of describing the total phase along the beam, the index of refraction in the nonlinear regime can be expressed more conveniently as

$$n = n_0 + n_2 I \quad (21)$$

One of the most significant demonstrations of this effect is the self-focusing phenomenon. The usual Gaussian transverse structure of a laser beam presents high intensity at the center of the beam, therefore creating an index variation in the isotropic sample due to this optical Kerr effect. An induced lens can then be applied to this refractive index gradient, following the field distribution. As a result, the beam focuses itself along the propagation and can result in a complete breakdown.

Third Harmonic Generation

In the third harmonic generation, i.e., the third-order nonlinear process where the frequency of the generated wave is three times the frequency of the input wave at ω , only two waves are in the sample (at ω and 3ω). For the nonlinear wave, the master equation is then:

$$\frac{\partial A_{3\omega}}{\partial z} = \frac{3i\omega}{8n(3\omega)c} \chi^{(3)} A_{\omega}^3 \exp((3ik(\omega) - ik(3\omega))z) \quad (22)$$

Here, propagation effects have to be carefully considered as these waves do travel at different velocities and will eventually be out of phase. Obviously this discrepancy of phase velocities precludes the co-propagation and strongly affects the global efficiency. The only way to ensure a coherent generation of the harmonic wave throughout the material is to fulfill the relation:

$$k(3\omega) = 3k(\omega) \quad (23)$$

This is the so-called phase matching condition. Although difficult because the usual dispersion of materials is very large for such a frequency difference, this can be satisfied using either geometrical arrangement or, if possible, using the birefringent properties of the material. The efficiency of this method is poor and a better approach is implemented when two $\chi^{(2)}$ processes are cascaded (doubling and sum frequency mixing).

Degenerate Four-Wave Mixing and Phase Conjugation

One of the most popular and intriguing interactions is depicted in Fig. 3. Where the sample is excited by three fields at the same frequency ω in this particular geometry: two-waves, named pump beams E_1 and E_2 , are exactly counter-propagating with opposite wave vectors of $+k_1$ and $k_2 = -k_1$, while the third wave (E_3 arrives at the sample with a given wave vector of k_3 .

Of possible couplings, one contribution E_4 corresponds to a re-emitted beam along $k_4 = -k_3$, i.e., opposite to the E_3 wave.

The third-order nonlinear polarization is given here by

$$P_{NL}^{(3)}(r, t) = \frac{\epsilon_0}{8} \chi^{(3)} (E_1(r, t) + E_1^*(r, t) + E_2(r, t) + E_2^*(r, t) + E_3(r, t) + E_3^*(r, t))^3 \quad (24)$$

This E_4 wave (along $-k_3$) originates in this product from source terms including:

$$E_1(r, t)E_2(r, t)E_3^*(r, t) \quad (25)$$

and thus present an evolution driven by:

$$\frac{\partial A_4}{\partial z} = \frac{3i\omega}{4n(\omega)c} \chi^{(3)} A_1 A_2 A_3^* \quad (26)$$

where the phase matching condition is automatically fulfilled. Interesting facts can be described using this expression. First, the radiated amplitude is proportional to the complex conjugate of the E_3 field. This nonlinear process is not only able to reverse the direction of propagation but also the whole phase of an arbitrary incoming beam of light. This 'phase conjugator' can be

Fig. 3 Two counter-propagating fields (E_1 , E_2) and the third field E_3 create a polarization (nonlinear). The sample responds while radiating a fourth field E_4 opposite to the E_3 wave.

Fig. 4 (a) Snell refraction in a conventional mirror; (b) Phase conjugate mirror.

Fig. 5 A basic two-pass system for imaging and distortion compensation using optical phase conjugation.

considered as a kind of mirror with very unusual reflection properties. Unlike a conventional mirror, where a ray is redirected according to the ordinary law of reflection, a phase-conjugate mirror (PCM) retro-reflects all incoming rays back to their origin (Fig. 4).

Second, the reflectivity of this mirror depends on the susceptibility and the amplitude of the first two fields, usually called pump beams. This will allow reflectivity that is much higher than the unity, unlike with conventional mirrors.

The remarkable reflection properties of the PCM have found many important applications. The most useful undoubtedly is related to distortion correction. If the image information has been distorted by the transmitting medium on its way to the PCM, then these aberrations will be corrected when the reflected signal retraces its original path through the medium. Through this amazing 'healing' property of optical phase conjugation, a high-quality optical beam can be double passed through a distorting medium, such as an imperfect imaging device or a turbulent atmosphere, without any loss of beam quality. Fig. 5 shows the basic two-pass geometry for imaging and aberration correction using a PCM.

The spherical wave from the object point P is aberrated by the distorting medium. The wave-front is reversed by the PCM and a second passage through the same distorting path restores the initial field. The resulting spherical wave converges to the image point P' , separated from P by the beamsplitter.

Numerous other applications for PCM and the various underlying nonlinear optical interactions have been proposed. These include effects as diverse as parametric oscillation, optical tracking and pointing, spatial and temporal image processing, optical computing, optical filtering, etc. The PCM is also successfully implemented for aberration correction in high-power laser resonators.

Nondegenerate Four-Wave Mixing

If the frequencies of the impinging fields build a nonlinear polarization with an oscillating term close to absorption (or emission) frequencies of the sample, the nonlinear susceptibility increases tremendously. The radiated field amplitude changes by orders of magnitude and allows spectroscopic studies of the sample. The most popular process used to perform gas spectroscopy is CARS, an acronym for coherent anti-Stokes Raman scattering (or spectroscopy). In this case, the three incoming beams have different frequencies and the phase matching condition is eventually fulfilled in the 3D space.

Usually, two beams at the same frequency ω_P (pump beams), are mixed with a third beam at a tunable frequency ω_S , according to the energy scheme in Fig. 6. As the radiated frequency ω_{CARS} is higher, the Raman spectroscopic notation is used and the subscripts 'S' hold for 'Stokes' and 'P' for 'anti-Stokes'.

Whenever $\omega_P - \omega_S = \omega_{\text{molecule}}$, then an increase of the CARS intensity by many orders of magnitude is observed. Therefore, a Raman spectrum can be obtained by continuously changing, the Stokes laser and simultaneously recording the intensity of the

Fig. 6 Energy diagram for a CARS experiment. Four-wave mixing efficiency increases when the frequency difference $\omega_P - \omega_S$ is close to a resonant frequency of the sample, ω_{molecule} .

Fig. 7 Layout of the CARS beams near a sample (a flame here). This particular arrangement is called folded (or 3D) Boxcars.

CARS beam. This procedure is called scanning CARS, an interesting technique insofar as it allows taking high-resolution spectra, as well as measuring temperature of the sample while scanning over the Boltzmann distribution of the electronic ground state.

Fig. 7 displays a classical geometrical arrangement where the phase matching condition fully determines the directionality of the radiated field at ω_{CARS} . Although the alignment of the setup can become tedious, this technique has been widely used, even in hostile industrial environments. The coherent aspect of this four-wave mixing process, imbedded in the phase matching condition, has a huge benefit over classical spectroscopic techniques and thus isotropic techniques, such as laser-induced fluorescence or Raman spectroscopy.

The CARS process is an interference process comparable to diffraction of a grating. The two fields at ω_P and ω_S form a laser-induced moving grating and the third field, at ω_P , undergoes a Doppler shift at ω_{CARS} . This scattered field undergoes a coherent amplitude addition in the Bragg direction.

Conclusion

In this article, we have discussed a set of optical nonlinear processes occurring at the third order of the development in series of the material polarization. At this order, wave mixing obviously shows most significant behavior and has been extensively studied and applied in many scientific areas. The general framework presented here can be further investigated using some books listed in Further Reading below.

Nomenclature

α	linear absorption coefficient	n_2	nonlinear refractive index coefficient,
α_2	nonlinear absorption coefficient	$\Theta(t)$	coefficient of optical Kerr effect
β	two-photon absorption coefficient	$\wp$	step function
$\chi^{(n)}$	n th-order nonlinear optical susceptibility	2PA	principal value
n	linear refractive index	KK relations	two-photon absorption
			Kramers–Krönig relations

Since their introduction nearly 75 years ago, the Kramers–Krönig (KK) dispersion relations have been widely appreciated and applied in the analysis of linear optical systems. Because they are a consequence of strict causality, the KK relations apply not only to optical systems, but also to any linear, causal system such as electrical networks and particle scattering. In this article, we review the formulation and application of these relations in nonlinear optical systems. Simple logical arguments are used to derive dispersion relations that relate the nonlinear absorption coefficient to the nonlinear refraction coefficient. More general formalisms are then derived that apply to all nonlinear susceptibilities including the harmonic generating cases. Examples of recent successful application of these dispersion relations in analyzing various nonlinear materials will be presented.

The mathematical formalism of the KK dispersion relations in nonlinear optics was studied in the formative days of the field. The great usefulness of these relations was appreciated only recently, however, when they were used to derive the dispersion of the optical Kerr effect in solids from the corresponding nonlinear absorption coefficients, including two-photon absorption.

Before examining the details of KK relations in nonlinear optical systems, it is instructive to revisit the linear dispersion relations and their derivation based on the logic of causality. We will begin this task by introducing the definition of the linear as well as nonlinear susceptibilities $\chi^{(n)}$. In most nonlinear optics texts, the total material polarization (P) that drives the wave equation for the electric field (E) is expressed as

$$P_i(t) = \epsilon_0 \int_{-\infty}^{\infty} R_{ij}^{(1)}(t-t_1) E_j(t_1) dt_1 + \epsilon_0 \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} R_{ijk}^{(2)}(t-t_1, t-t_2) E_j(t_1) E_k(t_2) dt_1 dt_2 + \dots$$

$$+ \epsilon_0 \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} R_{ijkl}^{(3)}(t-t_1, t-t_2, t-t_3) E_j(t_1) E_k(t_2) E_l(t_3) dt_1 dt_2 dt_3 + \dots$$
(1)

where $R^{(n)}$ is defined as the n th-order, time-dependent response function or time-dependent susceptibility. The subscripts are polarization indices indicating, in general, the tensor nature of the interactions. The summation over the various indices $j, k, l, \dots$ is implied for the various tensor elements of $R^{(n)}$. Upon Fourier transformation, we obtain:

$$\vec{P}_i(\omega) = \epsilon_0 \int_{-\infty}^{\infty} d\omega_1 \chi_{ij}^{(1)}(\omega_1) \vec{E}_j(\omega_1) \delta(\omega - \omega_1) + \epsilon_0 \int_{-\infty}^{\infty} d\omega_1 \int_{-\infty}^{\infty} d\omega_2 \chi_{ijk}^{(2)}(\omega_1, \omega_2) \vec{E}_j(\omega_1) \vec{E}_k(\omega_2) \delta(\omega - \omega_1 - \omega_2)$$

$$+ \epsilon_0 \int_{-\infty}^{\infty} d\omega_1 \int_{-\infty}^{\infty} d\omega_2 \int_{-\infty}^{\infty} d\omega_3 \chi_{ijkl}^{(3)}(\omega_1, \omega_2, \omega_3) \vec{E}_j(\omega_1) \vec{E}_k(\omega_2) \vec{E}_l(\omega_3) \delta(\omega - \omega_1 - \omega_2 - \omega_3), \dots$$
(2)

where δ is the Dirac delta-function. Here the $E(\omega)$ are Fourier transforms of the corresponding electric field. The n th-order susceptibility is defined as the Fourier transform of the n th-order response function:

$$\chi_{ijk\dots n}^{(n)}(\omega_1, \omega_2, \dots, \omega_m) = \int_{-\infty}^{+\infty} d\tau_1 \int_{-\infty}^{+\infty} d\tau_2 \dots \int_{-\infty}^{+\infty} d\tau_n R_{ijk\dots m}^{(n)}(\tau_1, \tau_2, \dots, \tau_m) e^{i(\omega_1 \tau_1 + \omega_2 \tau_2 + \dots + \omega_m \tau_m)}$$
(3)

For simplicity, we drop the polarization indices $i, j, \dots$, and thus ignore the tensor properties of $\chi^{(n)}$ as well as the vector nature of the electric fields.

Let us for the moment concentrate on the linear polarization alone and derive the linear KK relations for the first-order susceptibility $\chi^{(1)}(\omega)$. For this, we rewrite Eq. (3) for $n=1$:

$$\chi^{(1)}(\omega) = \int_{-\infty}^{\infty} R^{(1)}(\tau) e^{-i\omega\tau} d\tau$$
(4)

(As defined above, $\chi^{(1)}(\omega)$ and $R^{(1)}(\tau)$ are not a strict Fourier transform pair because of a missing factor of 2π .) Causality means that the effect cannot precede the cause. This can be restated mathematically as:

$$R^{(1)}(t) = R^{(1)}(t) \Theta(t)$$
(5)

i.e., the response to an impulse at $t=0$ must be zero for $t<0$. Here $\Theta(t)$ is the Heaviside step function defined as $\Theta(t)=1$ for $t>0$ and $\Theta(t)=0$ for $t<0$. Upon Fourier transforming this equation, the product in the time domain becomes a convolution integral in

frequency space

$$\begin{aligned}
 \chi^{(1)}(\omega) &= \chi^{(1)}(\omega) \left[\frac{\delta(\omega)}{2} + \frac{i}{2\pi\omega} \right] \\
 &= \frac{\chi^{(1)}(\omega)}{2} + \frac{i}{2\pi} \wp \int_{-\infty}^{\infty} \frac{\chi^{(1)}(\omega')}{\omega - \omega'} d\omega' \\
 &= \frac{1}{i\pi} \wp \int_{-\infty}^{\infty} \frac{\chi^{(1)}(\omega')}{\omega' - \omega} d\omega'
 \end{aligned} \tag{6}$$

which is the KK relation for the linear optical susceptibility. The symbol $\wp$ stands for the Cauchy principal value of the integral. The KK relation is thus a restatement of the causality condition (5) in the frequency domain. Taking the real part we have,

$$\Re\{\chi^{(1)}(\omega)\} = \frac{1}{\pi} \wp \int_{-\infty}^{\infty} \frac{\Im\{\chi^{(1)}(\omega')\}}{\omega' - \omega} d\omega' \tag{7}$$

Taking the imaginary part of Eq. (6) leads to a similar relation relating the imaginary part to an integral involving the real part. It is conventional to write the optical dispersion relations in terms of the more familiar quantities of refractive index, $n(\omega)$, and absorption coefficient, $\alpha(\omega)$. For $|\chi^{(1)}| \ll 1$ then $n - 1 = \Re\{\chi^{(1)}\}/2$ and $\alpha = \omega \Im\{\chi^{(1)}\}/c$, and Eq. (7) is transformed into

$$n(\omega) - 1 = \frac{c}{\pi} \wp \int_0^{\infty} \frac{\alpha(\omega')}{\omega' 2 - \omega^2} d\omega' \tag{8}$$

where we additionally used the reality conditions of $n(\omega) = n(-\omega)$, and $\alpha(\omega) = \alpha(-\omega)$ to change the lower integral limit to 0. More rigorous analysis shows that Eq. (8) is general and valid for any value of $|\chi^{(1)}|$. Although the KK dispersion relations and the extent of their applications in linear optics are well understood, some confusion sometimes exists about their applications to nonlinear optics. Causality clearly holds for both linear and nonlinear systems. The question is: what form do the resulting dispersion relations take in a nonlinear system? The linear Kramers–Krönig relations were derived from linear system theory, so it would appear to be impossible to apply the same logic to a nonlinear system. The key insight is that one can linearize the system. This is illustrated in Fig. 1 where a linear (and of course, causal) optical material is transformed into a ‘new’ linear system that now contains the material and an external perturbation denoted by ξ . Although we are interested in perturbations of an optical nature, this formalism is general under any type of perturbation. It is important to appreciate the fact that our new system is causal even in the presence of the perturbation. This allows us to write down a modified form of the Kramers–Krönig relation linking the index of refraction to the absorption:

$$[n(\omega) + \Delta n(\omega; \xi)] - 1 = \frac{c}{\pi} \wp \int_0^{\infty} \frac{\alpha(\omega') + \Delta \alpha(\omega'; \xi)}{\omega' 2 - \omega^2} d\omega' \tag{9}$$

which, after subtracting the linear relation between n and α leaves a relation between the changes in index and absorption:

$$\Delta n(\omega; \xi) = \frac{c}{\pi} \wp \int_0^{\infty} \frac{\Delta \alpha(\omega'; \xi)}{\omega' 2 - \omega^2} d\omega' \tag{10}$$

where ξ denotes a general perturbation. An equivalent relation also exists whereby the change in absorption coefficient can be calculated from the change in the refractive index. It is essential that the perturbation be independent of frequency of observation, ω' , in the integral (i.e., the excitation ξ must be held constant as ω' is varied).

Eq. (10) has been used to determine refractive changes due to ‘real’ excitations such as thermal and free-carrier nonlinearities in semiconductors. In those cases, ξ denotes either ΔT (change of temperature) or ΔN (change of free-carrier density), respectively. In the former case, one calculates the refractive index change resulting from a thermally excited electron–hole plasma and the temperature shift of the band edge. For cases where an electron–hole plasma is injected (e.g., optically), the change of absorption gives the plasma contribution to the refractive index. In this case, the ξ parameter in Eq. (10) is taken as the change in plasma density regardless of the mechanism of generation or the optical frequency.

Fig. 1 (a) A causal linear system obeying KK relations. (b) The system in (a) when externally perturbed by ξ . The dotted box now represents our new linear causal system whose altered $\chi^{(1)}$ obeys the KK relations.

Let us now extend this formalism to the case where the perturbation is virtual, occurring at an excitation frequency Ω that is below any material resonance. To the lowest order in the excitation irradiance I_Ω , we write

$$\Delta\alpha(\omega; \zeta) = \Delta\alpha(\omega; \Omega) = 2\alpha_2(\omega; \Omega)I_\Omega \quad (11)$$

and

$$\Delta n(\omega; \zeta) = \Delta n(\omega; \Omega) = 2n_2(\omega; \Omega)I_\Omega \quad (12)$$

where n_2 and α_2 are the nonlinear refractive index and absorption coefficients of the material, respectively. By definition, these coefficients are related to the third-order nonlinear susceptibility $\chi^{(3)}(\omega_1, \omega_2, \omega_3)$ via

$$n_2(\omega; \Omega) = \frac{3}{4\varepsilon_0 n_0(\omega) n_0(\Omega) c} \Re \left\{ \chi^{(3)}(\omega, -\Omega, \Omega) \right\} \quad (13)$$

and

$$\alpha_2(\omega; \Omega) = \frac{3\omega_a}{2\varepsilon_0 n_0(\omega) n_0(\Omega) c^2} \Im \left\{ \chi^{(3)}(\omega, -\Omega, \Omega) \right\} \quad (14)$$

We can therefore write the dispersion relations between α_2 and n_2 :

$$n_2(\omega; \Omega) = \frac{c}{\pi} \mathcal{P} \int_0^\infty \frac{\alpha_2(\omega'; \Omega)}{\omega' 2 - \Omega^2} d\omega' \quad (15)$$

Note that even when the degenerate $n_2(\omega) = n_2(\omega; \omega)$ is desired (at a given ω), the dispersion relation requires that we should know the nondegenerate absorption spectrum $\alpha_2(\omega'; \omega)$ at all frequencies ω' .

Let us pause here and discuss some physical mechanisms that can be involved for a given system of interest. Consider a material characterized by an optical resonance occurring at, say ω_0 (i.e., a degenerate two-level system). For a solid, this resonance can be regarded as that of the fundamental energy gap; $\omega_0 = \omega_g = E_g/\hbar$ in a two-band system. Now, let us examine how the presence of an optical excitation at $\Omega < \omega_0$ can alter the absorption spectrum (at a variable probe ω'). In the quantum mechanical picture, this gives rise to a 'new' material whose perturbed wave functions are 'dressed' by the intensity and frequency of the applied optical field. The lowest-order correction to the absorption is given by $\alpha_2(\omega'; \Omega)$ which involves three major physical processes. Recalling that $\Omega < \omega_0$, these processes include (1) two-photon absorption (2PA) when $\omega' + \Omega \rightarrow \omega_0$ and (2) Raman-induced absorption when $\omega' - \Omega \rightarrow \omega_0$, both implying an absorption of a photon at the probe frequency ω' (i.e., $\alpha_2 > 0$). The third process can be identified as resulting from the blue-shift (for $\Omega < \omega_0$) of the resonance (known as the quadratic optical Stark effect) caused by the excitation field. For our two-level system, the latter results in a decrease followed by an increase in absorption in the vicinity of ω_0 . An example of the overall absorption changes due to such processes is shown in Fig. 2 where $\alpha_2(\omega'; \Omega)$ is qualitatively plotted for a degenerate two-level system. We should note that the relative magnitude of each contribution as well as the width and shape of the resonances are chosen arbitrarily for the purpose of illustration. Using the KK relation in Eq. (15), we can now arrive at the nonlinear index coefficient $n_2(\omega; \Omega)$. The result of this transformation is also given in Fig. 2. The above simple example elucidates the key concepts involving the relationship between nonlinear absorption and refraction in materials for third-order processes. These concepts, when applied more rigorously to semiconductors, have been successful in predicting the sign, magnitude, and

Fig. 2 Upper trace: the nonlinear absorption coefficient in a fictitious 'degenerate' two-level system. Lower trace: the resulting nonlinear refractive index obtained using the KK relations. The insets show the three possible physical mechanisms involved.

dispersion of n_2 due to the anharmonic motion of bound electrons. This will be briefly discussed later. Returning to the mathematical foundation of KK relations, we use Eqs. (13) and (14) to write Eq. (15) in terms of the nonlinear susceptibility $\chi^{(3)}$:

$$\Re\{\chi^{(3)}(\omega_1, \omega_2, -\omega_2)\} = \frac{1}{\pi} \wp \int_{-\infty}^{\infty} \frac{\Im\{\chi^{(3)}(\omega', \omega_2, \omega_2)\}}{\omega' - \omega_1} d\omega' \quad (16)$$

The above dispersion relation for $\chi^{(3)}$ was obtained using the physical and intuitive arguments that followed the linearization scheme depicted in Fig. 1. General dispersion relations can be formulated following a mathematical procedure that is similar to the derivation of the linear KK relations. In this case we apply the causality condition directly to the n th-order nonlinear response $R^{(n)}$. For example, without loss of generality, we can write

$$R^{(n)}(\tau_1, \tau_2, \dots, \tau_n) = R^{(n)}(\tau_1, \tau_2, \dots, \tau_n) \Theta(\tau_j) \quad (17)$$

and then calculate the Fourier transform of this equation. Here j can apply to any one of the indices $1, 2, \dots, n$. Following the same procedure as for a linear response, we obtain

$$\chi^{(n)}(\omega_1, \omega_2, \dots, \omega_j, \dots, \omega_n) = \frac{-i}{\pi} \wp \int_{-\infty}^{\infty} \frac{\chi^{(n)}(\omega_1, \omega_2, \dots, \omega', \dots, \omega_n)}{\omega_j - \omega'} d\omega' \quad (18)$$

By separating the real and imaginary parts of this equation, we get the generalized Kramers–Krönig relation pairs for a non-degenerate, n th-order nonlinear susceptibility:

$$\Re\{\chi^{(n)}(\omega_1, \omega_2, \dots, \omega_j, \dots, \omega_n)\} = \frac{1}{\pi} \wp \int_{-\infty}^{\infty} \frac{\Im\{\chi^{(n)}(\omega_1, \omega_2, \dots, \omega', \dots, \omega_n)\}}{\omega' - \omega_j} d\omega' \quad (19)$$

and

$$\Im\{\chi^{(n)}(\omega_1, \omega_2, \dots, \omega_j, \dots, \omega_n)\} = -\frac{1}{\pi} \wp \int_{-\infty}^{\infty} \frac{\Re\{\chi^{(n)}(\omega_1, \omega_2, \dots, \omega', \dots, \omega_n)\}}{\omega' - \omega_j} d\omega' \quad (20)$$

In particular, for $\chi^{(3)}$ processes having $\omega_1 = \omega_a$, $\omega_2 = \omega_b$, and $\omega_3 = \omega_c$, this becomes identical to Eq. (16).

Note that in describing the nonlinear susceptibilities, no special attention was given to the harmonic generating susceptibility $\chi^{(N)}(N\omega) \equiv \chi^{(N)}(\omega, \omega, \dots, \omega)$, i.e., the susceptibility generating the N th harmonic at $N\omega$. It turns out that in addition to the KK relations given by Eqs. (19) and (20), the real and imaginary parts of $\chi^{(N)}(N\omega)$ can also be related in different sets of dispersion integrals that involve only the degenerate forms of the susceptibilities. A more general yet simple analysis gives the most general form of KK relations for any type of $\chi^{(n)}$:

$$\chi^{(n)}(\omega_1 + p_1\omega, \omega_2 + p_2\omega, \dots, \omega_m + p_m\omega) = \frac{1}{i\pi} \wp \int_{-\infty}^{\infty} \frac{\chi^{(n)}(\omega_1 + p_1\Omega, \omega_2 + p_2\Omega, \dots, \omega_m + p_m\Omega)}{\Omega - \omega} d\Omega \quad (21)$$

for all $p_1, p_2, \dots, p_m \geq 0$. Setting $\omega_1 = \omega_2 = \dots = \omega_m \equiv 0$, and $p_1 = p_2 = \dots = p_m = 1$ in Eq. (21) yields an interesting form of the KK relations for the N th-harmonic susceptibilities:

$$\Re\{\chi^{(N)}(N\omega)\} = \frac{1}{\pi} \wp \int_{-\infty}^{\infty} \frac{\Im\{\chi^{(N)}(N\omega')\}}{\omega' - \omega} d\omega' \quad (22)$$

These dispersion relations have allowed calculations of $\chi^{(2)}(2\omega)$ and $\chi^{(3)}(3\omega)$ in semiconductors using full band structures.

At the beginning of this article, it was noted that all the KK relations for nonlinear optics were known in the early days of the field. Their application in unifying nonlinear absorption (in particular two-photon absorption) and the optical Kerr effect (n_2) in solids came only much later. More recent work demonstrated that the KK relations are a powerful analytical tool in nonlinear optics. Following the picture of a degenerate two-level system shown in Fig. 2, a simple two-band model has been used to calculate the nonlinear absorption coefficient, $\alpha_2(\omega_1; \omega_2)$, resulting from three mechanisms: 2PA, the Raman absorption process, and the ac Stark effect. The optical Kerr coefficient $n_2(\omega_1; \omega_2)$ was then calculated using Eq. (15). Of particular practical interest is the degenerate case ($\omega_1 = \omega_2 = \omega$), from which the 2PA coefficient $\beta(\omega) = \alpha_2(\omega; \omega)$ can be extracted. Fig. 3 depicts the calculated dispersion of n_2 and β as a function of $\hbar\omega/E_g$ where E_g is the bandgap energy of the solid. The dispersion of n_2 and its sign reversal shown in Fig. 3 has been observed experimentally in many optical solids.

Finally, let us discuss a related implication of causality in nonlinear optics. The KK dispersion relations are traditionally derived in terms of internal material parameters such as susceptibility, absorption coefficient, and refractive index. Similar to the case of electrical circuits, one can obtain dispersion relations that apply to an external transfer function of the system that relates an input signal to an output signal. In this case, the dispersion of the transfer function includes system structure as well as the intrinsic dispersion of the material. As an optical (and linear) example, consider a Fabry–Perot etalon. The optical transmission of this system has well-known spectral features that are primarily caused by structural dispersion (i.e., interference) in addition to the intrinsic dispersion of the material. Causality still demands that the transmitted signal has a phase variation whose value and dispersion can be determined using a KK relation linking the real and imaginary parts of the transmission coefficient. In other words, the KK relations provide a spectral correlation between the real and imaginary components of the transfer function which in turn may translate to a spectral correlation between the phase and amplitude of the transmitted signal. However, the variations in phase do not necessarily imply the presence of a varying index of refraction, nor does an amplitude variation suggest the existence of material absorption (dissipation). Ultimately, this implies that any mechanism causing a variation in amplitude (including reflection, scattering, or absorption) must be accompanied by a phase variation. (One should note that the reverse of

Fig. 3 The two-photon absorption coefficient in semiconductors (β) calculated for a two-band model. The resultant nonlinear refractive index (n_2) obtained using a KK transformation of the calculated nondegenerate nonlinear absorption coefficient includes all major mechanisms.

the previous statement is not necessarily true; i.e., a variation in phase does not have to be accompanied by an amplitude modulation.)

In nonlinear optics with the ‘black box’ approach of Fig. 1, the optical perturbation ξ (with frequency Ω) can render an amplitude variation in the probe (at ω) using various frequency mixing schemes in a noncentrosymmetric material (i.e., with nonzero $\chi^{(2)}$). For instance, the probe at ω can be depleted by nonlinear conversion to $\omega_{\text{sum}} = \omega + \Omega$ via sum-frequency generation involving $\chi^{(2)}(\omega, \Omega)$ and/or to $\omega_{\text{diff}} = \omega - \Omega$ via difference-frequency generation involving $\chi^{(2)}(\omega, -\Omega)$. Such a conversion (or depletion) should be accompanied by a phase variation according to the KK dispersion relations. This type of nonlinear phase modulation is known as a $\chi^{(2)}\text{:}\chi^{(2)}$ cascaded nonlinearity. Such cascaded processes are routinely (and more simply) analyzed with Maxwell’s equations governing the propagation of beams in a second-order nonlinear material. The KK relations, however, provide an interesting physical perspective of the process. We find that cascaded second-order nonlinearities are yet another manifestation of causality in nonlinear optics.

Nonlinear Optical Phase Conjugation

BY Zeldovich, University of Central Florida, Orlando, FL, USA

Phase conjugation (PC) beams and their applications are best illustrated by Fig. 1, which shows the passage of a coherent planewave incident upon a transparent optical element with inhomogeneities of refractive index (Fig. 1(a)). Reversibility of light propagation implies the existence of such an 'anti-distorted' beam, which reverts back to a planewave after reversing through the same inhomogeneities (Fig. 1(b)). A real-valued monochromatic optical wave, $E_{\text{real}}(\mathbf{R}, t)$, may be represented by the complex amplitude $E(\mathbf{R})$ via $E_{\text{real}}(\mathbf{R}, t) = 0.5[E(\mathbf{R})\exp(-i\omega t) + E^*(\mathbf{R})\exp(i\omega t)]$, where $E^*(\mathbf{R})$ represents the complex conjugate of $E(\mathbf{R})$:

$$\begin{aligned} E(\mathbf{R}) &= |E(\mathbf{R})|\exp[i\varphi(\mathbf{R})] \\ E^*(\mathbf{R}) &= |E(\mathbf{R})|\exp[-i\varphi(\mathbf{R})] \end{aligned} \quad (1)$$

Mathematical expression of time-reversal, $E_{\text{real}}(\mathbf{R}, t \rightarrow E_{\text{real}}(\mathbf{R}, -t)$, becomes the exchange $E(\mathbf{R}) \leftrightarrow E^*(\mathbf{R})$ for monochromatic waves. The reversibility of propagation means that the complex propagating field $E(\mathbf{R})$ (for example, planewave $\exp(i\mathbf{k} \cdot \mathbf{R})$), is a wave equation solution equivalent to $E^*(\mathbf{R})$ (in this example, $\exp(-i\mathbf{k} \cdot \mathbf{R})$). Conjugation of complex amplitude means reversal of the sign of the phase, and a mixed label PC has been coined and nowadays is firmly established. Terms such as 'wave front reversal' and 'generation of time-reversed replica of the beam' are also used to describe PC.

Fig. 1 also illustrates one of the most important applications of PC. If the element in question is a laser-type amplifier, then double-passage allows the extraction of energy from the optically inhomogeneous laser medium in the form of a perfectly collimated beam of diffraction-limited divergence. A PC device may also serve as a mirror of a laser resonator, resulting in the same beam-correction purpose.

One of the most practical and robust methods of PC is based on stimulated Brillouin back-scattering (SBS). The incident beam illuminates the SBS-active transparent medium, for example, liquids (CS_2 , CCl_4 , acetone, etc.), compressed gases (CH_4 , SF_6 , etc.), or solids (fused or crystalline quartz, glass, etc.). This 'pump' beam, $E(\mathbf{R}) \equiv E(\mathbf{r}, z)$, must possess well-developed transverse inhomogeneities of intensity $|E(\mathbf{r}, z)|^2$. Here, $\mathbf{r} = \{x, y\}$ is the part of coordinate vector transverse with respect to the central direction z of the beam in question, and $\mathbf{R} = \{\mathbf{r}, z\}$. These inhomogeneities may constitute a narrow focal waist in the case of weakly distorted focused beams, speckle-inhomogeneities in cases of strong distortions, or a combination thereof; see Fig. 2, where solid lines symbolize the 'rays' of the incident pump.

Spontaneous scattering of the pump results in a multitude of possible transverse profiles $S(\mathbf{r}, z = 0)$ of the signal, whose 'rays' are depicted via the dotted lines on Fig. 2. The signal is amplified exponentially due to SBS processes. This exponent in a simplified

Fig. 1 (a) Collimated beam is distorted by propagation through inhomogeneous medium. (b) Conjugate, a.k.a. antidistorted beam becomes collimated after backward passage through the same medium.

Fig. 2 Stimulated Brillouin Scattering (SBS) method of PC. Solid lines symbolize the rays of incident 'beam', while dotted lines depict the rays of the signal amplified by the SBS process.

Fig. 3 (a) Recording of a hologram in a photosensitive medium by a reference wave A and signal wave S. (b) Read-out of that hologram by the wave B counter-propagating to A results in generation of the conjugated signal S^* .

form may be represented as $|S(\mathbf{r}, z)|^2 \propto \exp(\int g dz)$, with the gain $g(z)$ being the result of transverse overlapping of the intensity profiles of signal and pump:

$$g(z) \approx \text{const} \cdot \langle |E(\mathbf{r}, z)|^2 \cdot |S(\mathbf{r}, z)|^2 \rangle / \langle |S(\mathbf{r}, z)|^2 \rangle \quad (2)$$

Thus, the similarity of the intensity profile of the signal to that of the pump is rewarded by the exponential preference in the output signal level. However, this is not enough to guarantee that the output backward-scattered signal $S(\mathbf{r}, z)$ is phase conjugate with respect to the pump. It is here that the mutual reversibility of propagation of strongly inhomogeneous signal and pump becomes crucial. Namely, good transverse overlapping is sustained along the entire interaction length z , only if $S(\mathbf{r}, z) \propto E^*(\mathbf{r}, z)$. This constitutes the ‘discrimination mechanism’ of SBS-PC: the ‘conjugate mode’ of the signal has a z -sustained advantage in exponential gain and, under appropriate conditions, suppresses all nonconjugate signal configurations in competition for pump power. Nonlinear-optical wave theory of this discrimination process has been developed further.

The holographic mechanism of PC has a different nature. It may take the form of static holography or dynamic holography; the latter essentially may be considered as a part of nonlinear optics. Here is a simplified description of one of the variants. Suppose one wants to obtain a conjugate replica of the incident monochromatic signal, whose complex profile is $S(\mathbf{R})$. A plane reference wave $A(\mathbf{R}) = \exp(i\mathbf{k}_A \cdot \mathbf{R})$ is also directed to the registering medium. If $S(\mathbf{R})$ and $A(\mathbf{R})$ are mutually coherent, then an interference pattern of intensity is produced $\{S^*(\mathbf{R})A(\mathbf{R}) + \text{compl.conj.}\}$. The medium records this pattern in the form of the modulation of refractive index and/or of the absorption coefficient, $\delta\epsilon(\mathbf{R}) \propto (c_1 + ic_2)\{S^*(\mathbf{R})A(\mathbf{R}) + \text{c.c.}\}$ (Fig. 3(a)). At the ‘reconstruction’ stage, the hologram is illuminated by another plane reference wave, $B(\mathbf{R}) = B_0 \exp(i\mathbf{k}_B \cdot \mathbf{R})$. In the specific case, when $\mathbf{k}_B = -\mathbf{k}_A$, the source δD_{conj} of the reconstructed wave becomes, as shown by Fig. 3(b):

$$\delta D_{\text{conj}} = (c_1 + ic_2)[S^*(\mathbf{R})A(\mathbf{R})] \cdot B(\mathbf{R}) \propto S^*(\mathbf{R})(c_1 + ic_2)A_0B_0 \quad (3)$$

Reversibility of propagation laws guarantees that this source will indeed excite a conjugate wave with high efficiency. Both processes, recording of the interference pattern and reconstruction of the conjugate wave, may occur simultaneously, if one deals with the dynamic holography. The same process may also be described as nonlinear-optical four-wave mixing (FWM) via cubic nonlinearity $\chi^{(3)}$:

$$\delta D_{\text{conj}}(\mathbf{R}) = \chi^{(3)} S^*(\mathbf{R}) A(\mathbf{R}) B(\mathbf{R}) = \chi^{(3)} S^*(\mathbf{R}) A_0 B_0 \quad (4)$$

with the four waves; A, B, S, S^* .

Important characteristics of a PC device are: fidelity of conjugation, efficiency of returning back-reflected power/energy, and reaction time or build-up time. The fidelity parameter must show how close the output of the device $E_{\text{out}}(\mathbf{r})$ is to the perfectly conjugate profile $S^*(\mathbf{R})$ of the incident signal (up to an arbitrary constant complex factor). Among other definitions, the square modulus of the normalized transverse overlapping integral of the fields is often discussed:

$$f = \frac{|\int \int E_{\text{out}}(x, y) S(x, y) dx dy|^2}{(\int \int |E_{\text{out}}(x, y)|^2 dx dy \cdot \int \int |S(x, y)|^2 dx dy)} \quad (5)$$

To achieve good (close to 1) fidelity of PC in the holographic or FWM scheme, one has to guarantee that the reference waves, $A_0 \exp(i\mathbf{k}_A \cdot \mathbf{R})$ and $B_0 \exp(i\mathbf{k}_B \cdot \mathbf{R})$ are exactly conjugate to each other, $\mathbf{k}_A = -\mathbf{k}_B$. That, in turn, requires the absence of any distortions in the holographic or nonlinear medium. To the contrary, there are very modest requirements on the phase inhomogeneities of the medium in the SBS scheme of PC, and for that reason it is usually labeled as a scheme of self-phase conjugation.

Fig. 4 Tail-biting scheme of phase conjugation.

A hybrid scheme, Brillouin-assisted FWM, has been suggested and implemented, where mutually conjugate reference waves are produced via SBS-PC, while FWM, in a separate medium, exploits SBS nonlinearity. This scheme has produced extremely high, up to about 10^{10} , reflectivity, accompanied by an extremely low-noise detection of incoming signals.

A number of other PC schemes were first realized with the use of an important class of materials for nonlinear optics: photo-refractive crystals (PRC). These are crystals where ionization of the dopants by the incident light creates interference pattern of charge separation. The linear electro-optic (Pockels) effect transforms the resulting patterns of the electrostatic field into patterns of refractive index, thus creating dynamic holograms. A remarkable property of these crystals is that most of them act as very good electrical insulators. Therefore, the only source of conductivity, which tends to erase the hologram, is photoconductivity, the value of the latter being proportional to the intensity of incident light itself. For this reason, the steady-state strength of the hologram turns out to be independent of the intensity. It is the build-up time that must be increased, if intensity is low. One can achieve various processes in PRC, including those similar to the $\chi^{(3)}$ -type optical Kerr effect, stimulated scattering, etc.

The simplest use of PRC for generation of PC waves is to devise a FWM scheme (see Fig. 3). However, a multitude of other, nontrivial schemes have been devised and implemented. The most impressive use of PRC for PC is based on interactions of the beams in the vicinity of a corner of a rectangular crystal, typically BaTiO₃, these interactions being of the stimulated scattering type. To honor J. Feinberg's cat, whose image was reconstructed in the first demonstration, this scheme is universally called 'cat conjugator'. It turned out to be a very reliable and robust scheme of self-phase-conjugation (SPC).

Another important group of the SPC scheme is called 'tail-biting'. One of the variants of the latter is shown in Fig. 4. Incident 'pump' wave $A(\mathbf{R})$ whose transverse profile one wants to conjugate, enters the medium, and then is redirected by mirrors back into the same medium, to 'bite itself'. For the purpose of discussion, this redirected pump is labeled as wave $B(\mathbf{R})$ on its second arrival into the medium. Spontaneous scattering results in a seed for the amplification of the wave $C(\mathbf{R})$ via the process of stimulated scattering (SS) $A(\mathbf{R}) \rightarrow C(\mathbf{R})$.

Wave $C(\mathbf{R})$ is also redirected into the medium by the same mirrors, and is labeled as wave $D(\mathbf{R})$ on its second arrival into the medium. Both $C(\mathbf{R})$ and $D(\mathbf{R})$ are depicted in Fig. 4 by white arrows. Wave $D(\mathbf{R})$ is also amplified due to the SS process $B(\mathbf{R}) \rightarrow D(\mathbf{R})$.

As it follows from the macroscopic description of SS process, volume gratings of refractive index are recorded in the medium, $\delta n(\mathbf{R}) \propto -i[A^*(\mathbf{R})C(\mathbf{R}) + B^*(\mathbf{R})D(\mathbf{R})]$. Among all the transverse profiles for the seed $C(\mathbf{R})$ the one that happens to be proportional to $B^*(\mathbf{R})$ will be reflected by the mirrors into the medium in the form $D(\mathbf{R}) \propto A^*(\mathbf{R})$. The latter case is again a consequence of the reversibility of propagation laws, where both gratings have the same profile and add coherently in the form $A^*(\mathbf{R})B^*(\mathbf{R})$. What is even more important, the grating $B^*(\mathbf{R})D(\mathbf{R}) \propto B^*(\mathbf{R})A^*(\mathbf{R})$ serves to close the feedback loop for seeding the appropriate $C(\mathbf{R})$. This, and other variants of tail-biting schemes, have also proved to be reliable and robust. Quite often a laser amplifier is inserted in the path $A \rightarrow B$ and $C \rightarrow D$, thus enhancing the feedback.

Another important scheme is traditionally called 'double PC'; albeit it may be better described as 'mutual PC'. Fig. 5 should help in understanding that scheme. Consider the beam $A(\mathbf{R})$ incident to a medium active with respect to the stimulated-scattering-type process $A(\mathbf{R}) \rightarrow C(\mathbf{R})$. This process originates from a random seed and results in a fan of different waves $C(\mathbf{R})$. Such a process is characteristic of PRCs and is a consequence of recording dynamic gratings of refractive index $\delta n(\mathbf{R}) \propto -i[A^*(\mathbf{R})C(\mathbf{R})]$. Suppose another beam $B(\mathbf{R})$, typically incoherent with respect to $A(\mathbf{R})$, illuminates the medium from the other side, and also is engaged in the fanning process, this time $B(\mathbf{R}) \rightarrow D(\mathbf{R})$, with the grating of refractive index $\delta n(\mathbf{R}) \propto -i[B^*(\mathbf{R})D(\mathbf{R})]$ involved. Among all the

Fig. 5 Towards the mechanism of double PC (mutual PC).

transverse profiles for the seed grating $C(R)A^*(R)$, the one that happens to be proportional to $B^*(R)A^*(R)$ will be supported by similar profiles in the $B(R) \rightarrow D(R)$ scattering. In this way, two fanning processes enhance each other and close the feedback loop. An important consequence is that one obtains the following output waves:

$$\begin{aligned} C(R) &= \text{const}_1 \times B^*(R) \\ D(R) &= \text{const}_2 \times A^*(R) \end{aligned} \quad (6)$$

One can say that the output wave $C(R)$ presents a conjugate replica of $B(R)$ -beam, while the output wave $D(R)$ presents a conjugate replica of $A(R)$ -beam; hence the label 'mutual PC'. In some experiments the incident beams, $A(R)$ and $B(R)$, were of somewhat different colors (i.e., from different lasers), or their pulses did not overlap in time in the medium. It is the grating memory that 'informs' one beam about the presence of the other. The mechanism of cat conjugator is considered to be a combination of tail-biting and double PC schemes.

Pumped laser material with saturable gain often serves as an important nonlinear-optical medium for implementing PC. One of the evident advantages is that possible low efficiency of properly nonlinear process may be compensated by the gain in the same piece of material.

Considerable attention is paid nowadays to the chirp reversal of optical pulses that are used in fiber optical communications. Such chirped pulses, $S(t) = \exp(-i\omega_0 t + i\beta t^2/2 - t^2/\tau_1^2)$, with the value of the 'chirp' $d\omega/dt = -\beta$ and an increased pulse duration τ_1 , arise as a result of propagation in a fiber which possesses group velocity dispersion (GVD). Pulse stretching and chirp are the consequences of different propagation times for the different frequency constituents of the pulse. If some device changes the sign of that chirp, then subsequent propagation of the pulse, through a piece of fiber with the same GVD, restores the duration of the pulse to original shorter value τ_0 . A scheme has been suggested to use nonlinear optical FWM in a $\chi^{(3)}$ -medium or three-wave mixing (ThWM) in a $\chi^{(2)}$ -medium:

$$\begin{aligned} \delta D_{\text{conj}}(t) &= \chi^{(3)} S^*(t) A(t) B(t) \\ \delta D_{\text{conj}}(t) &= \chi^{(3)} S^*(t) C(t) \end{aligned} \quad (7)$$

Indeed, complex conjugation of the time dependence of the signal's field is equivalent to the change of the chirp sign. The second (ThWM) expression is written assuming that the reference wave $C(t) \propto \exp(-2i\omega_0 t)$, so that it has the frequency double that of the signal. The same process of ThWM has been shown to yield the conjugation of transverse phase profile of the beams, but for a number of reasons it was not applied.

As for the applications of PC, one of them was discussed above (Fig. 1: double-pass scheme of a laser amplifier). Lasers with one or two PC mirrors, or with more complicated PC scheme, promise generation of high-transverse-quality beams with the use of realistic laser media, the latter inevitably possessing thermal and other distorting inhomogeneities. Another important potential application is free-space optical communications: Earth–Earth or Earth–satellite through atmosphere, or satellite–satellite communications. An 'interrogating' beam may be sent in one direction through an imperfect optical system and/or through turbulent atmosphere. Conjugation of transverse profile of the 'interrogating' beam at the other end of the communication link leads to an almost perfect redirection of the reflected beam towards the 'beacon' source, while time modulation may carry the information.

Readout of information data from a holographic storage is almost always performed in the regime of reading the conjugate wave, since it corrects for the most part of aberrations of optical systems in question.

To conclude, one may use a citation from the two consecutive *Scientific American* popular papers on PC: 'at present the number of applications would seem to be limited only by imagination.'

Reviews of various aspects of phase conjugation may be found in monographs and *Scientific American* papers listed below. The author of the present article was introduced to PC by his colleague V. V. Ragulskii, and has greatly benefited from collaboration with V. V. Ragulskii and V. V. Shkunov.

Introduction and Basics of the Photorefractive Effect

In 1966 Ashkin and coworkers were pursuing research on optical devices using the electro-optic material lithium niobate. They noticed that the refractive index of lithium niobate would change when it was exposed to laser light, and upset the expected operation of their devices. They called the effect optical damage. Shortly thereafter, Chen, LaMacchia, and Fraser reported on the use of the optical damage effect for holographic data storage. Thus began the field of photorefractive nonlinear optics, which has been used in various applications such as real-time holography, optical data storage, optical image amplification, nondestructive testing, distortion compensation by phase conjugation, pattern recognition, and radar signal processing. Many inorganic and organic materials have been investigated for their photorefractive effects, including ferroelectrics, semiconductors, and sensitized polymers. The most well-known inorganic materials are lithium niobate, bismuth silicon oxide, barium titanate, and strontium barium niobate. Most organic photorefractive materials are based on polymeric photoconductors such as those used in xerography that are doped with electro-active molecules, some plasticizers, and sensitizers.

While in its broadest interpretation, the photorefractive effect occurs whenever light incident on a material causes a refractive index change, one usually applies the term to electro-optic index changes resulting from optically generated space charge fields. Materials that are photorefractive in this sense share the following properties

- high transmission at the operating wavelengths;
- linear electro-optic coefficients or orientational Kerr effects;
- charge carriers that become mobile when optically excited;
- trapping centers for these charge carriers to enable spatially non-uniform redistribution of charge.

Consider two beams from the same laser crossing inside a photorefractive material such as barium titanate. The interference pattern will have bright and dark fringes. Charge carriers are excited where the light is bright, then drift and diffuse to regions of relative darkness where they preferentially recombine into trapping centers. In this way, a net excess charge develops in the dark regions, and a net deficit of charge develops in the bright regions. The spatially varying charge distribution has an electric field associated with it and this electric field causes a spatially varying refractive index profile. Because the space charge, its field, and resulting refractive index have the same spatial periodicity as the original interference pattern we have a holographic phase grating. The diffraction efficiency of the hologram can easily approach 100% for materials such as barium titanate and strontium barium niobate which have high electro-optic coefficients. Likewise, such high diffraction efficiencies are easily obtained in 100 micrometer-thick photorefractive polymer films.

The Standard Rate Equation Model

The development of photorefractive gratings can be modeled using standard semiconductor rate equations. Fig. 1 shows two beams incident symmetrically on a photorefractive crystal or polymer. They form an interference pattern whose intensity may be written:

$$I(x) = I_0(1 + m \cos(k_g x)) \quad (1)$$

Fig. 1 Diagram of two-beam coupling process showing optical interference pattern, space charge, resultant electric field, and $\pi/2$ phase shifted electro-optically induced refractive index grating.

where x is the direction perpendicular to the interference fringes, I_0 is the average intensity, m is the modulation index, and k_g is the wavenumber of the interference pattern.

The crystal may be considered a wide bandgap semiconductor containing electron donors in the bandgap with density N_D and electron acceptors with density N_A . It is assumed that some electrons ionized from the donors permanently occupy these acceptors so that when charge in the crystal is distributed uniformly in the dark, the number density of ionized donors N_D^i is equal to N_A . Likewise, polymers contain donor and acceptor-like molecules that can be neutral or ionized. The spatially varying light distribution ionizes the donors at the following rate, assuming that $N_D^i \ll N_D$:

$$\frac{\partial N_D^i}{\partial t} = s I N_D - \gamma_R n_e N_D^i \quad (2)$$

where s is a photoionization coefficient, γ_R is a recombination parameter, and n_e is the density of excited charge carriers, which we assume here to be electrons. The model can easily be generalized to include holes. We also use the equation of charge conservation:

$$\frac{\partial N_D^i}{\partial t} = \frac{\partial n_e}{\partial t} - \frac{1}{e} \nabla \cdot \mathbf{j} \quad (3)$$

where e is the charge of an electron, and $\mathbf{j}$ is the current in the conduction band.

$$\mathbf{j} = \mu e n_e \mathbf{E} + k_B T \mu \nabla n_e \quad (4)$$

where μ is the electron mobility, k_B is Boltzmann's constant, and T is the temperature. The electric field obeys Gauss's law:

$$\nabla \cdot \mathbf{E} = -e(n_e + N_A - N_D^i)/\epsilon \quad (5)$$

where N_A is the density of acceptors. These equations may be linearized by approximating the electron density, ionized donor density, and electric field with their first Fourier components:

$$\begin{aligned} E &= E_0 + \frac{1}{2} (E_1 \exp(ik_g x) + E_1^* \exp(-ik_g x)) \\ N_D^i &= N_{D0}^i + \frac{1}{2} (N_{D1}^i \exp(ik_g x) + N_{D1}^{i*} \exp(-ik_g x)) \\ n_e &= n_{e0} + \frac{1}{2} (n_{e1} \exp(ik_g x) + n_{e1}^* \exp(-ik_g x)) \end{aligned} \quad (6)$$

This assumption is strictly valid only when the modulation index m is much less than unity. Otherwise, a generalization to higher orders in the Fourier series is required. However, the linearized theory is sufficient to illustrate the most important features of the photorefractive effect. The solution for the space charge field E_1 for the case when the interference pattern is applied at time $t=0$ is

$$E_1 = m \frac{-iE_Q(E_0 + iE_D)}{E_0 + i(E_D + E_Q)} (1 - \exp(-t/\tau)) \quad (7)$$

where E_0 is an externally applied or photovoltaic field (if any), E_D is the diffusion field

$$E_D = \frac{k_B T k_g}{e} \quad (8)$$

and E_Q is the limiting space charge field

$$E_Q = \frac{eN_A}{\epsilon k_g} \quad (9)$$

Some photorefractive crystals, most notably LiNbO_3 , exhibit the photovoltaic effect in which optical illumination induces a dc field across the crystal.

The sinusoidally varying space charge field E_1 operates through the linear electro-optic effect with effective coefficient r to produce a sinusoidal variation in the refractive index n of the crystal:

$$n(x) = n_0 + \frac{1}{2} (n_1 \exp(ik_g x) + n_1^* \exp(-ik_g x)) \quad (10)$$

where

$$n_1 = -\frac{1}{2} r n_0^3 E_1 \quad (11)$$

The effective electro-optic coefficient r may be found from tensor analysis of the electro-optic tensor and the vector space charge and optical fields. Notice that there is a 90-degree phase shift between the interference pattern and the refractive index grating when E_0 is zero. The time constant τ is given by

$$\tau = \frac{N_A}{sN_D I_0} \frac{E_0 + i(E_D + E_\mu)}{E_0 + i(E_D + E_Q)} \quad (12)$$

where E_μ is a mobility field

$$E_\mu = \frac{\gamma_R N_A}{\mu k_g} \quad (13)$$

When E_0 is nonzero, there is an oscillatory component to the time constant.

In contrast to the case of ordinary optical nonlinearities such as the optical Kerr effect, in which the nonlinear coupling strength is proportional to the optical intensity, the steady state strength of the photorefractive effect is independent of optical intensity while the time constant is inversely proportional to intensity in the basic model described above. The time constant varies with the photoconducting performance of a given material. In the fastest polymeric and inorganic materials it is, at the time of writing, of the order of a few milliseconds at 1 W cm^{-2} of incident optical intensity.

At low intensities (below the equivalent dark intensity, 1 W cm^{-2} in barium titanate), the above equations need to be modified to include the effect of dark conductivity. Even in the dark, there will be a few mobile charge carriers in the conduction band that tend to erase the grating. This will result in the effect appearing more Kerr-like, except still with the 90-degree phase shift between the index grating and the interference pattern.

Coupled Wave Equations

The change in refractive index n_1 can be large enough to produce substantial interactions between the writing beams. The writing beams generate a phase grating that diffracts the beams into each other. The grating influences the writing beams, which in turn influence the grating. In the cases where the diffusion field dominates, for example when the externally applied or photovoltaic field E_0 is absent, one beam is amplified by in-phase diffraction of the other beam from the grating. As shown in Fig. 2, this amplification results from a 90-degree phase shift due to diffraction from a phase grating coupled with a -90 -degree phase shift from the spatial phase shift between the interference pattern and the index grating. The second beam is attenuated by destructive

Fig. 2 Two-beam coupling amplification. Beam 1 is amplified by constructive interference. Beam 2 is de-amplified by destructive interference.

interference with the first beam diffracted by the grating. These interactions can be modeled by standard coupled wave theory. Let the electric field amplitude associated with the j th beam be

$$E_j(\mathbf{r}, t) = \mathbf{e}[A_j(\mathbf{r})\exp(i(\mathbf{k}_j \cdot \mathbf{r} - \omega t)) + A_j^*\exp(-i(\mathbf{k}_j \cdot \mathbf{r} - \omega t))] \quad (14)$$

where $\mathbf{e}$ is the polarization unit vector. Using the scalar wave equation

$$\nabla^2 E + k^2 E = 0 \quad (15)$$

and the slowly varying envelope approximation

$$\frac{d^2 A_j}{dz^2} \ll k \frac{dA_j}{dz} \quad (16)$$

we find

$$\begin{aligned} \frac{dA_1}{dz} &= +\gamma \frac{A_1 |A_2|^2}{I_0} \\ \frac{dA_2^*}{dz} &= -\gamma \frac{A_2^* |A_1|^2}{I_0} \end{aligned} \quad (17)$$

with the coupling constant γ given by

$$\gamma = -\frac{i\omega\Delta n_m}{c \cos\vartheta} \quad (18)$$

where ϑ is the half-angle between the writing beams and Δn_m is given by

$$\Delta n_m = -\frac{1}{2}n_0^3 r \frac{E_1}{m} \quad (19)$$

Eq. (17) shows that beam 1 is amplified and beam 2 is attenuated. That beam 1 is amplified instead of beam 2 is a result of the choice of crystal orientation and hence the sign of γ . These nonlinear equations can be solved for normalized intensity $I_j = |A_j|^2$:

$$\begin{aligned} I_1(z) &= \frac{I_0}{1 + (I_2(0)/I_1(0))\exp(+\Gamma z)} \\ I_2(z) &= \frac{I_0}{1 + (I_1(0)/I_2(0))\exp(-\Gamma z)} \end{aligned} \quad (20)$$

where $\Gamma = \gamma + \gamma^*$ is the intensity coupling constant. In the limit where $I_1 \ll I_2$, the weak beam, beam 1, experiences exponential amplification. This amplification can be used to build optical oscillators with many of the same properties as conventional laser oscillators. The solution can be generalized to the case where γ has an imaginary component due to an applied or photovoltaic field E_0 . Linear absorption can also be included.

Materials

Photorefractive materials may be separated into two broad classes: inorganic and organic. The first materials investigated were inorganic oxides and semiconductors. Their success led to efforts to endow more easily produced organic materials with the required photoconductivity, charge trapping centers, and electro-optic coefficients.

Inorganic Materials

The first requirement in a classic photorefractive material is a linear electro-optic coefficient, such as appears in sillenites such as bismuth silicon oxide $\text{Bi}_{12}\text{SiO}_{20}$ and bismuth germanium oxide $\text{Bi}_{12}\text{GeO}_{20}$. These were some of the first photorefractive materials used for image processing and phase conjugation applications. However, their electro-optic coefficients (a few pm/V) are not large enough to easily give rise to large diffraction efficiencies, or to photorefractive oscillators. Materials at a temperature near a phase transition generally have higher electro-optic coefficients because their crystal structures are on the verge of changing. They are extremely susceptible to the effect of any external influence such as the application of electric fields including photorefractive space charge fields. That is why ferroelectric materials are good candidates for photorefractive materials. These include barium titanate BaTiO_3 , potassium niobate KNbO_3 , and strontium barium niobate $\text{Sr}_x\text{Ba}_{1-x}\text{Nb}_2\text{O}_6$. The mean free path of charge transport is less than that in sillenites, so they require more photons to reach a steady state. Therefore, ferroelectric materials are typically less sensitive than sillenites.

The second requirement is for photoconductivity. This requires the existence of photoexcitable charge carriers, either from valence band to conduction band or from intraband trapping centers. The latter source of photocarriers is used most often because the absorption length of light whose energy is greater than the bandgap is usually only a few micrometers. This places a severe restriction on the beams' interaction length ℓ . Thus there has been considerable research on suitable dopants, most commonly Fe^{2+} and Fe^{3+} . These dopants also act as trapping centers.

Lithium niobate is an example of a material with a large photovoltaic effect. When illuminated, this crystal develops a large dc field, which acts to enhance the grating strength. In those cases where the photorefractive effect is not wanted, such as in the design of lithium niobate waveguide devices, the photovoltaic effect can be greatly diminished by the addition of MgO to the crystal melt during growth.

For photorefractivity in the near infrared, semiconductors such as gallium arsenide and indium phosphide have been used with success. These materials also have the advantage that they can be grown in layered structures to produce, for example, multiple quantum wells that can be used to tailor the characteristics of optical excitation and charge transport.

Organic Materials

First-generation photorefractive polymers were designed to mimic the properties of their inorganic counterparts. Owing to their rich structural flexibility, organic synthetic materials with suitable charge transport, trapping, linear electro-optic effects and low optical absorption, were developed. This approach did build on the know-how developed previously in making photoconducting polymers for xerography and electro-optic polymers for optical modulation. Current polymers are based on an orientational photorefractive effect that leads to higher refractive index changes compared with traditional photorefractive materials. In materials with orientational photorefractivity, the refractive index change is produced by the field induced reorientation of anisotropic conjugated molecules that possess a permanent dipole moment and that have a high polarizability anisotropy. The photorefractive space charge field together with the applied field will periodically reorient these molecules and produce a periodic refractive index modulation through an orientational Kerr effect. The build-up and dynamics of this space-charge field are similar to those of traditional photorefractive crystals and can be described by Eqs. (2)–(7). The time constant of the hologram is a convolution of the build-up time of the space-charge and the orientational diffusion time of the dipolar molecules in the total electric field. In contrast to crystals, polymers are nearly amorphous and the transport properties are described by charge hopping processes instead of band-type transport in crystals. Consequently, the photoconducting properties of polymers are strongly field dependent and photorefractivity is mainly observed under strong applied voltages. Numerous polymer composites have been developed using the hole transport polymer poly(N-vinylcarbazole). Several materials with a refractive index modulation amplitude of the order of a percent and two-beam coupling constants $\gamma > 100 \text{ cm}^{-1}$ have been reported. New polymer composites are continuously being tested. Photorefractivity is also studied in other organic materials including organic crystals, liquid crystals, nanocomposites such as polymer-dispersed liquid crystals, or hybrid materials such as sol-gels.

Applications

Holographic Data Storage

Holographic data storage takes advantage of the Bragg selectivity of thick gratings. This allows many holograms to be superimposed in the same small volume, typically of the order of one cubic centimeter. A page of data is displayed on a spatial light modulator and a laser beam passing through the modulator is holographically recorded in the crystal with a reference beam at a specific angle. Many pages of data can be superimposed by recording many holograms with angularly multiplexed reference beams. Other multiplexing schemes are implemented by changing the shape of the wavefront of the reference beam. In principle, the upper limit of recording density is determined by the wavelength of light: one bit per cubic wavelength. If the recording wavelength is $0.5 \text{ }\mu\text{m}$, then one cubic centimeter can contain 1000 gigabytes of data. In practical circumstances, when noise is taken into consideration, the capacity is more realistically of the order of one gigabyte if a 1000×1000 spatial light modulator is used.

Distortion Compensation by Phase Conjugation

Photorefractive materials can be used to make high-reflectivity phase conjugate mirrors. The phase conjugate of a laser beam is produced when a hologram of the beam is read by another beam traveling in the opposite direction to the original reference beam. The phase conjugate reconstruction is a time-reversed copy of the original beam. If the original beam has passed through distorting optics, then the phase conjugate beam will retrace the path of the original beam through the distortion and emerge in its undistorted original state. In the standard nomenclature of phase conjugation, the input beam is called the signal, or probe, and the two reference beams are called the pumps. The output beam at $z=0$ is called the phase conjugate beam and has zero amplitude at its input at $z=\ell$, where ℓ is the interaction length. Applications for phase conjugation exist, for example, in signal transmission through distortions and laser cavity design. If a phase conjugate mirror is used as a cavity mirror, then the effects of intracavity distortions are removed.

Since the photorefractive gratings can be very strong, the diffraction efficiency of the counterpropagating reference beam can be so high that the phase conjugate reflectivity can exceed unity. The simplest generalization of Eq. (17) to the four-wave mixing phase conjugation case is when only transmission gratings are important, as occurs in many circumstances depending on the mutual

coherence properties of the beams, and the material's properties. The coupled wave equations are

$$\begin{aligned}\frac{dA_1}{dz} &= \gamma \frac{(A_1A_4^* + A_2^*A_3)A_4}{I_0} \\ \frac{dA_2^*}{dz} &= \gamma \frac{(A_1A_4^* + A_2^*A_3)A_3^*}{I_0} \\ \frac{dA_3}{dz} &= -\gamma \frac{(A_1A_4^* + A_2^*A_3)A_2}{I_0} \\ \frac{dA_4^*}{dz} &= -\gamma \frac{(A_1A_4^* + A_2^*A_3)A_1^*}{I_0}\end{aligned}\quad (21)$$

In the undepleted pumps approximation, $(I_1, I_2 \gg I_3, I_4)$, the equations become linear and the solution for phase conjugate reflectivity $R = I_3(0)/I_4(0)$ is

$$R = \frac{\sinh[\gamma\ell/2]}{\cosh[(\gamma\ell + \ln r)/2]^2} \quad (22)$$

where $r = I_2/I_1$ is the ratio between the intensities of the pumping beams.

The fact that the reflectivity of the phase conjugate mirror can be greater than unity means that we can build an optical oscillator bounded by a regular mirror and a phase conjugate mirror only. Not only does it not require any additional optical gain, but it also compensates for intracavity distortions. The regular mirror can have any shape, provided that it is sufficiently reflective.

Self-pumped Phase Conjugate Mirrors

If a laser beam passes through a crystal placed inside an optical cavity formed by two facing mirrors, light scattered by imperfections in the crystal can be amplified through the photorefractive effect. The cavity provides feedback and optical oscillation can build up. The oscillation beams pump the crystal as a phase conjugate mirror for the incident beam, thus forming a self-pumped phase conjugate mirror. The feedback can even be provided by total internal reflection in the crystal in which case the crystal by itself can become a phase conjugate mirror.

Pattern Recognition and Image Filtering

Photorefractive wave mixing can be used to perform pattern recognition by matched filtering. One example would be to identify a tank in a battlefield scene, another would be to identify all of the occurrences of a particular word on a page of text. Suppose the input beams contain the corresponding pictorial information, such as might be obtained by passing the beams through an image-bearing transparency or spatial light modulator. Eq. (21) shows that the source for beam 3 contains a term proportional to the product of the amplitudes of the three input beams. If lenses are placed in the input beams so that the crystal receives the Fourier transforms of those beams, then the output beam at the crystal, beam 3, will be proportional to the product of the Fourier transforms of the input beams 1, 2, and 4. A lens may then be used to perform the inverse Fourier transform of the product of the Fourier transforms of the input beams, producing an output proportional to beam 1 convolved with beam 2 correlated with beam 4. If beam 1 is a point source before its Fourier transforming lens, then it will be a plane wave at the crystal. Beam 3 after inverse Fourier transformation by its lens will be the correlation of beams 4 and 2. For example, suppose we want to find all the occurrences of a particular word, say 'optics' in a given page of text. Then we would make a transparency of the word 'optics' and place that in input beam 4. We would then place an image of the page of text in beam 2. Beam 3 would then contain a field with bright spots at the places containing the word 'optics' in the original text.

The real-time holographic recording properties of photorefractive materials can also be exploited in medical imaging applications by performing time-gated holography. In this method, a hologram is formed by the temporal overlap in the photorefractive sample of a reference pulse and the first-arriving (ballistic photons) light from a stretched image-bearing pulse that has propagated through a scattering medium. The filtering of the useful photons from the scattered ones is achieved by reconstructing the hologram formed with the ballistic photons in a four-wave mixing geometry.

Optical Limiting, the Novelty Filter, and Laser Ultrasonic Inspection

The attenuation of beam 2 in Eq. (17) can be used in several applications including optical limiting and novelty filtering. If one wants to protect a sensor from high-intensity laser radiation, then one could split a small portion of the input beam directed at the sensor and use it as beam 1 in a photorefractive recording setup with the input beam acting as beam 2. If the laser intensity is above the equivalent dark intensity such that the optically excited charge density is greater than the thermally excited charge density, the photorefractive effect will be activated and the input beam will be de-amplified by destructive interference with beam 1, thus protecting the sensor. In materials with high gain-length products ($\gamma\ell > 1$), separate provision of beam 1 is unnecessary

Fig. 3 Photorefractive barium titanate exhibiting amplified scattering. A helium neon laser beam is incident from the lower left, passes through the crystal to a screen where it is blacked out to prevent saturation of the camera. The screen shows brushes of amplified scattering, or fanning.

because light scattered from the input beam by imperfections in the material and other scattering centers will be greatly amplified, often to such an extent that the input beam is almost completely attenuated. This photorefractive amplification of scattered radiation is known as the fanning effect, because the amplified scattered light often appears as a fan, or brush of light, as can be seen in Fig. 3. The effect can also be used to make a novelty filter, which transmits only the moving portion of a scene. The crystal is only fast enough to respond to the slowly changing or static components of an image-bearing beam. Since the grating formed is Bragg-matched only to the slow component, the grating will only attenuate that slow component. Any rapidly changing parts of a scene pass through the crystal unattenuated. Such a filter is useful for picking out moving objects in a static cluttered background, for example a tank on a battlefield, or a micro-organism swimming against a stationary background.

A related application is in laser ultrasonic inspection. Defects in industrial material processing such as welding have characteristic ultrasonic signatures. The part under test is pinged by a pulsed laser and a probe laser is reflected from the part. As the part is shaken by the ultrasound, speckle in the reflected beam vibrates. A photorefractive recording is made of the speckle beam. Electrodes are placed on the photorefractive material, so that any optically induced currents can be detected. If the speckle pattern is not moving, or is moving more slowly than the speed of response of the photorefractive material, the photorefractive grating will be essentially at steady state: the drift currents balance the diffusion currents so there is no net current. There is no signal as the part moves through the process line. However, if the speckle beam is moving faster than the response time of the material, it will move photoexcited charge back and forth past the quasistatic grating and generate a net current for detection via the electrodes.

Adaptive Signal Processing

The relatively slow speed of photorefractive devices can be used to advantage in radio-frequency (RF) signal processing, such as signal extraction and coherent combination of signals from antenna arrays. The signal extraction application depends on grating competition in two-beam coupling. Suppose we wish to separate signals on two different RF carrier frequencies ω_1 and ω_2 , respectively. The combined signal is applied to an optical carrier beam using a high-speed modulator. The resulting optical field may be represented as

$$S_1(t)\exp(i\omega_1 t) + S_2(t)\exp(i\omega_2 t) \quad (23)$$

It is used to pump a unidirectional ring resonator so that grating competition allows oscillation only on the strongest component of the combined signal, say S_1 . The output of the oscillator is proportional to the extracted component S_1 . The effectiveness of the intersignal competition is enhanced by placing another photorefractive material in the cavity. A portion of the intracavity beam is picked off by a beamsplitter and used as a two-beam coupling pump in the second material. The crystal is oriented so that the photorefractive grating diffracts the picked-off beam back into the cavity. The return of the picked-off component is most effective for the stronger component S_1 thus decreasing its loss compared to that of the weaker component S_2 . This beamsplitter/crystal combination is known as a reflexive coupler.

Photorefractive Solitons

Under favorable conditions, a single beam incident on a photorefractive crystal will induce a positive refractive index change at the center of the beam. This provides a self-focussing tendency that counteracts the beam's divergence due to diffraction. When these two effects balance each other, the beam can propagate with a constant diameter. Such a beam is known as a spatial soliton in

analogy with temporal solitons in optical fibers and can occur when there is a component of the photorefractive response due to drift. The drift component of the photorefractive effect appears when a dc field E_0 is applied to the material. Potential applications are optically written waveguides and couplers.

Introduction

The tremendous development of high-powered femtosecond laser systems since the 1980s, has opened up new areas of research in nonlinear optics, plasma physics, atomic and molecular dynamics, and intense-field physics. For many of these applications, it is important to understand how ultrashort light pulses propagate through a medium under conditions in one or more of the processes in which nonlinear optics play an important role.

The starting point for the modeling of light propagation under these conditions is Maxwell's wave equation for the electric field $E(\mathbf{r}, t)$ which is given in Gaussian units as

$$\nabla^2 E - \frac{\partial^2 E}{\partial t^2} = 4\pi \frac{\partial^2 P}{\partial t^2} \quad (1)$$

where the $P(\mathbf{r}, t)$ is the polarization inside the medium. Typically, the polarization is separated into a term P_l that depends linearly on the field E and into a term P_{nl} that depends nonlinearly on the applied field. The Fourier transform of the linear polarization can be expressed as $\tilde{P}_l(\mathbf{r}, \omega) = \chi^{(1)}(\omega) \tilde{E}(\mathbf{r}, \omega)$, where $\tilde{E}(\mathbf{r}, \omega)$ is the Fourier transform of electric field $E(\mathbf{r}, t)$. For the laser-matter interactions that we consider here, we assume that the linear susceptibility $\chi^{(1)}(\omega)$ is real, in which case the wave equation can be expressed as

$$\nabla^2 \tilde{E} + \left[\frac{n_l(\omega)\omega}{c} \right]^2 \tilde{E} = -\frac{4\pi\omega^2}{c^2} \tilde{P}_{nl} \quad (2)$$

where $n_l(\omega) = \sqrt{1 + 4\pi\chi^{(1)}(\omega)}$ is the frequency-dependent linear refractive index of the medium.

For light pulses that are longer than an optical period, the envelope description is valid and the electric field can be described by an amplitude envelope $A(\mathbf{r}, t)$ and a carrier frequency ω_0 such that

$$E(\mathbf{r}, t) = A(\mathbf{r}, t) e^{i(k_0 z - \omega_0 t)} + c.c. \quad (3)$$

where $k_0 = k(\omega_0) = n_0 \omega_0 / c$ is the wavevector amplitude and $n_0 = n_l(\omega_0)$. This envelope description is advantageous for performing analytical and numerical studies of pulse propagation. However, for sufficiently short laser pulses, where the shape of the envelope function does not depend on the carrier phase of the carrier wave, such a description is no longer applicable. Nevertheless the envelope description can be made valid for pulses that are nearly as short as a single cycle or, alternatively, that have spectral bandwidths that are comparable to the central frequency ω_0 . To derive an equation for the spatio-temporal evolution of the pulse envelope, the relation for the electric field is substituted into the wave equation (Eq. (2)) and the following two approximations are made: i) $k_0 \partial A / \partial z \ll \partial^2 A / \partial z^2$, which signifies that the envelope varies slowly in space over a distance compared to the central wavelength; ii) $v_{ph} \sim v_{gr}$ where $v_{ph} = c/n_0$ is the phase velocity and $v_{gr} = (dk/d\omega)^{-1}$ is the group velocity. This latter approximation is invariably well satisfied when the frequencies contained in the laser field are highly nonresonant with any transition frequencies of the medium.

For an input pulse at $z=0$ with a peak amplitude A_0 , and characteristic widths in space and time given by w_0 and τ_p , respectively, the equation for the normalized amplitude $u(r_\perp, z, t) = A(r_\perp, z, t) / A_0$ can be expressed as

$$\frac{\partial u}{\partial \xi} = \frac{i}{4} \left(1 + \frac{i}{\omega_0 \tau_p} \frac{\partial}{\partial \tau} \right)^{-1} \nabla_\perp^2 u - i \sum_{n=2} \frac{L_{ds}}{n! L_{ds}^{(n)}} \frac{\partial^n u}{\partial \tau^n} + i \left(1 + \frac{i}{\omega_0 \tau_p} \frac{\partial}{\partial \tau} \right) p^{nl} \quad (4)$$

where $\tau = (t - z/v_g) / \tau_p$ is the normalized retarded time for the pulse traveling at the group velocity v_g , $L_{ds}^{(n)} = \tau_p^n / \beta_n$ is the n th-order dispersion length, $\beta_n (n \geq 2)$ is the n th-order dispersion constant, $L_{ds} = |L_{ds}^{(2)}|$ is the dispersion length, $\zeta = z / L_{df}$ is the normalized distance, $L_{df} = k w_0^2 / 2$ is the diffraction length, p_{nl} is the normalized nonlinear polarization, and $\nabla_\perp^2$ is the transverse Laplacian. The presence of the operator $(1 + i\partial/\omega_0 \partial\tau)$ in the diffraction term ($\nabla_\perp^2 u$) of Eq. (4) leads to space-time focusing, while its presence in the nonlinear term results in self-steepening and both these terms arise from not making the slowly varying envelope approximation in time (i.e., $k_0 \partial A / \partial t \ll \partial^2 A / \partial t^2$) in deriving Eq. (4). For a self-consistent analysis of pulse propagation in the nonlinear regime, both the effects of space-time focusing and self-steepening must be included.

Nonlinear Refractive Index

For an isotropic medium in the highly nonresonant limit, the third-order term is the lowest-order contribution to the nonlinear susceptibility. This term gives rise to the nonlinear refractive index, that is, the index of refraction depends on the local intensity of

the laser field. For many materials there are two contributions to the nonlinear refractive index: i) an instantaneous part that arises from the electronic response of the medium; and ii) a noninstantaneous contribution due to the nuclear motion of the molecules (i.e., the Raman contribution). For such a medium, the nonlinear polarization may be expressed as

$$p_{\text{nl}}(\zeta, \tau) = \frac{L_{\text{ds}}}{L_{\text{nl}}} \left[(1-f)|u(\zeta, \tau)|^2 + f\gamma_R \int_{-\infty}^{\tau} d\tau' R(\tau - \tau') |u(\zeta, \tau')|^2 \right] u(\zeta, \tau) \quad (5)$$

where $L_{\text{nl}} = (c/\omega_0 n_2 I_0)$ is the nonlinear length, $I_0 = n_0 c |A_0|^2 / 2\pi$ is the peak input intensity, f is the fraction of the Raman contribution to the nonlinear refractive index, and $R(\tau) = \{ [1 + (\Omega_R \tau_R)^2] / \Omega_R \tau_R \} \exp(-\tau/\tau_R) \sin(\Omega_R \tau)$ is the Raman response function, τ_R is the characteristic Raman response time, Ω_R is the characteristic Raman frequency, and $\gamma_R = \tau_p / \tau_R$. For example, for fused silica $f=0.15$, $\tau_R = 50$ fs, and $\Omega_R \tau_R = 4.2$. For a noble gas such as Xe, there is no Raman contribution and $f=0$.

Self Focusing, Supercontinuum Generation, and Filamentation

The presence of the nonlinear refractive index with $n_2 > 0$ can lead to self-focusing of a laser beam. For sufficiently long pulses such that dispersion, self-steepening, and space-time focusing effects can be neglected, it is found that laser beams with input powers greater than the critical power $P_{\text{cr}} = \alpha \lambda^2 / 4\pi n_0 n_2$ will undergo catastrophic self-focusing collapse. The dimensionless parameter $\alpha \geq 1.86$ depends on the spatial profile of the input beam and for a Gaussian input beam is given by $\alpha = 1.9$, in which case the ratio of the input power P to the critical power satisfies the relation $P/P_{\text{cr}} = 1.055 L_{\text{df}} / L_{\text{nl}}$. Extensive studies have been made on the dynamics of laser beams undergoing self-focusing. For example, it has been shown that the shape of the collapsing beam evolves to a radially symmetric profile as it approaches the collapse point and that the total power contained in the collapsing portion always corresponds to the minimum value (i.e., $\alpha \sim 1.86$) regardless of the initial power in the beam.

For light pulses shorter than a picosecond, the role of material dispersion plays an important role and completely alters the dynamics of the self-focusing process. These dispersive effects lead to a temporal splitting of the pulse into two pulses and the arrest of its collapse. At even higher powers, other phenomena can occur, such as 'optical shock' formation at the rear edge of the pulse, due to self-steepening and space-time focusing. Shock formation leads to the emission of a broad spectrum of radiation extending from the ultraviolet to the mid-infrared, known as supercontinuum generation (SCG). This phenomenon was first observed in 1970, and since then it has been observed in many different solids, liquids, and gases, under a wide variety of experimental conditions.

If the peak intensity of the pulse approaches intensities of $< 10^{13}$ W/cm², either through self-focusing or external focusing, multiphoton ionization occurs and a plasma is formed in the medium. (See section below on Plasma Nonlinearities and Relativistic Effects.) The generation of the plasma lowers the refractive index and effectively counteracts the self-focusing process, resulting in the spatial confinement of the pulse for distances far beyond what would be allowed by ordinary linear diffraction and has been observed in gases, liquids, and solids. A striking example of this apparent self-waveguiding is the observation of 'light strings' in air which can extend more than 10 km into the atmosphere. This phenomenon was first observed with 100 fs laser pulses in the near infrared ($\lambda = 800$ nm). Researchers found that pulses with energies greater than 10 mJ undergo self-focusing collapse in air and produce a highly intense ($> 10^{13}$ W/cm²) 100-micron-diameter light filament tens of meters long.

Multiphoton Absorption

Multiphoton absorption is a process in which an atom or molecule makes a transition from a ground state to an excited state by means of the simultaneous absorption of N photons. In the lowest order of perturbation theory, such a process can be described by means of a susceptibility of order $(2N-1)$, that is, by $\chi^{(2N-1)}$. Alternatively, this process can be described in terms of an N -photon cross-section $\sigma^{(N)}$ defined such that the transition rate per atom is given by

$$R^{(N)} = \sigma^{(N)} I^N \quad (6)$$

where I is the intensity of the laser field. Quantum mechanical expressions for the N -photon cross-sections are readily obtained. One finds, for instance, that

$$R_{\text{ng}}^{(2)} = \left| \sum_m \frac{\mu_{\text{nm}} \mu_{\text{mg}} E^2}{\hbar^2 (\omega_{\text{mg}} - \omega)} \right|^2 2\pi \rho_f (\omega_{\text{ng}} - 2\omega)$$

$$R_{\text{og}}^{(3)} = \left| \sum_{mn} \frac{\mu_{\text{on}} \mu_{\text{nm}} \mu_{\text{mg}} E^3}{\hbar^3 (\omega_{\text{ng}} - 2\omega) (\omega_{\text{mg}} - \omega)} \right|^2 2\pi \rho_f (\omega_{\text{og}} - 3\omega) \quad (7)$$

In each of these expressions, the quantity ρ_f represents the density of final states, or equivalently the atomic lineshape function, evaluated at the N -photon transition frequency.

Optical Damage

High-intensity laser fields can produce unwanted damage to optical materials. As a point of reference, the threshold for laser damage to fused silica at a wavelength of 1.05 micrometers for a pulse of 30 ps duration corresponds to an intensity of 230 GW/cm² or a fluence of 7 J/cm². Over a wide range of pulselengths (approximately 1 ps to 1 μs), the threshold intensity for laser damage decreases with pulse length T as $T^{-1/2}$ and correspondingly the threshold fluence for laser damage increases with pulse length $T^{1/2}$. In this range of pulse durations, the dominant mechanism of laser damage is avalanche breakdown. In this process, free electrons are accelerated by the laser field until they acquire sufficient energy to impact-ionize other atoms in the sample. These additional electrons are similarly accelerated and create still more free electrons. The combined action of the breaking of chemical bonds and the deposition of heat energy leads to the fracturing of the optical material. For pulses shorter than 1 ps, processes such as multiphoton absorption and multiphoton dissociation contribute to the mechanism of optical damage. For laser pulses longer than approximately 1 μs (including continuous wave laser beams), the dominant damage mechanism is direct heating of the optical material by linear absorption.

High-Harmonic Generation

Let us consider how nonlinear optical effects are modified when excited by a super-intense pulse. Nonlinear optical effects are traditionally modeled using a power-series expansion, such as

$$P = \chi^{(1)}E + \chi^{(2)}E^2 + \chi^{(3)}E^3 + \dots \quad (8)$$

but this series is not expected to converge if the laser field strength E exceeds the atomic unit of field strength $E_{at} = e/a_0^2 = 2 \times 10^7$ statvolt/cm = 6×10^9 V/cm. This field strength corresponds to a laser intensity of $I_{at} = 4 \times 10^{16}$ W/cm², which constitutes the threshold intensity for exciting nonperturbative nonlinear optical response.

One of the consequences of excitation with intensities comparable to the atomic unit of intensity I_{at} , is the occurrence of high-harmonic generation. In a typical experimental arrangement, a gas jet is irradiated by high-intensity laser radiation, and all odd harmonics of the fundamental laser frequency, up to some maximum value N_{max} , are observed. The various harmonics below N_{max} are typically emitted with approximately equal intensity; such an observation is incompatible with a perturbative explanation of this phenomenon. Recent work has demonstrated harmonic generation with N_{max} as large as 341.

The phenomenon of high-harmonic generation can be understood in terms of a simple physical model. One imagines an atomic electron that has received kinetic energy from the laser field and is excited to a highly elliptical orbit. The positively charged atomic nucleus is at one focus of this ellipse, and each time the electron passes near the nucleus it undergoes strong acceleration and emits a short pulse of radiation. This radiation will occur in the form of a train of short pulses; the spectrum of the radiation will be the square of the Fourier transform of this pulse train, which will contain the odd harmonics of the oscillation frequency up to some maximum frequency, that is approximately the inverse of the time the electron spends near the atomic core. This argument can be made quantitative to show that the maximum harmonic number is given by

$$N_{max}\hbar\omega = 3.17K + U_p \quad (9)$$

where $K = e^2E^2/m\omega^2$ is the 'ponderomotive energy' (the kinetic energy of an electron in a laser field) and U_p is the ionization energy of the atom.

Plasma Nonlinearities and Relativistic Effects

The process of multiphoton ionization can liberate a sufficient number of free electrons to transform the optical medium into a plasma, that is, a fully or partially ionized gas. The process of plasma formation is described by the equation

$$\frac{dN_e}{dt} = \frac{dN_i}{dt} = (N_T - N_i)\sigma^{(N)}I^N - rN_eN_i \quad (10)$$

where N_e is the number density of electrons, N_i is the number density of ions, N_T is the total number of atoms (both ionized and un-ionized) in the material, and r is the electron-ion recombination coefficient. The optical properties of plasmas are very different from those of typical dielectric materials; the plasma contribution to the dielectric constant is given by

$$\varepsilon(\omega) = 1 - \frac{\omega_p^2}{\omega^2} \quad (11)$$

where $\omega_p = \sqrt{4\pi N e^2/m}$ is known as the plasma frequency.

Nonlinear effects can occur in the propagation of light through a plasma. One example is the nonlinear response resulting from the relativistic change in mass of the electron due to the large velocity that it can attain in the field of an intense

laser beam. Detailed consideration of this effect shows that the nonlinear change in refractive index can be described as $\Delta n = n_2 I$ where

$$n_2 = \frac{2\pi\omega_p^2 e^2}{n_0^2 m^2 c^3 \omega^4} = \frac{1}{2\pi n_0^2} \left(\frac{\omega_p}{\omega}\right)^2 1.1 \times 10^{-26} \frac{\text{cm}^2}{\text{W}} \quad (12)$$

Nonlinear Quantum Electrodynamics

One can imagine an electric field so intense that it could lead to the spontaneous creation of electron–positron pairs. Such a field would have a strength of the order of $E_{\text{QED}} = mc^2/e\lambda_c$ where $\lambda_c = \hbar/mc$ is the reduced Compton wavelength of the electron. The intensity of a light beam with a peak field amplitude of E_{QED} is $I_{\text{QED}} = 4 \times 10^{29} \text{ W/cm}^2$. Detailed consideration shows that even for fields weaker than I_{QED} there will be a field-induced change in the dielectric tensor given by

$$\varepsilon_{ik} = \delta_{ik} + \frac{e^4 \hbar}{45\pi m^4 c^7} [2(E^2 - B^2)\delta_{ik} + 7B_i B_k] \quad (13)$$

Because of the unusual tensor properties of this relation, it displays a different polarization dependence than typical optical nonlinearities. Nonetheless, to an order of magnitude one can describe the strength of this response as

$$n_2 = \frac{7}{15c} \frac{e^2}{\hbar c} \frac{1}{E_{\text{QED}}^2} = 5.6 \times 10^{-34} \text{ cm}^2/\text{W} \quad (14)$$

Electromagnetically Induced Transparency

JP Marangos, Imperial College of Science, Technology and Medicine, London, UK

Introduction

In this article we examine how the process of electromagnetically induced transparency (EIT) can be used to increase the efficiency of non-linear optical frequency mixing schemes. We illustrate the basic ideas by concentrating upon the enhancement of resonant four-wave mixing schemes in atomic gases. To start we introduce the quantum interference phenomenon that gives rise to EIT. The calculation of EIT effects in a three-level atomic medium using a density matrix approach is presented. Next we examine the modified susceptibilities that result and that can be used to describe nonlinear mixing, and show how large enhancements in nonlinear conversion efficiency can result. Specific examples are briefly discussed along with a further discussion of the novel aspects of refractive index and pulse propagation modifications that result from EIT. The potential benefits to nonlinear optics of electromagnetically induced transparency are discussed. In an article of this nature it is not possible to credit all of the important contributions to this field, but we include a bibliography for further reading indicating some of the seminal contributions.

Electromagnetically induced transparency is the term applied to the process by which an otherwise opaque medium can be rendered transparent through laser-induced quantum mechanical interference processes. The linear susceptibility is substantially modified by EIT. Absorption is cancelled due to destructive interference between excitation pathways. The dispersion of the medium is likewise modified such that where there is no absorption the refractive index is unity and there can be a large value of normal dispersion leading to low values of group velocity. In contrast to the linear susceptibility the nonlinear susceptibility involving these same resonant laser fields will undergo constructive rather than destructive interference. This leads to a strong enhancement in nonlinear frequency mixing. For a normally transparent medium the nonlinear optical couplings will be small unless large-amplitude fields are applied. The most important consequence of EIT, in contrast to the usual case when a medium is transparent, is that the dispersion is not vanishing and the nonlinear couplings can be very large.

To understand how this comes about we must consider the system illustrated in Fig. 1(a) where because of the resonant condition satisfied for the applied fields the atom can be simplified to just three-levels. The important parameters in this model system are that state $|2\rangle$ is metastable and has a dipole-allowed coupling to state $|3\rangle$. The coupling between states $|1\rangle$ and $|3\rangle$ is also dipole-allowed and as a consequence state $|3\rangle$ can decay radiatively to either $|1\rangle$ or $|2\rangle$. Let a coupling field be applied resonantly to the $|2\rangle - |3\rangle$ transition, which may be cw or pulsed but should in the latter case be transform-limited. We define the Rabi coupling as $\Omega_{23} = \frac{\mu_{23}E}{\hbar}$ where E is the laser electric field amplitude and μ_{23} is the dipole moment of the transition. The Rabi frequency needs to be larger than the inhomogeneous broadening of the sample. A second field, the probe, typically of much lower intensity, is then applied in resonance with the $|1\rangle - |3\rangle$ transition. If the condition $\Omega_{23} \gg \Omega_{13}$ is satisfied then it is convenient to replace the bare atomic states $|2\rangle$ and $|3\rangle$ with the dressed states (see Fig. 1(b)):

$$|a\rangle = \frac{1}{\sqrt{2}}[|2\rangle + |3\rangle] \quad (1a)$$

$$|b\rangle = \frac{1}{\sqrt{2}}[|2\rangle - |3\rangle] \quad (1b)$$

Fig. 1 A three-level atomic system coupled to laser fields in the lambda configuration is shown on the left-hand side. In the limit of a strong coupling field this is equivalent to the dressed states $|a\rangle$ and $|b\rangle$ coupled to the ground state by the probe field alone as shown on the right-hand side.

Transitions from state $|1\rangle$ induced by the probe field to this pair of near-resonant dressed states are subject to exact cancellation at resonance if $|2\rangle$ is perfectly metastable. This is because the only contribution to the excitation amplitude comes from the matrix elements $\langle 1|\mathbf{r}\cdot\mathbf{E}|3\rangle$ as the $|1\rangle - |2\rangle$ transition is dipole forbidden. The contributions from the equally detuned states $|a\rangle$ and $|b\rangle$ thus enter into the overall amplitude with opposite signs and equal magnitude as can be seen by inspection of Eqs. (1a) and (1b). This leads to cancellation of the absorption amplitude. This type of absorption cancellation is well known and closely related to the so-called *dark states*.

Theoretical Treatment of EIT in a Three-Level Medium

It was realized by several workers in the 1970s that laser-induced interference effects could lead to a cancellation of absorption at certain frequencies. To gain a more quantitative understanding of the effects of the coupling field upon the optical properties of a dense ensemble of three-level atoms we require a treatment that computes the optical susceptibility of the medium. A treatment originally carried out by Harris *et al.* for a Λ scheme similar to that illustrated in Fig. 1 was the first to derive the modified susceptibilities that will be discussed below. In that treatment the state amplitudes in the three-level atom were solved in the steady-state limit and from these the linear and nonlinear susceptibilities (see below) are then derived. In what follows we adopt a density matrix treatment as employed by various workers. This readily allows the inclusion of dephasing as well as population decay terms. The critical parameters in this system are the strengths of the fields (described in terms of the Rabi couplings), the detuning of the fields from resonance $\Delta\omega_{13} = \omega_{13} - \omega_p$ and $\Delta\omega_{23} = \omega_{23} - \omega_c$ (see Fig. 2), the radiative decays from $|3\rangle$ to $|1\rangle$ and $|2\rangle$, γ_c and γ_d and from $|2\rangle$ to $|1\rangle$ γ_a (although the latter is anticipated to be smaller). Extension to other configurations of the three states, such as a V or ladder scheme is implicit within this general treatment.

Fig. 2 illustrates the system considered. This treatment will also address the nonlinear response in a four-wave mixing scheme completed by the two-photon resonant coupling applied between state $|1\rangle$ and $|2\rangle$.

We write the interaction Hamiltonian as:

$$H = H_0 + V \quad (2)$$

where H_0 is the unperturbed Hamiltonian of the system and is written as

$$H_0 = \hbar\omega_1|1\rangle\langle 1| + \hbar\omega_2|2\rangle\langle 2| + \hbar\omega_3|3\rangle\langle 3| \quad (3)$$

Fig. 2 A four-wave mixing scheme incorporating the three-level lambda system in which electromagnetically induced transparency has been created for the generated field ω_d by the coupling field ω_c . The decay rates γ_i from the three atomic levels are also shown. For a full explanation of this system see text.

and V is the interaction Hamiltonian and can be expressed

$$V = \hbar\Omega_a e^{-i\omega_a t} |2\rangle \langle 1| + \hbar\Omega_c e^{-i\omega_c t} |2\rangle \langle 3| + \hbar\Omega_d e^{-i\omega_d t} |3\rangle \langle 1| + c.c. \quad (4)$$

Note that the Rabi frequencies in the equation can be described as $\hbar\Omega_{ij} = \mu_{ij}|E(\omega_{ij})|$, where μ_{ij} is the dipole moment of the transition between states $|i\rangle$ and $|j\rangle$, the Rabi frequency Ω_a is a two-photon Rabi frequency that characterizes the coupling between the laser field a and the atom for this two-photon transition. We have assumed for simplicity that $\omega_a = \omega_b = \omega_{12}/2$.

Assuming all the fields lie close to the resonance, the rotating wave approximation can be applied to the interaction picture and the interaction Hamiltonian V^I is given as

$$V^I = \hbar\Omega_a e^{i\Delta_a t} |2\rangle \langle 1| + \hbar\Omega_c e^{i\Delta_c t} |2\rangle \langle 3| + \hbar\Omega_d e^{i\Delta_d t} |3\rangle \langle 1| + c.c. \quad (5)$$

where Δ_a , Δ_c and Δ_d refer the detunings of the fields and can be written as:

$$\begin{aligned} \Delta_a &= \omega_{12} - 2\omega_a \\ \Delta_c &= \omega_{32} - \omega_c \\ \Delta_d &= \omega_{13} - \omega_d \end{aligned} \quad (6)$$

For the evaluation of the density matrix with this interaction V^I , the Schrödinger equation can be restated in terms of the density matrix components. This form is called the Liouville equation and can be written as:

$$\hbar \frac{\partial}{\partial t} \rho_{ij}(t) = -i \sum_k H_{ik}(t) \rho_{kj}(t) + i \sum_k \rho_{ij}(t) H_{ik}(t) + \Gamma_{ij} \quad (7)$$

where Γ_{ij} represents phenomenologically added decay terms (i.e. spontaneous decays, collisional broadening, etc.). This formalism leads to a set of nine differential equations for nine different density matrix elements that describe the three-level system.

To remove the optical frequency oscillations, a coordinate transform is needed and to incorporate the relevant oscillatory detuning terms into the off-diagonal elements we make the substitution:

$$\begin{aligned} \tilde{\rho}_{12} &= \rho_{12} e^{-i\Delta_a t} \\ \tilde{\rho}_{23} &= \rho_{23} e^{-i\Delta_c t} \\ \tilde{\rho}_{31} &= \rho_{31} e^{-i\Delta_d t} \end{aligned} \quad (8)$$

This operation conveniently eliminates the time dependencies in the rate equations and the equations of motion for the density matrix are given by:

$$\begin{aligned} \frac{\partial}{\partial t} \rho_{11} &= i \frac{1}{2} \Omega_a \tilde{\rho}_{12} + i \frac{1}{2} \Omega_d \tilde{\rho}_{13} - i \frac{1}{2} \Omega_a^* \tilde{\rho}_{21} - i \frac{1}{2} \Omega_d^* \tilde{\rho}_{31} + \Gamma_{11} \\ \frac{\partial}{\partial t} \rho_{22} &= i \frac{1}{2} \Omega_c^* \tilde{\rho}_{23} + i \frac{1}{2} \Omega_a \tilde{\rho}_{21} - i \frac{1}{2} \Omega_c \tilde{\rho}_{32} - i \frac{1}{2} \Omega_a \tilde{\rho}_{12} + \Gamma_{22} \\ \frac{\partial}{\partial t} \rho_{33} &= i \frac{1}{2} \Omega_c^* \tilde{\rho}_{23} - i \frac{1}{2} \Omega_d^* \tilde{\rho}_{31} + i \frac{1}{2} \Omega_d \tilde{\rho}_{13} - i \frac{1}{2} \Omega_c \tilde{\rho}_{32} + \Gamma_{33} \\ \frac{\partial}{\partial t} \rho_{23} &= i \frac{1}{2} \Omega_c \tilde{\rho}_{22} - i \frac{1}{2} \Omega_c \tilde{\rho}_{33} - i \Delta_a \tilde{\rho}_{23} + i \frac{1}{2} \Omega_d \tilde{\rho}_{21} - i \frac{1}{2} \Omega_c \tilde{\rho}_{13} + \Gamma_{23} \\ \frac{\partial}{\partial t} \rho_{21} &= i \Omega_a \tilde{\rho}_{22} + \Omega_a \tilde{\rho}_{33} + i \Omega_d \tilde{\rho}_{23} - i \Delta_c \tilde{\rho}_{21} - i \frac{1}{2} \Omega_c \tilde{\rho}_{31} - i \frac{1}{2} \Omega_a \tilde{\rho}_{31} + \Gamma_{21} \\ \frac{\partial}{\partial t} \rho_{31} &= i \frac{1}{2} \Omega_d \tilde{\rho}_{22} - i \Omega_d \tilde{\rho}_{33} + i \Omega_d \tilde{\rho}_{23} - i \Delta_c \tilde{\rho}_{21} - i \frac{1}{2} \Omega_c \tilde{\rho}_{31} - i \frac{1}{2} \Omega_a \tilde{\rho}_{31} + \Gamma_{31} \end{aligned} \quad (9)$$

Using the set of equations above and the relation $\tilde{\rho}_{ij} = \tilde{\rho}_{ij}^*$ we obtain equations for $\tilde{\rho}_{12}$, $\tilde{\rho}_{32}$, and $\tilde{\rho}_{13}$. For the incoherent population relaxation the decays can be written:

$$\begin{aligned} \Gamma_{11} &= \gamma_a \rho_{22} + \gamma_d \rho_{33} \\ \Gamma_{22} &= -\gamma_a \rho_{22} + \gamma_c \rho_{33} \\ \Gamma_{33} &= -(\gamma_c + \gamma_d) \rho_{33} \end{aligned} \quad (10)$$

and for the coherence damping:

$$\begin{aligned} \Gamma_{21} &= -\left\{ \frac{1}{2} [\gamma_a + \gamma_c] + \gamma_{21}^{\text{col}} \right\} \rho_{21} \\ \Gamma_{23} &= -\left\{ \frac{1}{2} [\gamma_a + \gamma_c + \gamma_d] + \gamma_{23}^{\text{col}} \right\} \rho_{23} \\ \Gamma_{31} &= -\left\{ \frac{1}{2} [\gamma_d + \gamma_c] + \gamma_{31}^{\text{col}} \right\} \rho_{31} \end{aligned} \quad (11)$$

where γ_{ij}^{col} represents collisional dephasing terms which may be present.

This system of equations can be solved by various analytical or numerical methods to give the individual density matrix elements. Analytical solutions are possible if we can assume for instance that $\Omega_c \gg \Omega_a, \Omega_d$ and that there are continuous-wave fields so a steady-state treatment is valid. For pulsed fields or in the case where the generated field may be significant numerical solutions are in general required.

We are specifically interested in the optical response to a probe field at ω_d (close to resonance with the $|1\rangle - |3\rangle$ transition) that is governed by the magnitude of the coherence ρ_{13} . We find ρ_{13} making the assumption that only the coupling field is strong, i.e., that $\Omega_c \gg \Omega_a, \Omega_d$ holds. From this quantity the macroscopic polarization is obtained from which the susceptibility can be computed. The macroscopic polarization P at the transition frequency ω_{13} can be related to the microscopic coherence ρ_{13} via the expression:

$$P_{13} = N\mu_{13}\rho_{13} \quad (12)$$

where N is the number of equivalent atoms in the ground state within the medium, and μ_{13} is the dipole matrix element associated with the transition. In this way real and imaginary parts of the linear susceptibility χ at frequency ω can be directly related to ρ_{13} via the macroscopic polarization since the latter can be defined as:

$$P_{13}(\omega) = \epsilon_0 \chi(\omega) E \quad (13)$$

where E is the electric field amplitude at frequency ω_d . The linear susceptibility (real and imaginary parts) is given by the following expressions:

$$\text{Re}\chi_D^{(1)}(-\omega_d, \omega_d) = \frac{|\mu_{13}|^2 N}{\epsilon_0 \hbar} \left[\frac{-4\Delta_{21}(|\Omega_2|^2 - 4\Delta_{21}\Delta_{32}) + 4\Delta_{31}\gamma_a^2}{(4\Delta_{31}\Delta_{21} - \gamma_d\gamma_a - |\Omega_2|^2)^2 + 4(\gamma_d\Delta_{21} + \gamma_a\Delta_{31})^2} \right] \quad (14)$$

$$\text{Im}\chi_D^{(1)}(-\omega_d, \omega_d) = \frac{|\mu_{13}|^2 N}{\epsilon_0 \hbar} \left[\frac{8\Delta_{21}\gamma_d + 2\gamma_a(|\Omega_2|^2 + \gamma_d\gamma_a)}{(4\Delta_{31}\Delta_{21} - \gamma_d\gamma_a - |\Omega_2|^2)^2 + 4(\gamma_d\Delta_{21} + \gamma_a\Delta_{31})^2} \right] \quad (15)$$

We now consider the additional two-photon resonant field ω_a . This leads to a four-wave mixing process that generates a field at ω_d (i.e., the probe frequency). The nonlinear susceptibility that describes the coupling of the fields in a four-wave mixing process is given by the expression:

$$\chi_D^{(3)}(-\omega_d, \omega_a, \omega_a, \omega_c) = \frac{\mu_{23}\mu_{13}N}{6\epsilon_0 \hbar^3 ((\Delta_{21} - j\gamma_a/2)(\Delta_{31} - j\gamma_d/2) - (|\Omega_c|^2/4))^*} \sum_i \mu_{i1}\mu_{i3} \left(\frac{1}{\omega_i - \omega_a} + \frac{1}{\omega_i - \omega_b} \right)$$

Nonlinear Optical Processes

The dependence of the susceptibilities upon the detuning is plotted in [Fig. 3](#). In this plot the effects of inhomogeneous (Doppler) broadening are also incorporated by computing the susceptibilities over the inhomogeneous profile (see below for more details).

By inspection of [Eq. \(14\)](#) we see that the absorptive loss at the minimum of $\text{Im}[\chi^{(1)}]$ varies as γ_a/Ω_c^2 . This dependence is a consequence of the interference discussed above. In the absence of interference (i.e., just simply Autler-Townes splitting) the minimum loss would vary as γ_d/Ω_c^2 . Since $|3\rangle - |1\rangle$ is an allowed decay channel (in contrast to $|2\rangle - |1\rangle$) it follows that $\gamma_b \gg \gamma_a$ and so the absorption is much less as a consequence of EIT. $\text{Re}[\chi^{(1)}]$ in [Eq. \(15\)](#) and [Fig. 3](#) is also modified significantly. The resonant value of refractive index is equal to the vacuum value where the absorption is a minimum, the dispersion is normal in this region with a gradient determined by the strength of the coupling laser, a point we will return to shortly. For an unmodified system the refractive index is also unity at resonance but in that case there is high absorption and steep anomalous absorption. Reduced group velocities result from the steep normal dispersion that accompanies EIT. Inspection of the expression [\(16\)](#) and [Fig. 3](#) shows that $\chi^{(3)}$ is also modified by the coupling field. The nonlinear susceptibility depends upon $1/\Omega_c^2$ as is expected for a laser dressed system, however in this case there is not destructive but rather constructive interference, between the field-split components. This result is of great importance: it ensures that the absorption can be minimized at frequencies where the nonlinear absorption remains large.

As a consequence of constructive interference the nonlinear susceptibility remains resonantly enhanced whilst the linear susceptibility vanishes or becomes very small at resonance due to destructive interference. Large nonlinearity accompanying vanishing absorption (transparency) of course match conditions for efficient frequency mixing as a large atomic density can then be used. Moreover the dispersion (controlling the refractive index) also vanishes at resonance; this leads to perfect phase matching (i.e., zero wavevector mismatch between the fields) in the limit of a simple three-level system. As a result of these features a large enhancement of the conversion efficiency in this type of scheme can be achieved.

To compute the generated field strength Maxwell's equations must be solved using these expression for the susceptibility to describe the absorption, refraction, and nonlinear coupling in the medium. We will treat this within the slowly varying envelope approximation since the fields are cw or nanosecond pulses. To be specific we assume that the susceptibilities are time independent, i.e., that we are in the steady-state (cw) limit. We make the assumptions also that there is no pump field absorption and

Fig. 3 Electromagnetically induced transparency is shown in the case of significant Doppler broadening. The Doppler averaged values of the imaginary $\text{Im}[\chi^{(1)}]$ and real $\text{Re}[\chi^{(1)}]$ parts of the linear susceptibility and the nonlinear susceptibility $\chi^{(3)}$ are plotted in the three frames. The Doppler width is taken to be $20\gamma_d$, $\Omega_c = 100\gamma_d$ and $\gamma_d = 50\gamma_a$, $\gamma_c = 0$.

that we have plane waves. Under these assumptions the generated field amplitude A_d is given in terms of the other field amplitudes A_i by:

$$\frac{\partial}{\partial z} A_d = i \frac{\omega_d}{4c} \chi^{(3)} A_a^2 A_c e^{-i\Delta k_d z} - \frac{\omega_d}{2c} \text{Im}[\chi^{(1)}] A_d + i \frac{\omega_d}{2c} \text{Re}[\chi^{(1)}] A_d \quad (16)$$

where the wavevector mismatch is given by:

$$\Delta k_d = k_d + k_c - 2k_a \quad (17)$$

The wavevector mismatch will be zero on resonance for the three-level atom considered in this treatment. In fact the contribution to the refraction from all the other atomic levels must be taken into account whilst computing Δk_d and it is implicit that these make a finite contribution to the wavevector mismatch.

We can solve this first-order differential equation with the boundary condition $A_d(z=0) = 0$ to find the generated intensity $I(\omega_d)$ after a length z :

$$I(\omega_d) = \frac{3n\omega_d^2}{8Z_0c^2} |\chi^{(3)}|^2 |A_a|^4 |A_c|^2 \frac{\left\{ 1 + e^{-\frac{\omega_d}{c} \text{Im}[\chi^{(1)}] z} - 2e^{-\frac{\omega_d}{c} \text{Im}[\chi^{(1)}] z} \cos\left(\Delta k + \frac{\omega_d}{2c} \text{Re}[\chi^{(1)}] z\right) \right\}}{\frac{\omega_d^2}{4c^2} \text{Im}[\chi^{(1)}]^2 + \left\{ \Delta k + \frac{\omega_d}{2c} \text{Re}[\chi^{(1)}] \right\}^2}$$

where Z_0 is the impedance of free space. This expression is quantitatively correct for the case of the assumptions made. More generally the qualitative predictions and general scaling remain valid in the limit where the pulse duration is significantly longer than the time required to traverse the medium. Note that both real and imaginary parts of $\chi^{(1)}$ and $\chi^{(3)}$ play an important role, as

we would expect for resonant frequency mixing. The influence of that part of the medium refraction which is due to other levels is contained in the terms with Δk . In the case of a completely transparent medium this becomes a major limit to the conversion efficiency.

Propagation and Wave-Mixing in a Doppler Broadened Medium

Doppler shifts arising from the Maxwellian velocity distribution of the atoms in the medium lead to a corresponding distribution in the detunings for the various members of the atomic ensemble. The response of the medium, as characterized by the susceptibilities, must therefore include the Doppler effect by performing a weighted sum over possible detunings. The weighting is determined by the Gaussian form of the Maxwellian velocity distribution. From this operation the effective values of the susceptibilities at a given frequency are obtained, and these quantities can be used to calculate the generated field. This step is of considerable practical importance as in most up-conversion schemes it is not possible to achieve Doppler-free geometries and the use of laser cooled atoms, although in principle possible, limits the atomic density that can be employed. The interference effects persist in the dressed profiles providing the coupling laser Rabi frequency is comparable to or larger than the inhomogeneous width. This is because the Doppler profile follows a Gaussian distribution which falls off much faster in the wings of the profile than the Lorentzian profile due to the natural broadening.

In the case considered with weak probe field, excited state populations and coherences remain small. The two-photon transition need not be strongly driven (i.e., a small two-photon Rabi frequency can be used) but a strong coupling laser is required. The coupling laser must be intense enough that its Rabi frequency is comparable to or exceeds the inhomogeneous widths in the system (i.e., Doppler width), and a laser intensity of above 1 MW cm^{-2} is required for a typical transition. This is trivially achieved even for unfocused pulsed lasers, but does present a serious limit to cw lasers unless a specific Doppler-free configuration is employed. The latter is not normally suitable for a frequency up-conversion scheme if a significant up-conversion factor is required, e.g., to the vacuum ultraviolet (VUV); however recent experiments report significant progress in cw frequency up-conversion using EIT and likewise a number of other possibilities, e.g., laser-cooled atoms and standing-wave fields, have been proposed.

A transform-limited single-mode laser pulse is essential for the coupling laser field since a multimode field will cause an additional dephasing effect on the coherence, resulting in a deterioration of the quality of the interference. In contrast, whilst it is advantageous for the field driving the two-photon transition to be single mode (in order to achieve optimal temporal and spectral overlap with the EIT hole induced by the dressing laser), this is not essential since this field does not need to drive the coherence responsible for interference.

When a pulsed laser field is used additional issues must be considered. The group velocity is modified for pulses propagating in the EIT large reductions, e.g., by factors down to $<c/100$, in the group velocity have been observed. Another consideration beyond that found in the simple steady-state case is that the medium can only become transparent if the pulse contains enough energy to dress all the atoms in the interaction volume. The minimum pulse energy to prepare a transparency is:

$$E_{\text{preparation}} = \frac{f_{13}}{f_{23}} NL \hbar \omega \quad (18)$$

where f_{ij} are the oscillator strengths of the transitions and NL the product of the density and the length. Essentially the number of photons in the pulse must exceed the number of atoms in the interaction volume to ensure all atoms are in the appropriate dressed state. This puts additional constraints on the laser pulse parameters.

Up-conversion to the UV and vacuum UV has been enhanced by EIT in a number of experiments. Only pulsed fields have so far been up-converted to the VUV with EIT enhancement. The requirements on a minimum value of $\Omega_c > \Delta_{\text{Doppler}}$ constrains the conversion efficiency that can be achieved because the $1/\Omega_c^2$ factor in Eq. (17) ultimately leads to diminished values of $\chi^{(3)}$. The use of gases of higher atomic weight at low temperatures is therefore highly desirable in any experiment utilizing EIT for enhancement of four-wave mixing to the VUV. Conversion efficiencies, defined in terms of the pulse energies by E_d/E_a or E_d/E_c of a few percent have been achieved using the EIT enhancement technique. It is typically most beneficial to maximize the conversion efficiency defined by the first ratio since ω_a is normally in the UV and is the lower energy of the two applied pulses.

Nonlinear Optics with a Pair of Strong Coupling Fields in Raman Resonance

An important extension of the EIT concept occurs when two strong fields are applied in Raman resonance between a pair of states in a three-level system. Considering the system illustrated in Fig. 1 we can imagine that both applied fields are now strong. Under appropriate adiabatic conditions the system evolves to produce the maximum possible value for the coherence $\rho_{12}=0.5$. Adiabatic evolution into the maximally coherent state is achieved by adjusting either the Raman detuning or the pulse sequence (counter to intuitive order). The pair of fields may also be in single-photon resonance with a third level, in which case the EIT-like elimination of absorption will be important. This situation is equivalent to the formation of a darkstate, since neither of the two strong fields is absorbed by the medium. For sufficiently strong fields the single-photon condition need not be satisfied and a maximum coherence will still be achieved.

An additional field applied to the medium can participate in sum- or difference-frequency mixing with the two Raman resonant fields. The importance of the large value of coherence is that it is the source polarization that drives the new fields generated in the frequency mixing process. Complete conversion can occur over a short distance that greatly alleviates the constraints usually set by phase-matching in nonlinear optics. Recently near unity conversion efficiencies to the far-UV were reported in an atomic lead system where maximum coherence had been created. In a molecular medium large coherence between vibrational or rotational levels has also been achieved using adiabatic pulse pairs. Efficient multi-order Raman sideband generation has been observed to occur. This latter observation may lead the way to synthesizing very short duration light pulses since the broadband Raman sideband spectrum has been proved to be phase-locked.

Pulse Propagation and Nonlinear Optics for Weak CW Fields

In a Doppler-free medium a new regime can be accessed. This is shown in Fig. 4 where the possibility now arises of extremely narrow transparency dips since very small values of Ω_c are now sufficient to induce EIT. The widths of these features are typically subnatural and are therefore accompanied by very steep normal dispersion, which corresponds to a much reduced group velocity. The ultraslow propagation of pulses is one of the most dramatic manifestations of EIT in this regime. Nonlinear susceptibilities are now very large as there is constructive interference controlling the value and the splitting of the two states is negligible compared to their natural width. Nonlinear optics at very low light levels, i.e., at the few-photon limit, is possible in this regime.

Fig. 4 Electromagnetically induced transparency is shown in the case where there is no significant Doppler broadening. The values of the imaginary $\text{Im}[\chi^{(1)}]$ and real $\text{Re}[\chi^{(1)}]$ parts of the linear susceptibility and the nonlinear susceptibility $\chi^{(3)}$ are plotted in the three frames. We take $\Omega_c = \gamma_d/5$ and $\gamma_d = 50\gamma_a$, $\gamma_c = 0$.

Propagation of pulses is significantly modified in the presence of EIT. Fig. 4 shows the changes to $\text{Re}[\chi^{(1)}]$ that arise. Within the transparency dip there exists a region of steep normal dispersion. In the vicinity of resonance this is almost linear and it becomes reasonable to consider the leading term only that describes the group velocity. An analysis of the refractive changes has been provided by Harris who expanded the susceptibilities (both real and imaginary parts) of the dressed atom around the resonance frequency to determine various terms in $\text{Re}[\chi^{(1)}]$. The first term of the series (zero order) $\text{Re}[\chi^{(1)}](\omega_{13})=0$ corresponds to the vanishing dispersion at resonance. The next term $\partial[\text{Re}\chi^{(1)}](\omega)/\partial\omega$ gives the slope of the dispersion curve; at ω_{13} this takes the value:

$$\frac{\partial \text{Re}\chi^{(1)}(\omega_{13})}{\partial\omega} = \frac{|\mu_{13}|^2 N 4(\Omega_c^2 - \gamma_a^2)}{2\pi\epsilon_0(\Omega_c^2 + \gamma_a\gamma_d)} \quad (19)$$

The slope of the dispersion profile leads to a reduced group velocity v_g :

$$\frac{1}{v_g} = \frac{1}{c} + \frac{\pi}{\lambda} \frac{\partial \chi^{(1)}}{\partial\omega} \quad (20)$$

From the expression for $\partial\chi/\partial\omega$ we see that this slope is steepest (and so v_g minimum) in the case where $\Omega_c \gg \Gamma_2$ and $\Omega_c^2 \gg \Gamma_2 \Gamma_3$ but is still small compared to Γ_3 (i.e., $\Omega_c < \Gamma_3$) and hence $\partial\chi/\partial\omega \propto 1/\Omega_c^2$. In the limit of small Ω_c the following expression for v_g therefore holds:

$$v_g = \frac{\hbar c \epsilon_0 [\Omega_c]^2}{2\omega_d |\mu_{13}|^2 N} \quad (21)$$

Extremely low group velocities, down to a few meters per second, are achieved in this limit using excitation of the hyperfine split ground states in either laser cooled atomic samples or Doppler-free configurations in finite temperature samples. Recently similar light slowing has been observed in solids. Storage of the optical pulse within the medium has also been achieved by adiabatically switching off the coupling field and thus trapping the optical excitation as an excitation within the hyperfine ground states for which the storage time can be very long (> 1 ms) due to very low dephasing rates. Since the storage scenario should be valid even for single photons this process has attracted considerable attention recently as a means to enable quantum information storage.

Extremely low values of Ω_c are sufficient to induce complete transparency (albeit in a very narrow dip) and at this location the nonlinear response is resonantly enhanced. Very high efficiency nonlinear frequency mixing and phase conjugation at low light levels have been reported under these conditions. It is expected that high-efficiency nonlinear optical processes will persist to ultralow intensities (the few photon level) in an EIT medium of this type.

One example of highly enhanced nonlinear interactions is the predicted large values of the Kerr type nonlinearity (nonlinear refractive index). The origin of this can be seen by considering the steep dispersion profile in the region of the transparency dip in Fig. 4. Imagine that we apply an additional field ω_f , perhaps a very weak one, at a frequency close to resonance between state $|2\rangle$ and a fourth level $|4\rangle$. The ac Stark shift caused by this new field to the other three level, although small, will have a dramatic effect upon the value of the refractive index because of the extreme steepness of the dispersion profile. Essentially even a very small shift of the resonant wavelength causes a large change in the refractive index for a field applied close to this frequency. It is predicted that strong cross-phase modulations will be created in this process between the fields ω_f and ω_d , even in the quantum limit for these fields. This is predicted to lead to improved schemes for quantum nondemolition measurements of photons through the measurement of the phaseshifts they induce (through cross-phase modulation) on another quantum field. This type of measurement has direct application in quantum information processing.

Nomenclature

CARS	Coherent anti-Stokes Raman scattering	OPO	Optical parametric oscillation/oscillator
c.c.	Complex conjugate	2PA, TPA	Two-photon absorption
CSRS	Coherent Stokes Raman scattering	PCM	Phase conjugate mirror
DFG	Difference frequency generation	QPM	Quasi phase matching
DFM	Difference frequency mixing	RIKES	Raman-induced Kerr effect spectroscopy
DFWM, FWM	(Degenerate) Four wave mixing	RSA	Reverse saturable absorption
DRO	Doubly resonant OPO	SBS	Stimulated Brillouin scattering
EIT	Electromagnetically induced transparency	SFG	Sum frequency generation
ESA	Excited state absorption	SHG	Second harmonic generation
GVD	Group velocity dispersion	SIT	Self-induced transparency
GVM	Group velocity mismatch	SRO	Singly resonant OPO
NLA	Nonlinear absorption	SRS	Stimulated Raman scattering
NLR	Nonlinear refraction	SRWS	Stimulated Rayleigh wing scattering
OFID	Optical free-induction decay	SVEA, SVAA	Slowly varying envelope (amplitude) approximation
OPA	Optical parametric amplification/amplifier	THG	Third harmonic generation
OPG	Optical parametric generation/generator	TPF	Two-photon fluorescence
OPL	Optical power limiter		

Nomenclature Associated with the Excitation Light

Particular care must be used when characterizing the excitation beam in nonlinear optical experiments compared to linear measurements. By definition, nonlinear optical phenomena depend on the electric field to high order. The higher the order, the more sensitive the observed behavior depends on the input. Extracting a representative nonlinear coefficient from an experiment, for example, becomes progressively more difficult as the order of the optical nonlinearity increases. In other words: the errors associated with optical beam characterization get magnified by the order of the nonlinearity under study.

There is an extensive nomenclature for characterizing the light (almost always laser light) interacting with the nonlinear optical medium. Different descriptions may be used depending on whether the excitation light is pulsed, continuous, or a continuous train of pulses. When a laser beam is constant or continuous, it is often described by its 'cw power'. 'Cw' stands for 'continuous wave', an acronym taken from the nomenclature of electronics. The cw power of a laser is determined by placing a power meter in the path of a beam. Repetitively pulsed lasers can be characterized in the same way, provided the response time of the power meter is slower than the pulse separation period. This will almost certainly be the case with a continuously pumped mode-locked laser such as a dye laser, fiber laser, or Ti:sapphire laser, which produce pulses at repetition frequencies of tens of megahertz. Cw power may also be suitable for describing pulsed flashlamp lasers, gas discharge lasers, or any laser that is excited in a periodic fashion.

When the optical output can be distinguished as individual pulses, additional metrics are used. A pulse, by definition, exists during a window of time, i.e., there is a time when light is present and a time when light is absent. How one characterizes the time light is present – the pulse duration – is critically important and not always obvious. There are a myriad of ways the pulse temporal envelope can manifest itself; common examples include square pulses, triangular pulses, Gaussian pulses, and hyperbolic secant pulses. These names refer to the mathematical waveforms that map the pulse envelope as a function of time.

A pulse waveform that exhibits symmetry about the peak in its temporal envelope is commonly characterized by its 'full-width, half-maximum', abbreviated FWHM. One obtains the full-width, half-maximum by locating the two points on the pulse profile that are at half the peak value. The temporal separation of these two points is the FWHM. One uses this measure because in a strict mathematical sense, waveforms such as the Gaussian or hyperbolic-secant exist even at times $t = \pm \infty$. A less common term is the 'half-width, half-maximum' or HWHM. As the name implies, the HWHM is exactly half the FWHM value. Not all light-pulses are temporally symmetric, however, so greater detail may be needed when giving a mathematical description of asymmetric pulses.

Light pulses are also characterized by their energy and peak power. The temporal envelope recorded by a so-called square-law detector (all laboratory detectors are square-law detectors) shows the power of the pulse as a function of time, provided the detector response time is sufficiently fast. Integrating this waveform gives the pulse energy. It makes no sense to talk about the energy of a cw beam of light, unless that beam is composed of repetitive, distinguishable pulses. Each pulse in the train carries a distinct amount of optical energy.

'Ultrafast' or 'ultrashort' laser pulses generally refer to light pulses that are of such small duration they cannot be measured directly with detectors and oscilloscopes because of bandwidth limitations. To infer the pulse duration, so-called intensity autocorrelation measurements are often made. The temporal power profile is then deduced from the autocorrelation signal with the appropriate mathematical conversion factor. Equally important is the spectrum of a short pulse. The optical bandwidth determines the lower limit of temporal compression; such ideally compressed pulses are said to be 'transform limited'. If different components of the spectrum can be distinguished at specific positions on the pulse temporal profile, then the pulse is 'chirped'.

Nonlinear optical effects take place when light is concentrated on a target – there is a cross-section or 'footprint' of the beam on the medium. The interaction of the light and material takes place in a region called the beam area, beam cross-section, focal area, or focal volume. One must then define the appropriate interaction area or volume.

Specification of the beam area allows one to define two important quantities used frequently in nonlinear optics. The power/area is known as irradiance or power density. This quantity is commonly called the intensity, although the strict radiometric definition of intensity is power/(solid angle). The second important quantity is energy/area, which is called the energy density or fluence.

The convention in nonlinear optics is to define the optical electric field as:

$$\mathbf{E}(\mathbf{z}, t) = \frac{1}{2} E_0 \exp[i(\mathbf{k} \cdot \mathbf{z} - \omega t)] + \text{c.c.} \quad (1)$$

where E_0 is the peak field, $\mathbf{k}$ is the propagation vector, ω is the angular frequency of the light, and c.c. stands for complex conjugate. This represents a forward- and backward-propagating (in the z -direction) infinite, transverse plane wave. Other definitions are also used. In SI/mks units and using the convention of Eq. (1), the irradiance (I in units of W/m^2) inside a material of refractive index n is related to the electric field vector of the light ($\mathbf{E}$ in units of V/m) as follows:

$$I = \frac{1}{2} c n \epsilon_0 |\mathbf{E}|^2 \quad (2)$$

Here c is the speed of light (2.998×10^8 m/s) and ϵ_0 is the permittivity of free space (8.854×10^{-12} F/m). Nonlinear optics has an unfortunate tradition of mixing mks and cgs units, resulting in a lot of confusion. Irradiance is usually expressed in units of W/cm^2 . One can calculate the peak electric field (in units of V/cm) of a laser beam given its irradiance (in units of W/cm^2) by using this simple formula:

$$E_0 = 38.82 \sqrt{\frac{I}{n}} \left(\frac{\text{V}}{\text{cm}} \right) \quad (3)$$

The root-mean-square value of the electric field is obtained by replacing the factor 38.82 by 27.45. In Gaussian/cgs units, irradiance is expressed in units of $\text{ergs}/(\text{cm}^2 \text{ sec})$ and is related to the field as:

$$I = \frac{cn}{8\pi} |\mathbf{E}|^2 \quad (4)$$

where the field is in units of statvolt/cm and $c = 2.998 \times 10^{10}$ cm/sec. Conversion between mks and cgs for the electric field is $3 \times 10^4 \text{ V/m} = 1 \text{ statvolt/cm}$; irradiance is converted using $1 \text{ erg}/(\text{cm}^2 \text{ sec}) = 1 \times 10^{-3} \text{ W/m}^2$. The following point must be emphasized: depending on how the electric field is defined, there can be factors of 2 or even 4 discrepancies in the irradiance values quoted by different authors. The common definitions are used here, although they are certainly not universal.

A very common realization of the spatial irradiance profile of a laser beam is the radially symmetric Gaussian function:

$$I(r) = I_0 \exp\left(-\frac{2r^2}{w^2}\right) \quad (5)$$

where I_0 is the peak irradiance at the center of the beam ($r=0$) and w is the 'spot size'. The spot size changes continuously as the beam propagates and the minimum spot size is known as the waist. One often hears the spot size referred to as the radius, but the radius of a Gaussian beam traditionally denotes the curvature of the phase front. By definition, the phase front radius is infinite at the waist. The factor of 2 appearing in the argument of the exponential in Eq. (5) stems from the fact that the spot size w is conventionally defined for the electric field of the Gaussian beam. When the field is squared to obtain the irradiance, the factor of 2 appears. Using this function for the irradiance spatial profile leads to the common parameter '1/e² diameter'. The irradiance falls to 1/e² (0.1353) of its peak value when $r=w$.

The Gaussian spatial profile or 'Gaussian beam' results when the laser has been designed to operate in the lowest-order transverse mode, usually denoted TEM₀₀. The TEM₀₀ Gaussian beam is particularly convenient because the same relative power profile is maintained in the near- and far-field, whether or not the beam is collimated or focused.

The cross-sectional area of a TEM₀₀ Gaussian beam normally incident on a surface is found as follows. The power in the beam is obtained by integrating the irradiance profile (I) over the surface:

$$P = \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} I dA \quad (6)$$

Referring to Eq. (5), the integral becomes:

$$P = \int_0^{2\pi} d\theta \int_0^{\infty} r dr I_0 \exp\left(-\frac{2r^2}{w^2}\right) = I_0 \frac{\pi w^2}{2} \quad (7)$$

Hence the effective area of a TEM₀₀ Gaussian beam normally incident on a surface is:

$$A = \frac{\pi w^2}{2} \quad (8)$$

There are many situations where the Gaussian formulation of Eq. (5) is not suitable. Beams produced by unstable laser resonators, for example, are not Gaussian. A multitransverse mode beam profile obtained from a stable resonator does not usually lend itself to a simple mathematical characterization.

Nomenclature Associated with the Nonlinear Optical Medium

In nonlinear optics texts, the subject is often introduced by writing the macroscopic polarization in Maxwell's equations as a power series expansion in the electric field. This approach, proposed by Bloembergen and coworkers in the early 1960s, has been spectacularly successful for interpreting experiments, though it has also led to confusion in the definition of nonlinear optical coefficients. The confusion, which stems from arbitrary definitions and nomenclature used by different authors, cannot be resolved here. The reader should, however, be alert for these discrepancies. Comparison of results published by different laboratories requires that the fundamental equations for extracting the nonlinear coefficients from their data are known. As the discipline has matured, the nonlinear optics community largely recognized the ambiguities and confusion; precise definitions of terms and coefficients are now commonly provided in the research literature.

It should also be noted that the power-series framework may not always be the best formulation for modeling and characterizing nonlinear optical effects. A carefully designed optical limiter, for example, may exhibit an abrupt decrease of transmission at a specific 'threshold irradiance' or 'threshold fluence', perhaps at a given laser pulse duration. The physical phenomenon or phenomena driving this behavior may not readily succumb to characterization by an n th-order coefficient in a power series expansion. In this situation it may be appropriate to specify a threshold optical input parameter. Another example is a homogeneously broadened saturable absorber, in which the absorption of an optical medium decreases with increasing input irradiance. The irradiance-dependent absorption coefficient α (refer to Eq. (26)) is characterized by a 'saturation irradiance' I_{sat} :

$$\alpha(I) = \frac{\alpha_0}{1 + \frac{I}{I_{\text{sat}}}} \quad (9)$$

where α_0 is the linear absorption coefficient.

Nonlinear Susceptibility

The power-series expansion of the macroscopic polarization is the standard approach for modeling nonlinear optical behavior and categorizing the various phenomena. A common way to write the polarization, nonlinear in the electric field, is (mks units):

$$\mathbf{P} = \epsilon_0(\chi^{(1)} \cdot \mathbf{E} + \chi^{(2)} : \mathbf{E}\mathbf{E} + \chi^{(3)} : \mathbf{E}\mathbf{E}\mathbf{E} + \dots) \quad (10)$$

where the polarization $\mathbf{P}$ is a time- and space-dependent vector and the terms $\chi^{(n)}$ are the various orders of the nonlinear susceptibility (the cgs equation is obtained by dropping the free-space permittivity coefficient ϵ_0). A second-order effect is associated with $\chi^{(2)}$, a third-order with $\chi^{(3)}$, and so on. In general, there are distinguishable electric field vectors (in Eq. (10), the fields have not been individually designated for clarity). The susceptibility terms are generally tensors, which means the medium is sensitive to the orientation of the input fields. The dots in Eq. (10) indicate tensor products. The input field vectors can have different frequencies and the presence of complex conjugates in Eq. (1) indicates that the frequency components will have both + and - signs, i.e. the j th electric field term will have associated frequency factors $\exp(\pm i\omega_j t)$.

The nomenclature used here can be illustrated by example. In the case of the second-order nonlinear polarization (mks units):

$$\mathbf{P}_j = \epsilon_0 \chi_{jkl}^{(2)} : \mathbf{E}_k \mathbf{E}_l \quad (11)$$

Note that subscripts have been introduced. The indices correspond to Cartesian space vectors. This equation says that the polarization in the j -direction results from the tensor product of the appropriate $\chi^{(2)}$ with the input fields at $\mathbf{E}_k$ and $\mathbf{E}_l$. The j th component of polarization has an oscillation frequency that is determined by mixing of the input fields. In this example, the indices j , k and l can each take the value of x , y , and z . Let each input field be at one of two possible frequencies, call them ω_1 and ω_2 . There are an enormous number of permutations (81 to be exact) of Eq. (11). One term is:

$$P_x(\omega_1 + \omega_2) = \epsilon_0 \chi_{xyz}^{(2)}(\omega_1 + \omega_2) E_z(\omega_1) E_y(\omega_2) \exp[-i(\omega_1 + \omega_2)t] \quad (12)$$

Another possibility is:

$$P_z(\omega_2 - \omega_1) = \epsilon_0 \chi_{zyx}^{(2)}(\omega_2 - \omega_1) E_y(\omega_2) E_x(-\omega_1) \exp[-i(\omega_2 - \omega_1)t] \quad (13)$$

Eq. (12) corresponds to sum frequency generation ($\omega_1 + \omega_2$) and Eq. (13) shows difference frequency generation ($\omega_2 - \omega_1$).

Not explicitly written on the right-hand side of the above equations is the exponential containing the mixing of the propagation vectors. To maximize the nonlinear polarization, which is the source of nonlinear behavior in Maxwell's equations, the

vector sum $\sum \mathbf{k}_j$ for *all* the interacting fields should be close to zero. Arranging the propagation vectors to accomplish this is known as ‘phase matching’.

It is important to point out that there are eight more terms describing the nonlinear polarization at $P_x(\omega_1 + \omega_2)$ in addition to Eq. (12); likewise for $P_z(\omega_2 - \omega_1)$. Also note that the indices k and l may be identical, hence a nonlinear polarization driven by $\chi_{xy}^{(2)}$ for example, is allowed. Higher-order nonlinear polarizations get progressively more complicated. The general third-order nonlinear polarization is

$$\mathbf{P}_j = \epsilon_0 \chi_{jklm}^{(3)} : \mathbf{E}_k \mathbf{E}_l \mathbf{E}_m \quad (14)$$

Sometimes the second-order nonlinear susceptibility is written with the coefficient d instead of $\chi^{(2)}$. The relation between the d -coefficient and $\chi^{(2)}$ depends arbitrarily on how it is defined; a common definition is

$$d_{jkl} = \frac{1}{2} \chi_{jkl}^{(2)} \quad (15)$$

but the reader is cautioned that the factor $\frac{1}{2}$ is sometimes missing. In the preceding discussion it was pointed out how there can, in principle, be a large number of tensor components involved in the expansion of the nonlinear polarization. Simplification occurs when it is realized that there is no discernible physical difference between the frequency terms ω_j and $-\omega_j$ and that ordering of the fields in Eq. (14) – which suggests a time order in the arrival of the fields – is irrelevant. These symmetry arguments show that $d_{jkl} = d_{jlk}$, which reduces the number of independent d -coefficients from 81 to 18. A simpler subscript notation is then introduced that uses the integers 1–6 to represent pairs of Cartesian components k and l . This reduces the number of subscripts from three to two. An example of this notation is $d_{xxz} = d_{14}$.

In certain situations, one can take advantage of crystal symmetry to further reduce the complicated summations to a single scalar coefficient for the nonlinear susceptibility, which is referred to as ‘ d -effective’. For these specialized cases, the nonlinear polarization is

$$\mathbf{P} = \epsilon_0 d_{\text{eff}} \mathbf{E}_1 \mathbf{E}_2 \quad (16)$$

In SI/mks units, the polarization is in units of coul/m². The second-order susceptibility (i.e. $\chi^{(2)}$, d_{jkl}) must therefore have units of m/volt. The units of $\chi^{(3)}$ are m²/volt², $\chi^{(4)}$ is m³/volt³, and so on. In Gaussian/cgs units, $\chi^{(2)}$ has dimensions cm/statvolt, $\chi^{(3)}$ will be cm²/statvolt², etc. although sometimes in the Gaussian system *all* the coefficients $\chi^{(n)}$ are discussed with shorthand ‘electrostatic units’ or ‘esu’.

Complex Quantities

In linear optics, the susceptibility has real and imaginary parts

$$\chi^{(1)} = \chi_{\text{real}}^{(1)} + i\chi_{\text{imaginary}}^{(1)} \quad (17)$$

The complex linear index is, in turn, written as the sum of real and imaginary components, derived from the linear susceptibility as follows (mks units):

$$\sqrt{1 + \chi^{(1)}} = n_0 + i\kappa \quad (18)$$

where n_0 is the linear refractive index and κ is the imaginary term leading to absorption of light. In general, the nonlinear susceptibility $\chi^{(n)}$ is also a complex number:

$$\chi^{(n)} = \chi_{\text{real}}^{(n)} + i\chi_{\text{imaginary}}^{(n)} \quad (19)$$

As in linear optics, the complex notation is a bookkeeping method that conveniently accounts for what is known as ‘resonant enhancement’. Nonlinear optics research has revealed that the nonlinear susceptibility $\chi^{(n)}$ can be a strong function of frequency. Specifically, this quantity will be strongly enhanced when sums and/or differences of the photon energies in the interacting light beams coincide with quantum mechanical energy resonances in the material. When a resonance condition is achieved, $\chi^{(n)}$ will be dominated by its imaginary component. Far from the resonances, $\chi^{(n)}$ behaves more like a real quantity. These complex terms directly enter the wave equations describing how light propagates in a nonlinear medium and are particularly important for $\chi^{(3)}$; the complex quantity $\chi^{(3)}$ determines whether light will be refracted or absorbed and by how much. The real part of $\chi^{(3)}$ drives nonlinear refraction while the imaginary portion characterizes nonlinear absorption (e.g., two-photon absorption) and the inverse effect – gain.

Nonlinear Refraction

The most common manifestation of nonlinear refraction arises from the third-order nonlinear susceptibility, the so-called optical Kerr effect. In this case, the refractive index is linearly proportional to the irradiance (I) of a monochromatic light beam. The irradiance-dependent refractive index is

$$n(I) = n_0 + n_2 I \quad (20)$$

where n_0 is the linear, irradiance-independent refractive index and n_2 is the nonlinear refractive index coefficient. Because n is a dimensionless quantity, n_2 must be in units of area/power.

The optical Kerr effect is usually written in mks units with the expression shown in Eq. (20). In cgs units, the common (but by no means universal) convention is to write:

$$n(E) = n_0 + \frac{1}{2} \tilde{n}_2 |E|^2 \quad (21)$$

where the field is in units of statvolts/cm. The nonlinear coefficient $\tilde{n}_2$ (cgs) must therefore be in units of $\text{cm}^2/\text{statvolt}^2$, which is sometimes abbreviated to 'esu'. The conversion for n_2 between these two equations is:

$$\tilde{n}_2(\text{cgs}) = \frac{n_0 c}{40\pi} n_2(\text{mks}) \quad (22)$$

where $n_2(\text{mks})$ is in units of m^2/W and c is in m/sec. Also useful is the relation between n_2 and $\chi^{(3)}$, written in mks units as:

$$\Delta n = n_2 I = \frac{\text{Re}(\chi^{(3)})}{4\epsilon_0 n^2 c} I \quad (23)$$

where 'Re' denotes the real part of $\chi^{(3)}$. In cgs units we have:

$$\Delta n = \frac{1}{2} \tilde{n}_2 |E|^2 = \frac{4\pi^2 \text{Re}(\chi^{(3)})}{n^2 c} I \quad (24)$$

where I is in units of $\text{ergs}/(\text{cm}^2 \text{ sec})$ defined by Eq. (4). The reader is again advised that different authors will show discrepancies of 2, 4, or even 8 when writing these equations. The susceptibilities $\chi^{(3)}$ are related as follows:

$$\tilde{\chi}^{(3)}(\text{cgs}) = \frac{9 \cdot 10^8}{4\pi} \chi^{(3)}(\text{mks}) \quad (25)$$

If the coefficients n_0 and n_2 exist, does the nomenclature imply there are terms n_1 , n_3 , and others? These coefficients are certainly allowed, but not often seen in discussions of nonlinear refraction. When one refers to nonlinear refraction, the common understanding is that the index depends linearly on irradiance, which is conveniently modeled by Eq. (20). But there are other physically relevant situations to consider. The coefficient n_1 , for example, describes the linear electro-optic effect in which the change in index is linearly proportional to the electric field (although it is called the linear electro-optic effect, it is actually derived from the second-order nonlinear susceptibility). The electric field can be the oscillating field of a laser beam, for example, or a dc field applied to an electro-optic crystal (e.g., Pockel's cell). When other terms are added to Eqs. (20) or (21), the units of the coefficients must be chosen to keep the equation dimensionless.

In the preceding discussion, there is an implication that the nonlinear index is an instantaneous function of the irradiance or field. Although the material system can never respond instantaneously, this is a good approximation in many situations. Sometimes it is not. Consider a pulsed laser beam that heats the material. When the local temperature increases, the linear refractive index can change. A short, Q-switched laser can have a pulse duration far less than a microsecond, while the temperature change it induces can last many orders of magnitude longer. This means optical modification of the refractive index may persist long after the exciting pulse has vanished, i.e., when the irradiance is at zero.

Another example is when a laser beam promotes electrons from their ground state to higher energy states of the material system. These excited electrons may modify the refractive index of the material. In general, the excited electrons remain in high-energy states for some period of time before relaxing to the ground level – if this time is longer than the excitation, the change of the refractive index persists beyond the time the laser beam is present. In these situations, the model of nonlinear refraction suggested by the above equations is inaccurate. One cannot obtain the nonlinear refraction from a simple algebraic analysis. A system of time-dependent equations – describing the dynamics of excitation and relaxation – must be solved using numerical procedures. Such phenomena are sometimes loosely categorized as 'dynamic linear optical effects' or 'effective third-order nonlinearities'.

Nonlinear Absorption

Consider a single-frequency light beam passing through an optically absorbing region of length L . For simplicity, neglect reflections caused by surfaces that may define the region of interest, i.e., ignore reflections at surfaces that may be located on the optical axis z at points $z=0$, $z=L$, or any other point in the path. Linear absorption means that the optical power extracted from the light beam as it traverses the absorbing medium is a direct function of the power at a given point. This is described mathematically by an elementary, linear differential equation known as Beer's law:

$$\frac{d}{dz} I(z) = -\alpha I(z) \quad (26)$$

The constant of proportionality is α , which is the linear absorption coefficient. Eq. (23) is solved by direct integration:

$$\int_{I(0)}^{I(L)} \frac{dI}{I} = -\alpha \int_0^L dz \quad (27)$$

Table 1 Dimensions of optical absorption coefficients

Process	Coefficient	Units
Linear absorption	α, K_1	$(\text{length})^{-1}$
Two-photon absorption	β, K_2	$\text{length}/\text{power}$
Three-photon absorption	γ, K_3	$\text{length}^3/\text{power}^2$
Four-photon absorption	K_4	$\text{length}^5/\text{power}^3$

This has the solution:

$$\frac{I(L)}{I(0)} = \exp(-\alpha L) \quad (28)$$

which means the irradiance decreases exponentially as a function of propagation distance in a linearly absorbing medium.

In the nonlinear regime, we don't expect a classical Beer's law model to hold. By definition, the absorption will be a nonlinear function of irradiance at a given point. One makes the following power-series expansion to describe nonlinear absorption of monochromatic light:

$$\frac{d}{dz}I = -\alpha I - \beta I^2 - \gamma I^3 - \dots \quad (29)$$

The coefficient β corresponds to a two-photon absorption process and γ is the coefficient of three-photon absorption. What about four-photon and even higher-order processes? These are rarely encountered, but certainly possible. To make these distinctions, [Eq. \(29\)](#) is sometimes written with coefficients K_i or α_i instead of the sequential Greek alphabet:

$$\frac{d}{dz}I = -K_1 I - K_2 I^2 - K_3 I^3 - K_4 I^4 - \dots \quad (30)$$

The units of the various absorption coefficients must maintain the dimensional consistency of [Eqs. \(29\)](#) and [\(30\)](#), which is irradiance/length or power/(length)³. These are shown in [Table 1](#).

If there is linear absorption, the nonlinear processes at that wavelength are often (but not always) negligibly weak. This means we have the following inequalities:

$$K_1 I \gg K_i I^i, \quad \text{where } i \geq 2 \quad (31)$$

Nonlinear absorption is generally observed in the wavelength region where the medium is transparent to low-irradiance light, i.e., where linear absorption is negligible. It should be emphasized that there are situations where linear absorption is large and in fact a crucial component of the aggregate nonlinear effect. We will return to this point later in the discussion. For the moment, we neglect linear absorption. If the energy of the incident photons and energy levels of the system permit it, the lowest-order nonlinear process is two-photon absorption, described by the equation

$$\frac{d}{dz}I = -K_2 I^2 \quad (32)$$

which can be solved by elementary integration:

$$\frac{I(L)}{I(0)} = \frac{1}{1 + I(0)K_2 L} \quad (33)$$

Unfortunately, the situation is rarely this convenient. The above integration has ignored the fact that nonlinear absorption may enable significant linear absorption. This is possible because nonlinear absorption promotes electrons from low- to high-energy states in the medium. The change in excited electron density associated with absorption of light (both linearly and nonlinearly) is called 'photocarrier generation'. These photocarriers (e.g., photo-electrons) may modify the linear absorption as well as the refractive properties of the material. If two-photon absorption causes the linear absorption to increase, for example, the assumption that allowed us to ignore K_1 when writing [Eq. \(32\)](#) ceases to be valid. While [Eq. \(32\)](#) was appropriate at the very start of the light-matter interaction, the generation of photocarriers after the passage of time may change that condition. The behavior of the system is therefore time-dependent, i.e., it is dynamic. Simple analytic solutions are almost always not possible when dealing with nonlinear absorption.

The time rate of change of the photocarrier population (N) is modeled by the following equation:

$$\frac{\partial}{\partial t}N = \frac{K_1 I}{\hbar\omega} + \frac{K_2 I^2}{2\hbar\omega} + \frac{K_3 I^3}{3\hbar\omega} + \frac{K_4 I^4}{4\hbar\omega} + \dots - \text{recombination} - \text{diffusion} \quad (34)$$

where ω is the angular frequency ($\omega = 2\pi f$) of the incident light. Also included are place-holders for loss processes such as recombination and diffusion, which may themselves have complicated mathematical descriptions. The coefficients K_i have exactly the same units, dimensions, and interpretation as in [Eq. \(30\)](#) and [Table 1](#); in the spirit of the preceding discussion, these coefficients may be time dependent. Note that the dimensions of [Eq. \(30\)](#) describe absorption of light (irradiance/length), while [Eq. \(34\)](#) models the photocarrier population density (length⁻³ time⁻¹). The units of these two equations are very different.

Raman Spectroscopy

Introduction

Inelastic light scattering, the optical analogue of Compton scattering, had been predicted to occur by Smekal in 1923, but it was Chandrasekar Venkataraman Raman who provided the first experimental demonstration of the phenomenon in February 1928. Only a few months later in 1928 the Russian scientists, Landsberg and Mandelstam observed inelastic light scattering from a quartz crystal. In spite of initial claims to the contrary, this was the same effect that had been observed by Raman, although the Russian scientists did not acknowledge this, preferring to call the effect 'combinatorial scattering'. It was not until the 1970s that the effect became known as Raman scattering everywhere, including Russia.

As typically practised, Raman spectroscopy involves laser excitation of a sample and measurement of the wavelength and intensity distribution of the scattered Raman light. When a microscope is used for delivering laser excitation and/or collecting the inelastically scattered light, the technique is referred to as Raman microscopy. However, it is important to recognize that, apart from the differences in sampling configuration, there are no fundamental differences between Raman microscopy and Raman spectroscopy; the terms merely identify the different sampling techniques.

Since its invention in 1960, major advances in the technology of the laser have occurred, resulting in the wide variety of laser light sources that are currently available for Raman spectroscopy. Characteristic properties of laser systems for Raman microscopy will be described in this chapter, following an introduction to the technique and its applications in the next section below. Then, the commonly used laser sources for Raman microscopy are categorized according to the wavelength regions of their emissions, along with their merits and drawbacks for each application. The chapter will consider mainly continuous wave laser sources, because pulsed laser beams that are tightly focused with microscope optics give very high irradiance that would destroy most samples.

Raman Microscopy

The first experimental Raman microscopes were developed in the mid-1970s by two independent groups, and it was not long before the first generation of Raman microscopes were subsequently commercialized. Many of these early instruments simply consisted of commercial optical microscopes coupled to Raman spectrometers, as shown in Fig. 1. It was recognized that the use of a microscope for sampling in this way can facilitate the Raman examination of tiny particles of micrometer dimensions.

Fig. 1 Diagram of the optical layout of a visible Raman microscope. Reproduced from Turrell G, Delhay M and Dhamelincourt P (1996) Characteristics of Raman microscopy. In: Turrell G and Corset J (eds) *Raman Microscopy. Development and Applications*, 2. London: Academic Press.

The optical lay-out in Fig. 1 shows an infinity corrected microscope. The advantage of using this, rather than a standard tube length microscope, is that its length can be extended in order to incorporate additional optical elements that are required for coupling to the Raman excitation and collection optics. In the optical layout, the incident laser beam is spatially filtered by a pinhole, D_1 , in order to remove the diffraction rings and give a point source. The laser light is then partially reflected by beamsplitter, B_1 , and focused on to the sample by the microscope objective. The back-scattered Raman radiation is collected by the same microscope objective, partially transmitted by the beamsplitter, and directed into the entrance slit of the Raman spectrometer by means of coupling optics. The accurate location of an aperture, D_2 , at the focal point improves the spatial resolution and allows depth profiling of transparent samples. The two pinholes, D_1 and D_2 , act as spatial filters and are referred to as confocal diaphragms. The Raman microscope is described as being confocal, because out-of-focus light, collected from outside the focal volume, is rejected.

The use of the beamsplitter, in the optical path of early Raman microscope designs, gives rise to significant losses of the precious Raman scattered light. If a 50:50 beamsplitter is used then half of the incoming laser light is lost by transmission at B_1 and, more significantly, half of the Raman scattered light is lost by reflection at B_1 . As long as a higher laser power can be employed, it is better to use a 90:10 beamsplitter that transmits 90% of the light and reflects 10%; then, only 10% of the incoming laser light is directed by B_1 on to the sample, but 90% of the Raman scattered light is transmitted by B_1 towards the detector and only 10% of the Raman light is lost by reflection at B_1 . The efficiency of a beamsplitter can be defined as the product of the reflectivity at the laser wavelength and the transmission at the Raman-shifted wavelength. Thus, conventional 50:50 and 90:10 beamsplitters would have efficiencies of 25% and 9%, respectively. Recently, however, holographic notch filters have been developed which can be used as higher efficiency beamsplitters. These typically have a laser rejection contrast ratio of better than 10^4 , reflecting ca. 90% of the laser excitation and transmitting ca. 90% of the Raman scattered light, thus giving an efficiency of ca. 81%. Due to these considerations, higher throughput, commercial Raman microscope designs usually incorporate a holographic notch filter.

The importance of Raman microscopy stems from the fact that it is the only microanalytic method available today, by use of which it is possible to identify, or characterize, small particles of micrometer dimensions *in situ*. It is also advantageous that no sample preparation is required when performing Raman microscopy.

The fundamental limit of the lateral spatial resolution (i.e., for a diffraction limited focus) is the separation at which the maximum of one Airy disc function just touches the first minimum of an adjacent Airy disc, given by:

$$\text{Lateral spatial resolution} = \frac{1.22\lambda}{2NA} \quad (1)$$

where λ is the wavelength of the light and NA is the numerical aperture of the microscope objective.

The axial Airy disc function determines the resolution in the longitudinal direction. A good estimate of the axial resolution limit for low numerical aperture is given by:

$$\text{Axial spatial resolution} = \frac{2\lambda}{(NA)^2} \quad (2)$$

When the sample is heterogeneous and exhibits fluorescence that is not evenly distributed within the sample, a region of the sample can be selected with the microscope that shows the minimum amount of fluorescence. If the fluorescence is intrinsic to the sample itself, then it is possible to use the shift subtract technique and/or temporal discrimination between the fluorescence and the Raman scattering. The latter can be achieved by Kerr gate fluorescence rejection, in which a pulse of light is used to close a Kerr gate shutter. The problem with this approach, however, is that it uses a laser pulse, and even pulses of modest energy will have extremely high irradiance when focused to a tiny spot by a microscope objective. Such laser pulses would inevitably destroy the sample under a microscope.

Another approach for reducing fluorescence is to use near infrared excitation, which is low enough in energy so that absorption cannot occur to promote electronic transitions. The technique of Fourier Transform Raman (FTR) spectroscopy often offers the best chance of obtaining Raman spectra from fluorescent samples for this reason. Low energy excitation of wavelength equal to 1064 nm, provided by a Nd:YAG laser, is normally used for FTR. Disadvantages are that the Raman scattering efficiency is low relative to that obtained with visible excitation, due to the ν^4 dependency (ν^4 refers to Rayleigh scattering of the Raman light). This is compensated to some extent by employing a high throughput (Jacquinot advantage) interferometer. However, this works better for macro rather than micro samples. This is because the coupling of a microscope to an FT Raman spectrometer has a fundamental drawback; the microscope is throughput limited, so the high throughput advantage of the FTR spectrometer cannot be realized in FTR microscopy. The image of the Jacquinot stop (the large circular aperture which is the entrance to the interferometer) at the sample plane typically has a diameter of a few hundred μm , which is much larger than particles with diameters of ca. 1 μm having similar dimensions to the waist diameter of the 1064 nm light excitation at its diffraction-limited focus. Consequently the throughput advantage of the interferometer is not fully exploited and there is a trade-off of spatial resolution with signal-to-noise at the detector. For this reason, the typical spatial resolution that is achieved is in the range of 15–100 μm rather than 4 μm , as claimed in the literature. Bruker has commercialized an FTR microscope by coupling an optical microscope to an FTR spectrometer with near infrared optical fibers.

An approach that offers more promise for reducing fluorescence and achieving spatial resolution close to the diffraction limit is to use near infrared excitation in conjunction with dispersive Raman microscopy. For example, semiconductor lasers operating

from 785 to 852 nm can be used in conjunction with sensitive multichannel silicon-based CCD arrays. If longer excitation wavelengths are necessary, in order to overcome the problems with fluorescence, then diode lasers can be used that emit at longer wavelengths in conjunction with dispersive Raman spectrometers equipped with multichannel near infrared (NIR) detectors, e.g., Ge- or InGaAs-array detectors.

The applications of Raman microscopy cover many areas, including material science, the earth sciences, environmental science, biology and medicine, forensic science, and even the analysis of artworks. These areas are too wide ranging to be described in detail here, but the interested reader is referred to the Further Reading section at the end of this article.

Characteristics of Laser Sources

The laser is an excellent light source for Raman spectroscopy to such an extent that the terms 'Raman spectroscopy' and 'laser Raman spectroscopy' are synonymous for all but the most esoteric experiments, for example, with synchrotron sources. Indeed, the advent of the laser was the stimulation for the renaissance of Raman spectroscopy in the 1960s, given its special properties, such as monochromaticity, high intensity, beam collimation, and coherence.

The characteristics of laser light and the advantages it offers to Raman microscopy are now considered.

Beam Quality

The light inside a laser tube is formed from a number of standing waves having distinct vibrational modes. There are a limited number of these modes transverse to the beam and these are characterized by the TEM_{pq} number (where p and q can be 0, 1, 2, ...) where TEM is an acronym for 'transverse electromagnetic'. When a laser is operating in its fundamental TEM_{00} mode, light rays are reflected on axes between the end mirrors of the laser cavity. The '00' indicates that there are no nodes in the beam profile (Fig. 2(a)), and the laser beam has a Gaussian intensity profile in the radial direction:

$$I(r) = I_0 \exp\left(-\frac{2r^2}{w^2}\right) \quad (3)$$

where $I(r)$ is the irradiance at a radial distance r from the axis of the beam, I_0 is the axial irradiance, and w is the beam radius.

Fig. 2 Transverse electromagnetic modes formed with confocal concave mirrors, (a) TEM_{00} , and (b) TEM_{11} . Reproduced with permission from Young M (1977) *Optics and Lasers: an Engineering Approach*. Berlin, Heidelberg: Springer-Verlag.

For higher-order modes, a number of nodes are observed in the beam profile, which arise from off-axis light rays being reflected between the end mirrors, for example, the TEM₁₁ mode has two nodes which are mutually perpendicular (Fig. 2(b)).

The propagation characteristics of a Gaussian beam can be fully defined, either by the diameter of the beam waist or by the far-field divergence. Consequently, it is only necessary to know the diameter of the beam waist ($2w_0$), or the diameter of the beam ($2w_z$) at a longitudinal distance z from the waist, in order to determine the propagation characteristics of the beam:

$$w(z) = w_0 \sqrt{1 + \left(\frac{z}{z_R}\right)^2} \quad (4)$$

$$R(z) = z \left[1 + \left(\frac{z_R}{z}\right)^2 \right] \quad (5)$$

where the quantity $z_R = \pi w_0^2 / \lambda$ is known as the Rayleigh range of the beam, λ is the wavelength of the laser radiation, and $R(z)$ is the radius of curvature of the wavefront at a distance z from the beam waist.

The wavefront is planar at the minimum beam waist and the Rayleigh range is the distance from the beam waist to the location at which the wavefront is most curved (Fig. 3), the region from the waist to the Rayleigh range being the near field. Beyond approximately ten times the Rayleigh range, in the far field, the beam diverges as a cone with approximately straight sides. It can be seen by substituting $z = z_R$ into Eq. (4) that the beam diameter at the Rayleigh range is $\sqrt{2}$ times the waist diameter.

Unfortunately laser beams do not conform to pure Gaussian functions and therefore they do not propagate according to the above equations. As a result, a dimensionless beam propagation parameter was devised in the early 1970s. This parameter, known as the M^2 factor or the 'times diffraction limit', is based on the brightness theorem, which states that for any laser beam the product of the beam diameter and the far-field divergence is a constant. Thus, M^2 is defined as the ratio of the laser beam's multimode diameter-divergence product to the ideal diffraction-limited (TEM₀₀) beam diameter-divergence product:

$$M^2 = \left(\frac{2w_m \Theta_m}{2w_0 \theta_0} \right) \quad (6)$$

where Θ_m is the laser beam's multimode divergence, θ_0 is the theoretical diffraction-limited divergence, $2w_m$ is the laser beam's multimode waist diameter, and $2w_0$ is the ideal diffraction-limited beam waist diameter.

Alternatively, M^2 can be defined as the square of the ratio of the multimode beam diameter ($2w_m$) to the diffraction-limited beam diameter ($2w_0$):

$$M^2 = \left(\frac{2w_m}{2w_0} \right)^2 \quad (7)$$

The intensity of the beam has a Gaussian distribution in the radial direction, but the accepted definition of beam diameter is the distance at which the intensity has fallen to $1/e^2$ (i.e., ca. 13.5%) of its axial intensity, as can be seen by setting $r = w$ in Eq. (3) above. This definition only applies properly to Gaussian beams; for other beam profiles the diameter can be calculated using a second moment measurement of the entire beam.

The real beam, then, can be treated as Gaussian by substituting an artificial wavelength $M^2 \lambda$ into the equations that apply to an ideal diffraction-limited TEM₀₀ beam. The ideal TEM₀₀ Gaussian can be superimposed as an 'embedded Gaussian' on the optical

Fig. 3 The Rayleigh range and embedded Gaussian. Adapted from http://beammeasurement.mellesgriot.com/tut_m2.asp.

diagram of the real multimode beam (Fig. 3). It can be seen that the multimode beam has a waist diameter and a divergence that are both M times larger than those of the embedded Gaussian.

The M^2 factor has a value of unity for an ideal diffraction-limited TEM₀₀ beam, and values of greater than unity for all other beams; it can be as high as several hundred for a distorted beam of poor quality. This is an important parameter where a tightly focused laser spot (e.g., confocal Raman microscopy) or low divergence (e.g., remote sensing) are required.

Polarization

Although polarization is not an inherent property of laser light, lasers provide plane polarized light when the end windows of the laser tube are mounted at Brewster's angle (θ_B):

$$\theta_B = \tan^{-1} n \quad (8)$$

where n is the refractive index of the window material for the appropriate wavelength of laser light. For this angle, reflected light is completely plane polarized and consequently the laser light that is generated is also plane polarized. Brewster windows are often used inside the laser cavity in order to reduce reflection losses. This is important in low-gain lasers such as HeNe lasers where laser action could be prevented by reflection losses. Air-cooled ionic gas lasers typically deliver highly linearly polarised output with ratios exceeding 1000:1.

The polarization property of the exciting light is used a great deal in Raman spectroscopy. In combination with the polarization properties of the Raman scattered light, it can be used to determine the depolarization ratios, ρ , of Raman bands in the solution state. In solid state studies it can be used to determine the degree of orientation, for example, in polymeric fibers or films, and in single crystal studies it can be used to determine the symmetry classes of the Raman active vibrations. In such studies a linear polarizer is used to improve the degree of plane polarization of the laser light, and a half-wave plate is used to rotate the plane of polarization by 90° .

Plane polarized laser light can be converted to circularly polarized laser light which is required for Raman optical activity (ROA) studies. For example, plane polarized 514.5 nm laser light provided by an argon ion laser can be converted to circularly polarized light by an electro-optic modulator. As CCD detectors are usually employed in present-day ROA experiments and they have relatively long sampling times, slow polarization modulation is required which can be achieved by periodically rotating a quarter-wave plate or by applying a square quarter-wave voltage to a Pockels cell.

Whereas optical isomers or enantiomers give identical Raman spectra, they are distinguished in the ROA experiment by the sign of the ROA signal. Indeed, the sign can be used to determine the absolute configuration of a chiral molecule. Also the enantiomeric excess of mixtures of enantiomers can be determined in such experiments, with obvious applications in the pharmaceutical industry, and the conformations of biological molecules, for example, proteins, nucleic acids, sugars, and viruses, can be determined.

Up until now, the ROA technique has been practised by no more than a handful of research groups world-wide, but it is expected that this situation will change in the near future, since the first commercial ROA spectrometer (the ChiralRAMAN spectrometer) has recently been launched by Biotools Inc. This spectrometer makes use of a solid state laser as the source of the polarized laser light.

Beam Divergence

Referring to Fig. 3, the full divergence angle, Θ , for the fundamental TEM₀₀ Gaussian beam is given by:

$$\Theta = \lim_{z \rightarrow \infty} \frac{2w(z)}{z} = \frac{2\lambda}{\pi w_0} \quad (9)$$

From Eq. (4) it can be seen that the spot size increases linearly with the longitudinal distance z and, from Eq. (9), that it diverges at a constant cone angle, Θ . It can also be seen from Eq. (9) that the smaller the spot size, w_0 , the greater the beam divergence angle, Θ .

Indeed, a highly divergent beam is a problem with edge-emitting laser diodes due to the small dimensions of the light source. Furthermore, it is much smaller in the vertical direction than in the horizontal, giving rise to an elliptical output beam that diverges much more rapidly in the vertical direction than in the horizontal. The highly divergent, elliptical beam can be corrected, to an extent, with a cylindrical lens, but the inherent problem of a small, elliptical source can never be completely corrected.

In contrast, vertical-cavity surface-emitting semiconductor lasers (VCSELs) do not have the same limitations on beam divergence because the cavity is in the vertical direction and the light emission occurs from the surface, which has a much larger area than the light source of an edge emitter. Indeed, frequency-doubled green and blue semiconductor lasers are now available, having beams with M^2 values of less than 1.1 and beam divergences of a few milliradians. In terms of these beam characteristics, it appears that these lasers are beginning to challenge the argon ion laser.

Emission Linewidth

The laser linewidth limit, $\Delta\nu_L$, is given by the Schawlow–Townes expression:

$$\Delta\nu_L = \frac{2\pi h\nu(\Delta\nu_c)^2}{P_{\text{out}}} \quad (10)$$

where $\Delta\nu_c$ is the linewidth of the passive resonator, $h\nu$ is the photon energy, and P_{out} is the laser power output.

The power output, P_{out} , is equal to the number of photons, N_p , in the resonator times the energy per photon, $h\nu$, divided by the photon lifetime, τ_c :

$$P_{\text{out}} = \frac{N_p h\nu}{\tau_c} \quad (11)$$

Furthermore, the width $\Delta\nu$ of the resonance curve, at which the intensity has fallen off to half the maximum value, is given by:

$$\Delta\nu_c = (2\pi\tau_c)^{-1} \quad (12)$$

Substituting for P_{out} and $\Delta\nu_c$ from Eqs. (8) and (9) into Eq. (10) gives the limit for the linewidth, $\Delta\nu_L$:

$$\Delta\nu_L = \frac{\Delta\nu_c}{N_p} \quad (13)$$

The linewidth of a laser is characterized by its Q factor:

$$Q = \frac{\nu}{\Delta\nu} \quad (14)$$

where ν is the frequency of the laser line and $\Delta\nu$ is the linewidth.

Other useful relationships involving linewidth parameters are:

$$Q = \frac{\lambda}{\Delta\lambda} \quad (15)$$

and

$$\Delta\tilde{\nu} = -\frac{\Delta\lambda}{\lambda^2} \quad (16)$$

where λ and $\Delta\lambda$ are the wavelength and linewidth (in units of metres), respectively, and $\Delta\tilde{\nu}$ is the linewidth expressed as a wavenumber (in units of cm^{-1}).

The Q factor can be as high as 10^8 which is of great use in high resolution spectroscopy.

Visible Lasers

Helium-Neon Laser

The helium-neon laser is continuously pumped electrically using a high dc voltage of up to 1 kV. The gain medium consists of a gas mixture of about 10 parts helium to each part of neon at a pressure of about 3 Torr. The gain of this medium is extremely low, hence the requirement for Brewster-angle windows to eliminate reflection loss of the light polarized in the plane that includes the axis of the laser and the normal to the Brewster window. Due to this requirement, the light output is necessarily plane polarized.

The pumping excites helium atoms by electron impact, and resonant energy transfer to neon atoms then occurs via collisions of the gaseous atoms (Fig. 4). This creates a population inversion in the neon atoms, enabling the laser transition to occur at 632.8 nm. Following emission, the neon atoms decay nonradiatively down to their metastable $2p^53s^1$ level from which they decay back down to the ground state via collisional de-excitation with the walls of the tube. This mechanism restricts the maximum achievable power output to ca. 50 mW, because of the need to depopulate the metastable neon atoms by wall collisions.

Fig. 4 Energy levels of the He-Ne laser.

An advantage of using helium-neon lasers for Raman spectroscopy is that they generally operate in the fundamental TEM₀₀ mode, which is critically dependent on the ratio of the length of the tube to its diameter. For this reason they are designed to have small tube diameters of around a few millimetres and lengths of 0.15–0.50 m, the small diameter also aiding collisional deactivation with the walls due to the relatively large surface to volume ratio of the tube. Another advantage of this laser for Raman spectroscopy is that the linewidth of the 632.8 nm emission line is ca. 1.5 GHz.

A disadvantage of the helium-neon laser is that it emits a large number of spontaneous emission lines originating from the excited neon atoms. These plasma emissions are observed in the Raman spectrum as sharp lines unless they are filtered out, for example, by a pre-monochromator or an interference filter. It should be mentioned, in passing, that these plasma lines are not always unwanted, because they can be very useful for wavenumber calibration of the Raman spectrometer.

The low output power of < 50 mW is not generally a disadvantage for Raman microscopy since higher laser powers can often cause photolytic or thermal degradation of the sample. This is due to the high irradiance at the sample when the laser light is focused to a tight spot by the microscope objective. The excitation wavelength of 632.8 nm is suitable for combined use of the laser with a silicon-based CCD detector in Raman spectroscopy, because large Stokes shifts in the 3000–4000 cm⁻¹ region lie well within the quantum efficiency curve of this detector. It is also possible, though less common, to operate the helium-neon laser on weaker transitions that include the green 543.5 nm line.

Argon Ion Laser

The argon ion laser was one of the first lasers to be discovered following the invention of the laser and up until now it has been used extensively for Raman spectroscopy, among many other applications. Excitation is provided by a continuous electrical discharge, and because of the high energy required to ionize the argon atoms and then promote the ions to an excited state, the efficiency of the laser is very small (ca. 0.1%). In spite of this, once population inversion has been achieved, the gain of the laser is very high and output powers of up to 25 W can be obtained for the strong lines at 488.0 and 514.5 nm and up to 50 W for multiline operation.

An advantage of the argon ion laser is that it can provide emission at more than 35 discrete wavelengths, the strongest of which are listed in Table 1. These lie in the green, blue, and near ultraviolet regions of the spectrum, a number of the ultraviolet lines only being obtained on the larger frame argon ion lasers. Discrete laser emission lines are selected by tuning a prism or grating inside the cavity. The argon ion laser can also be operated in multiline mode, for example, for pumping dye or Ti:sapphire lasers.

The linewidths of the argon ion emission lines at 488.0 and 514.5 nm are around 4.0 GHz. The high temperature laser tube has a diameter of approximately 12 mm and a length in the range of 0.1 to 1.8 m. A 240 V three phase power supply and ca. 35 A are required for pumping a medium power 5 W argon ion laser. The tube also requires water cooling at a flow rate of ca. 10 L/min and a pressure of 25 psi because of the large amount of heat dissipation.

Table 1 Continuous wave argon ion laser wavelengths and output powers for the Coherent Inc. Innova 300 argon ion laser system

Wavelength (nm)	Power (mW)
228.9	30
238.3	100
244.0	400
248.3	180
257.3	750
275.4	5
300–305.5	20
333.4	40
333.8	30
335.8	20
351.1	200
351.4	60
363.8	240
454.5	140
457.9	420
465.8	180
472.7	240
476.5	720
488.0	1800
496.5	720
501.7	480
514.5	2400
528.7	420

The five lines below 260 nm are frequency doubled.

For Raman microscopy smaller, air-cooled argon ion lasers, which only require a 240 V single phase power supply, can be used to provide output of a few hundred milliwatts on the 488.0 and 514.5 nm lines. For this application, the excitation is provided by argon ion lasers, which are designed to operate in the TEM₀₀ mode.

Until recently, the argon ion laser has been a workhorse as the most common excitation source for Raman spectroscopy, but it is now losing ground to solid state lasers. The principle reasons for this are that the latter are much more efficient and consequently do not in general have three phase power and water-cooling requirements. Nevertheless, argon ion lasers still have a niche when high excitation powers on the order of watts are required in conjunction with a good beam quality ($M^2 < 1.1$), for example, for Raman spectroscopy of gaseous samples. Another advantage of argon ion lasers over solid state lasers is their multiline capability.

Krypton Ion Laser

The krypton ion laser has useful discrete emission lines in the near ultraviolet, blue, yellow, red, and near infrared regions of the electromagnetic spectrum; the strongest lines of a Coherent Inc. Innova 400 krypton ion laser are listed in Table 2.

The argon ion and krypton ion lasers are close relatives, thus the large frame krypton ion laser has similar power and water-cooling requirements to those mentioned above for the argon ion laser. Also, like the argon ion laser, air-cooled models with lower power output are available. The characteristics of the two lasers are also similar; for example, the linewidths of the krypton ion transitions at 530.9, 568.2, and 647.1 nm are about 4.0 GHz, the laser tube has similar dimensions (0.1–2.0 m in length) and the laser can be operated in either TEM₀₀ or multimode.

The krypton ion laser is even less efficient than the argon ion laser, consequently lower-power outputs of up to about 20 W can be achieved when operated in multiline mode.

Mixed argon and krypton ion laser tubes are also commonly used that provide laser lines originating from both argon ion and krypton ion transitions. As with the individual argon ion and krypton ion lasers, sharp plasma lines, due to spontaneous emission from the rare gas ions, are observed in the Raman spectrum unless they are filtered out. If interference filters are used for this, each laser line requires its own filter that is tailored to the specific emission wavelength.

HeCd Laser

Laser lines at 325 and 442 nm, both capable of providing milliwatts of output power, can be obtained from the helium-cadmium laser. These emission lines result from electronic transitions in free cadmium atoms.

It is obviously advantageous to use blue, rather than longer wavelength, excitation (e.g., provided by the 442 nm line of the HeCd laser) for off-resonance Raman spectroscopy, due to the ν^4 dependence of the Raman light scattering efficiency, provided that the efficiencies of the illumination/collection optics and Raman spectrometer throughput are optimized in the blue region of the spectrum. Unfortunately, far more samples fluoresce when excited with blue light than with red or near infrared radiation, which explains why red or near infrared lasers (e.g., HeNe, semiconductor lasers) are more commonly used for general Raman applications.

Table 2 Continuous wave krypton ion laser wavelengths and output powers for the Coherent Inc. Innova 400 krypton ion laser system

<i>Wavelength (nm)</i>	<i>Power (mW)</i>
206.5	4
234	8
337.5–356.4	2000
406.7	900
413.1	1800
415.4	280
468.0	500
476.2	400
482.5	400
520.8	700
530.9	1500
568.2	1100
647.1	3500
676.4	900
720.8	45
752.5	1200
793.1–799.3	300

The 206.5 and 234 nm lines are frequency doubled.

Near Infrared Lasers

Although the traditional laser systems for Raman spectroscopy have been the argon ion, krypton ion, and helium-neon lasers for discrete excitation wavelengths, the diode laser has gained popularity over recent years.

The principal advantage of near infrared semiconductor lasers for Raman microscopy is that they generally excite less fluorescence in the Raman spectrum than visible lasers due to their longer wavelength. Commonly available wavelengths are 670, 785, 830, and 852 nm and, of these, the first two can be used in conjunction with silicon-based CCD detectors to give Stokes Raman shifts over the whole range of fundamental vibrations, up to 4000 cm^{-1} . However, for excitation wavelengths of 830 and 852 nm, only Stokes Raman bands in the fingerprint region can be detected with a silicon-based CCD detector because higher wavenumber Raman shifts approach the bandgap of the silicon semiconductor ($\lambda > \text{ca. } 1050\text{ nm}$).

The disadvantages of diode lasers are that they cannot supply high power of narrow linewidth in single-mode and they are susceptible to mode hopping which gives rise to a shift in the excitation wavelength. This latter drawback is particularly disadvantageous for Raman spectroscopy because it results in a shift in the wavenumber positions of the Raman bands. When good beam quality is not required, broad stripe, high power laser diodes can be used; these can have output powers that are greater than 1 W but their emission linewidths are equal to ca. 2 nm, which is far too wide for Raman spectroscopic applications. These laser diodes find applications as pumps of solid state lasers, for example, Nd:YAG, Nd:YVO₄ lasers, however. Additionally, amplified stimulated emission (ASE) gives an unwanted background signal that can be very broad (ca. 20–30 nm) and 0.1–1% of the intensity of the laser line. This necessitates the use of bandpass filters in order to reduce this unwanted background.

Although laser diodes having an output of less than 200 mW can operate in TEM₀₀ and in single longitudinal modes, mode hopping can occur due to optical feedback or fluctuations in environmental factors and this causes severe broadening of the linewidth. The sensitivity to optical feedback can be greatly reduced, hence the laser linewidth can be narrowed appreciably, by confining the frequency of the photons either in an internal cavity containing a small diffraction grating or in an external cavity. The former types of laser are sometimes called 'distributed feedback' (DFB) lasers because the feedback is distributed over the length of the grating, rather than occurring all at once at a mirror. The wavelength that is fed back is determined by the period of the grating. Usually, a DFB laser has a grating fabricated into the entire length of the laser. A variation referred to as a distributed Bragg reflector (DBR) laser has a distinct grating fabricated into the substrate on each side of the active area. The external cavity semiconductor laser (ECSL) is fabricated by placing the laser diode in a separate resonator like a conventional gas or solid-state laser. The DBR and ECSL lasers are now discussed.

Distributed Bragg Reflector Lasers

The DBR laser consists of a grating on each side of the active region (Fig. 5); these gratings act as mirrors having a reflectivity that is optimized at one particular wavelength, in addition to narrowing the laser linewidth. At present, DBR lasers are only commercially available having an excitation wavelength of 852 nm.

The emission linewidth is less than 4 MHz, which is suitable for the vast majority of Raman spectroscopic applications and the laser operates in single TEM₀₀ mode. The disadvantages of DBR lasers are that the maximum output power is restricted to around 150 mW, so an optical isolator is usually necessary in order to prevent external facet damage caused by external optical feedback, and only an excitation wavelength of 852 nm is currently available.

External-Cavity Semiconductor Lasers (ECSL)

ECSLs provide higher output power (up to ca. 1 W) and a wider range of excitation wavelengths (630 nm to around 850 nm), as well as being less expensive than DBR lasers. They use the semiconductor chip only as the gain medium and employ an external grating, both as the frequency selector and the reflective mirror. Specific excitation wavelengths are becoming widely adopted in Raman microscopy employing single grating spectrograph in conjunction with CCD detection, such as 670, 785, 830, and 852 nm. The ECSLs have emission linewidths as low as a few MHz, but in general they span the range 2 MHz–30 GHz, and can operate in a nearly diffraction-limited transverse mode.

Fig. 5 Diagram of the cavity of the DBR laser. Adapted from Pan M-W, Benner RE and Smith LM (2002) Continuous lasers for Raman spectrometry. In: Chalmers JM and Griffiths PR (eds) *Handbook of Vibrational Spectroscopy*, 1. Chichester, UK: Wiley.

Fig. 6 Diagrams of the cavities of (a) Littrow type-I, (b) Littrow type-II, and (c) Littman external cavity diode lasers. Adapted from Pan M-W, Benner RE and Smith LM (2002) Continuous lasers for Raman spectrometry. In: Chalmers JM and Griffiths PR (eds) *Handbook of Vibrational Spectroscopy*, 1. Chichester, UK: Wiley.

Three different cavity designs employing a diffraction grating have been discussed in the literature: Littrow type-I, Littrow type-II, and Littman configurations. In the Littrow type-I design, the laser diode light is incident on the grating at an angle of incidence equal to θ_{Littrow} (Fig. 6(a)). The diffracted light in first order is re-directed back to the laser diode to provide feedback and the output is the zeroth order (i.e., specularly reflected) light. A disadvantage of this design is that the bandwidth of the grating is relatively large because a single pass geometry is used. In the Littrow type-II design, light from the rear facet of the laser diode is collimated by a lens and directed on to a grating at an angle of incidence equal to θ_{Littrow} (Fig. 6(b)). The diffracted light in first order is re-directed back to the laser diode, in a similar fashion to the Littrow type-I design, in order to provide optical feedback, and the output is the laser light emitted from the front facet. Disadvantages of the Littrow type-II design are the requirement for custom fabrication of antireflection coatings on both facets and the sensitivity to external optical feedback. In the Littman design, the laser diode light is collimated by a lens and directed on to a grating at a grazing angle of incidence. The diffracted light is reflected by a mirror and diffracted back to the laser diode by the grating in order to provide optical feedback (Fig. 6(c)). An advantage of this design is that the grating bandwidth is less than half that of the Littrow designs due to the double pass geometry, but a disadvantage is that the external cavity length is longer, resulting in a narrower spacing of the cavity modes. Another advantage of this design is that the tuning is accomplished by rotating the mirror instead of the grating, thus the alignment of the output beam is not altered when tuning. For Littrow type I and II and Littman ECSL designs, filtering of the ASE is required, as it can have an intensity of ca. 0.1 to 1% of the intensity of the laser line. Thus, these designs necessitate the incorporation of a bandpass filter (having a rejection of better than 10^{-4} at the ASE).

Nd:YAG Laser

Under normal conditions, the Nd:YAG laser oscillates on a transition in the near infrared at 1064 nm, and this is the excitation line that is used in most commercial Fourier Transform Raman spectrometers. The gain medium is a crystal of yttrium aluminium garnet ($\text{Y}_3\text{Al}_5\text{O}_{12}$, YAG) doped with ca. 1.0 mol% Nd^{3+} cations that substitute Y^{3+} ions in the cubic YAG lattice.

The Nd:YAG laser is a four-level system (Fig. 7), which has high gain and low threshold due to the narrow fluorescent linewidth of the laser transition. Absorption bands of the Nd^{3+} ions around 808 nm conveniently match the energy of commercially available high-power multimode diode lasers that serve as the pump. The Nd^{3+} ions decay nonradiatively to the upper laser level, the $^4\text{F}_{3/2}$ state, thereby creating a population inversion. This is because the lower laser level, the $^4\text{I}_{11/2}$ state, has no appreciable thermal population at room temperature, since it is $>2000\text{ cm}^{-1}$ above the $^4\text{I}_{9/2}$ ground state, and the $^4\text{F}_{3/2}$ excited state has a relatively long lifetime of 230 μs .

The high thermal conductivity of Nd:YAG enables the laser to operate at high power in either continuous wave (CW) or Q-switched modes, and the diode pumped solid state (DPSS) variety of the cw Nd:YAG laser can currently achieve an output power in excess of 20 W on the 1064 nm line. The laser can be designed to operate in the fundamental TEM_{00} mode and the full width at half maximum (FWHM) linewidth of the spontaneous emission of the 1064 nm laser transition is 120 GHz (ca. 0.45 nm). Advantages of the diode pumped Nd:YAG laser are that it is air-cooled and can be operated at 240 V single phase.

Fig. 7 Energy levels of the Nd:YAG laser.

Also, being all solid state and having a small footprint, it is robust and portable. The lifetime of the laser is dependent on the laser diodes used for pumping, but some Nd:YAG laser designs enable these to be replaced in the field.

The frequency-doubled Nd:YAG laser emitting green light, having a wavelength of 532 nm, is also commonly used nowadays for dispersive Raman spectroscopy, and an output power of 10 W on the 532 nm laser line is provided by commercially available frequency-doubled diode-pumped Nd:YAG lasers.

It is worth mentioning that Nd:YAG lasers have also been fabricated that emit either at 946 or 1330 nm, by suppressing the strong emission at 1064 nm and optimising the optics for the desired wavelength.

Nd:YVO₄ and Nd:YLF Lasers

An intracavity, frequency-doubled DPSS Nd:YVO₄ laser has recently become commercially available, and it has some advantages over the Nd:YAG laser including a larger stimulated emission cross-section and a higher absorption coefficient (along the extraordinary direction of the birefringent crystal). It has the same emission wavelength as the frequency-doubled Nd:YAG laser, i.e., 532 nm, and Nd:YVO₄ is the material of choice for cw end-pumped lasers having around 5 W output power. This is because the diode laser pump beam is tightly focused in the end-pumped system, but a small waist diameter cannot be retained over a distance of more than a few millimeters, consequently a high absorption coefficient and gain are very beneficial.

The gain medium of the Nd:YLF laser consists of a crystal of yttrium lithium fluoride (YLF) that is doped with Nd³⁺ ions on the Y³⁺ cation sites. Unlike the Nd:YAG and Nd:YVO₄ lasers, the emission does not occur at 1064 nm; instead the ⁴F_{3/2}–⁴I_{11/2} emission occurs at wavelengths of either 1047 or 1053 nm, depending on the polarization that is selected. The former is due to extraordinary polarized light, whereas the latter is due to ordinary polarization, and either of these emission wavelengths can be selected using an intracavity polarizer. The Nd:YLF laser can offer benefits in Q-switched operation when the longer fluorescence lifetime (480 μs) of Nd³⁺ ions in the ⁴F_{3/2} state enables a higher energy to be stored for the same number of pump laser diodes.

Ti:Sapphire Laser

The Ti:sapphire laser is tunable over the approximate range of 670–1070 nm with the peak of the gain curve at ca. 800 nm. In the gain medium, ca. 0.1% by weight Ti³⁺ is doped into a crystal of sapphire grown by the Czochralski method. The Ti³⁺ ions substitute for Al³⁺ ions in the Al₂O₃ of the sapphire and the laser emission is due to the ²E–²T₂ transition of the Ti³⁺ cation, which has a 3d¹ valence electronic configuration (Fig. 8). The laser has a large stimulated emission cross-section but the fluorescence lifetime of the upper laser level (²E state) is quite short (3.2 μs), thus the laser is usually laser (e.g., by argon ion or frequency-doubled Nd:YAG or Nd:YVO₄ lasers) rather than flashlamp pumped because a very high pump flux is required.

The absorption and emission bands are broad and widely separated, due to the vibronic coupling between the Ti³⁺ host and the Al₂O₃ lattice (Fig. 9). The lower laser level is any one of the vibronic levels of the ²T₂ state. Following the laser transition, the Ti³⁺ ions decay from the upper vibronic levels of the ²T₂ state down to the lower vibronic levels. Hence, this is a four-level laser.

The broad spontaneous emission linewidth of the ²E–²T₂ laser transition is around 100 THz, the output power can be as high as 50 W, and the laser can be operated in either TEM₀₀ or multimodes.

UV Lasers

UV laser sources offer numerous advantages over visible laser sources for Raman spectroscopy. A major consideration is that many analytes have absorptions in the near UV, making them amenable to resonance Raman spectroscopic studies. The signal enhancement (up to 10^6), that can be achieved in resonance Raman spectra, results in a large increase in detection sensitivity. Furthermore, some vibrational modes, which normally give rise to weak bands in the off resonance Raman spectrum, can show strong enhancement in the UV excited resonance Raman spectrum. A good example of this is the amide II band of peptides and proteins, which is due to a combination of N–H in plane bending and C–N stretching modes of the peptide linkage. This band is normally weak in the Raman spectrum but strong in the infrared spectrum; however, the amide II band can show strong enhancement in the UV excited resonance Raman spectrum and this can be useful for determining secondary structure in proteins. A further benefit of UV excited Raman spectroscopy is that fluorescence can often be avoided as it tends to occur at a lower energy, outside the Stokes Raman spectral window.

It can be advantageous to use cw rather than pulsed excitation for UV resonance Raman spectroscopy, if the analyte has a long excited state lifetime relative to the pulsewidth of the pulsed laser. This is because the concentration of analyte molecules in the ground state is significantly depleted during pulsed excitation, due to Raman saturation giving a lower signal to noise ratio in the Raman spectrum than for the case of cw excitation. It has been found that pulse energy flux densities should be less than

Fig. 10 Diagram of the optical layout of a UV Raman microscope. Adapted from Pajcini V, Munro CH, Bormett RW, Witkowski RE and Asher SA (1997) UV Raman microspectroscopy: Spectral and spatial selectivity and simplicity. *Applied Spectroscopy* 51: 81–86.

1 mJ/cm² and flowing or spinning samples should be used, in order to ensure that nonlinear phenomena and saturation effects do not occur.

For UV Raman microscopy, where the laser beam is focused into a small spot of micrometer dimensions on the sample, it is essential to avoid using pulsed lasers delivering high peak powers. This is because such pulsed lasers can cause dielectric breakdown, and even at lower peak powers they can cause nonlinear effects and Raman saturation phenomena. Consequently, with UV Raman microscopy, one is restricted to the use of cw or quasicontinuous laser excitation.

It is only recently that high throughput UV Raman microspectrometers have been developed. It has been demonstrated for visible Raman spectroscopy that a significantly higher throughput can be achieved by employing a single stage spectrograph with a notch filter instead of a double or triple monochromator. In the UV region, blocking the Rayleigh scattering is a problem because notch filters are not currently available. However, it has been discovered that this can be overcome by introducing two modifications to the design of the optical layout of a visible Raman microscope. First, two novel dielectric longpass filters were used instead of a notch filter in order to reject the elastically scattered light. Second, an all-reflecting Cassegrain microscope objective was used, instead of a lens, in order to block the specular reflection, and thereby further reduce the Rayleigh scattering background. These design modifications have enabled a single stage spectrograph with a holographic grating to be used to disperse the Stokes Raman radiation in a UV Raman microspectrometer (Fig. 10).

In the optical layout of Fig. 10 it can be seen that the laser excitation is not focused by the Cassegrain microscope objective because an epi-illumination configuration is not employed. Instead the laser is focused by a separate lens and directed on to the sample with a turning prism located directly underneath the Cassegrain objective. This minimizes loss of laser beam throughput or scattered light throughput to the spectrometer at the expense of spatial resolution, since the laser light is focused by a longer focal length lens than the microscope objective. An additional difference between the optical layouts of the visible and UV Raman microscopes shown in Figs. 1 and 10, respectively, is that pinhole spatial filters are not shown in the latter. However, better axial spatial resolution could be achieved if this UV Raman microscope was made confocal by introducing a pinhole and lens.

Frequency-Doubled Argon Ion Laser

The frequency doubled argon ion laser is a popular choice among UV laser sources. The cw UV laser contains a nonlinear optical beta-barium borate (BBO) crystal, which is located within the laser cavity; this crystal frequency doubles the strong Ar⁺ lines to give five UV lines below 260 nm which are listed in Table 1 for the Coherent Inc. Innova 300 Ar⁺ ion laser system. Of these UV lines, the 228.9 nm line is almost ideal for resonance Raman enhancement of tyrosine and tryptophan residues in proteins and the 244.0 nm line is well suited for studying tyrosinate groups. The 244.0 nm line has also been used to excite selectively UV resonance Raman spectra from spatially resolved areas of biological samples within the nucleus of a single cell, from DNA in particular, using low laser powers and short acquisition times to keep sample damage to a minimum under the microscope.

Frequency-Doubled Krypton Ion Laser

Like the cw frequency-doubled argon ion laser mentioned above, the cw frequency-doubled krypton ion laser contains a nonlinear optical BBO crystal, which is located within the laser cavity; this crystal frequency doubles the strong Kr⁺ lines to give 206.5 and 234 nm UV lines which are listed in Table 2 for the Coherent Inc. Innova 400 Kr⁺ ion laser system. The 206.5 nm laser line is useful for exciting resonance Raman spectra within the π - π^* amide transition of the peptide backbone of proteins, and the enhanced protein amide vibrational bands can be used to determine the protein secondary structure.

HeCd Laser

The 325 nm HeCd excitation line, in the near ultraviolet, can be used for combined micro-Raman/photoluminescence studies of, for example, semiconductors. These lasers are suitable for low-power applications, typically having output powers in the 1–100 mW range, and they can be designed to operate in TEM₀₀ single-mode or multimode.

Quasi-CW Mode-Locked Ti:Sapphire Laser

The second harmonic of the mode-locked Ti:sapphire laser (ca. 350–500 nm), third harmonic (ca. 233–333 nm), and fourth harmonic (ca. 200–250 nm), are all available with conventional nonlinear crystals.

Typically, the Ti:sapphire crystal is pumped by a cw argon ion laser, for example, as the excitation source for a UV Raman microscope. This quasicontinuous laser system produces 2–3 ps pulses at a 76 MHz repetition rate and is continuously tunable over the 200–300 nm range. The typical power output is ca. 50 mW at 250 nm, ca. 10 mW at 240 nm, and 1 mW at 230 nm. In future, it is anticipated that a frequency-doubled Nd:YAG laser will be increasingly favored as the pump, creating an all-solid-state laser source.

Conclusions

Laser systems for Raman microscopy have been described in this article. Although the differences in the terms 'Raman spectroscopy' and 'Raman microscopy' only refer to whether a macro or micro sampling configuration is used, this does have a bearing on the types of laser systems that are employed. This is because the latter imposes a restriction on using low duty pulsed lasers with high pulse peak power, as both spatial and temporal confinement of the laser excitation can lead to dielectric breakdown of the sample, nonlinear phenomena, or Raman saturation. Thus, for this reason, one is limited to cw lasers or quasi-cw lasers for Raman microscopy whereas there is no such restriction for Raman spectroscopy.

The quality of the laser beam, measured by the M^2 value or 'times diffraction limit' influences the ultimate spatial resolution that can be achieved in Raman microscopy.

In the visible region, argon ion, krypton ion, and frequency-doubled Nd:YAG lasers have good beam quality and high power, with helium-neon and helium-cadmium lasers also having good beam quality but lower power; this makes these lasers good light sources for visible Raman microscopy.

For FT Raman microscopy using Nd:YAG excitation, there is a lack of fluorescence interference from a wide variety of samples, but sensitivity and spatial resolution are compromised in comparison to visible dispersive Raman microscopy.

Red and near infrared semiconductor lasers operating in TEM₀₀ single mode can have good beam quality, approaching that of gas lasers, but they are power limited. Obviously, when good beam quality is not necessary, for example, for optically pumping other laser sources, high-power diode lasers can be used in multimode operation. Solid state red and near infrared laser sources are becoming very popular for routine Raman microscopic analysis due to their compactness, robustness, and economical power consumption.

Another reason for the popularity of the red and near infrared diode laser sources for Raman microscopy is that fluorescence is less of a problem due to the lower energy of the light, compared to conventional green 514.5 nm excitation. Although there is a penalty, due to the dependency of the scattering efficiency on the ν^4 term, present day silicon-based CCD arrays can exhibit excellent detection quantum efficiency of Stokes shifted Raman radiation, across the whole vibrational spectrum, when using standard 670 and 785 nm diode lasers and, at least across the fingerprint region, when using 830 and 852 nm diode lasers.

For ultimate spatial resolution in the Raman microscopic experiment, short wavelength excitation is advantageous because it is fundamentally possible to focus to a smaller diffraction-limited laser spot. In this regard, it would be preferable to use UV Raman microscopy where fluorescence is also not as problematic as it is in the visible region. However, in spite of recent improvements in UV laser sources such as the intracavity frequency-doubled argon and krypton ion cw lasers, there are current instrumental limitations on the throughput efficiency of the UV Raman microscope imposed by the lack of availability of suitable notch filters and low stray light and high throughput optics.

It is anticipated that in the future all-solid-state, quasi-cw, diode pumped, mode-locked Ti:sapphire lasers operating on their third or fourth harmonics will become increasingly popular for providing tunable UV excitation affording good beam quality. It is now also possible to fabricate hollow cathode metal ion deep UV lasers, 10–15 cm in length, 2–4 cm in diameter, weighing 50–100 g and requiring only 2–3 W of electrical power. These lasers have low beam quality (M^2 equal to ca. 18), but they make possible the development of portable UV fluorescence imaging and Raman microprobes for geobiological exploration of terrestrial and extraterrestrial environments.

Spatial Heterodyne

Mark F Spencer, Albuquerque, NM, United States

© 2018 Elsevier Ltd. All rights reserved.

Introduction

Many optics and photonics applications benefit from the use of spatial heterodyne, which the open literature often refers to as spatial-heterodyne interferometry, spatial-heterodyne detection, digital-holographic detection, digital holography, or coherent detection. This is said because spatial heterodyne provides us with an estimate of the complex field (i.e., both the amplitude and wrapped phase). As such, this encyclopedia article reviews the fundamentals of spatial heterodyne, so that future research efforts can benefit from the material presented within.

Spatial heterodyne, in practice, results from the interference between a signal and a reference. As described in Fig. 1, we can create the signal using the active illumination of an object. Note that the light for this active illumination comes from a master-oscillator (MO) laser. Also note that the surface of the object is often considered to be optically rough compared with the wavelength of the incident light; thus, the receiving aperture of an imaging system collects the resultant speckle (i.e., the constructive and destructive interference which results from the laser-object interaction and propagation to the receiving aperture). To make it all work, we need to then interfere the (signal) light from the speckle with the (reference) light from a local oscillator (LO). This LO, in general, is split off from the MO laser. We can then record the resultant interference pattern or hologram with a focal-plane array (FPA) and digitize it for digital-signal processing. It is this ability to perform digital-signal processing which makes spatial heterodyne practical and such a versatile tool within the optics and photonics research communities.

To ensure that the signal interferes with the reference, it is advantageous to use a MO laser with a coherence length that is greater than twice the distance to the object. For tactical applications, however, this specification becomes difficult to achieve. We can then attempt to path-length match the reference with the signal, for example, using fiber-optic relays and continuous-wave illumination with a coherence length that is greater than twice the depth of the object (McManamon, 2015). With that said, if path-length matching is impractical (and it often is), we can then use pulsed illumination and incur the efficiency losses associated with decreased fringe visibility in our digital holograms. In this regime, it is desirable (although not required) to use a MO laser with a coherence length that is greater than the pulse length (i.e., use transform-limited pulses).

Doppler shifts, fluorescence, and depolarization from the laser-object interaction, in addition to mismatches (in the reference-signal spatial overlap, pulse timing, etc.), extinction, and noise are other sources for efficiency losses that, in practice, degrade fringe visibility. With this in mind, this encyclopedia article uses a scalar formulation (and the assumptions therein) to study three separate recording geometries often used with spatial-heterodyne applications. As described in Fig. 1, these recording geometries include the off-axis image plane recording geometry (IPRG), the off-axis pupil plane recording geometry (PPRG), and the on-axis phase shifting recording geometry (PSRG). Each of these recording geometries has its benefits and drawbacks depending on the spatial-heterodyne application of interest. Thus, the goal for the following analysis is to study these recording geometries in detail, so that we can ultimately develop closed-form expressions for their signal-to-noise ratios (SNRs).

In what follows, we will explore the background information needed to investigate the three recording geometries described in Fig. 1. In particular, we will review the optics relationships needed to propagate from the object plane to the FPA and the photonics principles needed to record digital holograms with the FPA. Following these two background sections, there are detailed sections on the three recording geometries described in Fig. 1. A final section then contains an illustrative comparison of the different recording geometries and an appendix provides example MATLAB[®] code. The goal throughout is to show that we can process spatial-heterodyne measurements to obtain an estimate of the complex field. Provided the complex field, we can then pursue the spatial-heterodyne application of interest (e.g., wave-front sensing, coherent imaging, etc).

Background Material: Part I

With Fig. 1 in mind, we need to further define the experimental parameter space. To help orient the reader, Fig. 2 pictorially describes the various planes of interest within the analysis. The reader should note that the entrance pupil of our proposed imaging system effectively collimates the monochromatic light from the object plane, whereas the exit pupil effectively focuses the monochromatic light to form the image plane at focus.

In the background material that follows, we will develop a relationship that says that the pupil and image planes of our proposed imaging system form a Fourier-conjugate pair. As such, we can use spatial heterodyne to exploit this relationship and obtain an estimate of the desired complex field. Depending on the spatial-heterodyne application of interest (e.g., wavefront sensing, coherent imaging, etc.), this estimate is what makes spatial heterodyne such a versatile tool within the optics and photonics research communities.

Fig. 1 A description of three spatial-heterodyne recording geometries.

Object Plane

Depending on the spatial-heterodyne application of interest, the object plane of the proposed imaging system takes on different forms. For example, given a point-source object (which is desirable for wavefront sensing),

$$U_O^+(x_0, y_0) = a_S e^{-j k z_0} \delta(x_0) \delta(y_0) \quad (1)$$

Fig. 2 A description of an imaging system.

where $U_O^+(x_0, y_0)$ is the complex field leaving the object plane, a_s is a real constant, $k=2\pi/\lambda$ is the angular wavenumber, λ is the wavelength, z_p is the distance to the object plane from the pupil plane, and $\delta(x)$ is an impulse function (cf. Eq. (80) in Appendix A). This point-source object gives rise to an ideal-spherical wave which propagates through the various planes of interest in our proposed imaging system (cf. Fig. 2). In the image plane, the irradiance associated with our imaged point source becomes a very special quantity known as the point-spread function (PSF) and is a quantity that we can measure with our FPA. In the presence of no aberrations, the PSF is an Airy disk (given a circular entrance/exit pupil), whereas in the presence of isoplanatic phase aberrations, the rings of the Airy disk start to wash out. For spatial-heterodyne applications, the sampling of the PSF with the FPA pixels becomes an important variable within the analysis and is a point that we will explore in more detail in the section on the off-axis IPRG.

For an extended object (which is desirable for coherent imaging),

$$U_O^+(x_0, y_0) = R_O(x_0, y_0) U_O^-(x_0, y_0) \quad (2)$$

where $R_O(x_0, y_0) = U_O^+(x_0, y_0)/U_O^-(x_0, y_0)$ is the object-plane complex reflectance function and $U_O^-(x_0, y_0)$ is the complex field entering the object plane. Let's assume that we actively illuminate the object plane with a uniform-amplitude, on-axis plane wave, so that

$$U_O^-(x_0, y_0) = A_s e^{-jkz_p} \quad (3)$$

where A_s is a complex constant. In addition, let's assume that the surface of the object that we are actively illuminating is optically rough compared to the wavelength of the monochromatic light (Spencer, 2014). If we then assume that the optically rough surface is delta correlated (Goodman, 2007),

$$R_O(x_0, y_0) = O(x_0, y_0) e^{j\phi_1(x_0, y_0)} \quad (4)$$

where $O(x_0, y_0)$ is the generalized complex object function and $\phi_k(x, y)$ is the k th realization of uniformly distributed, real-valued random numbers in the interval $[-\pi, \pi]$. In practice, Eqs. (2)–(4) provide us with a phase-screen model for rough-surface scattering that gives the correct speckle-correlation statistics upon propagation from the object plane to the pupil plane. For spatial-heterodyne applications, the sampling of the speckle-correlation statistics with the FPA pixels becomes an important variable within the analysis and is a point that we will explore in more detail in the section on the off-axis PPRG.

Pupil Plane

Using the convolution form of the Fresnel diffraction integral, we can represent the complex field $U_P^-(x_1, y_1)$ entering the pupil plane as

$$U_P^-(x_1, y_1) = \frac{e^{jkz_p}}{j\lambda z_p} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} U_O^+(x_0, y_0) \exp\left(j\frac{k}{2z_p} [(x_1 - x_0)^2 + (y_1 - y_0)^2]\right) dx_0 dy_0 \quad (5)$$

where again, $k=2\pi/\lambda$ is the angular wavenumber, λ is the wavelength, z_p is the distance to the pupil plane from the object plane, and $U_O^+(x_0, y_0)$ is the complex field leaving the object plane (cf. Eqs. (1) and (2) above).

As mentioned previously, the entrance pupil of the proposed imaging system effectively collimates the monochromatic light from the object plane, whereas the exit pupil effectively focuses the monochromatic light to form the image plane at focus (cf. Fig. 2). With this in mind, we can represent the complex field $U_P^+(x_1, y_1)$ leaving the pupil plane as

$$U_P^+(x_1, y_1) = T_P(x_1, y_1) U_P^-(x_1, y_1) \quad (6)$$

where

$$T_P(x_1, y_1) = \frac{U_P^+(x_1, y_1)}{U_P^-(x_1, y_1)} = \exp\left[-j\frac{k}{2z_p} (x_1^2 + y_1^2)\right] \exp\left[-j\frac{k}{2z_i} (x_1^2 + y_1^2)\right] P(x_1, y_1) \quad (7)$$

is the pupil-plane complex transmittance function, z_I is the distance to the image plane from the pupil plane, and

$$P(x_1, y_1) = \text{cyl}\left(\frac{\sqrt{x_1^2 + y_1^2}}{d_p}\right) e^{j\phi(x_1, y_1)} \quad (8)$$

is the generalized complex pupil function. In Eq. (8), $\text{cyl}\left(\frac{\sqrt{x_1^2 + y_1^2}}{d_p}\right)$ is a cylinder function (cf. Eq. (81) in Appendix A), d_p is the exit-pupil diameter, and $\phi(x_1, y_1)$ is the isoplanatic phase function, which represents all of the linear, shift-invariant phase aberrations present within the imaging system (Gaskill, 1978).

Substituting Eq. (7) into Eq. (6), we arrive at the following relationship:

$$U_P^+(x_1, y_1) = \exp\left[-j\frac{k}{2z_I}(x_1^2 + y_1^2)\right] U_P(x_1, y_1) \quad (9)$$

Here,

$$U_P(x_1, y_1) = \exp\left[-j\frac{k}{2z_P}(x_1^2 + y_1^2)\right] P(x_1, y_1) U_P^-(x_1, y_1) \quad (10)$$

is the pupil-plane complex field (i.e., the complex field that exists in the pupil plane of the proposed imaging system). It is important to note that $U_P(x_1, y_1)$ is being multiplied by a positive-thin-lens complex transmittance function in Eq. (9). This multiplication will allow us to form an image at focus upon propagation from the pupil plane to the image plane – our going-in disposition.

Image Plane

Provided Eq. (9), we can now account for the image-plane complex field $U_I(x_2, y_2)$ (i.e., the complex field that exists in the image plane of the proposed imaging system). In particular,

$$U_I(x_2, y_2) = \frac{e^{jkz_I}}{j\lambda z_I} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} U_P^+(x_1, y_1) \exp\left(j\frac{k}{2z_I}[(x_2 - x_1)^2 + (y_2 - y_1)^2]\right) dx_1 dy_1 \quad (11)$$

which again makes use of the convolution form of the Fresnel diffraction integral. Substituting Eq. (9) into Eq. (11), we arrive at the following relationship:

$$U_I(x_2, y_2) = \frac{e^{jkz_I}}{j\lambda z_I} \exp\left[j\frac{k}{2z_I}(x_2^2 + y_2^2)\right] \mathcal{F}\{U_P(x_1, y_1)\}_{x_x = \frac{x_2}{\lambda z_I}, y_y = \frac{y_2}{\lambda z_I}} = \frac{e^{jkz_I}}{j\lambda z_I} \exp\left[j\frac{k}{2z_I}(x_2^2 + y_2^2)\right] \tilde{U}_P\left(\frac{x_2}{\lambda z_I}, \frac{y_2}{\lambda z_I}\right) \quad (12)$$

This relationship says that the pupil plane and image plane form a Fourier-conjugate pair. Moving forward we can use spatial heterodyne to exploit this relationship and obtain an estimate, $\hat{U}_P(x_1, y_1)$ or $\hat{U}_I(x_2, y_2)$, of the desired complex field, $U_P(x_1, y_1)$ or $U_I(x_2, y_2)$, that exist in the pupil or image plane of our proposed imaging system.

Background Material: Part II

In the background material that follows, we will derive a relationship for the hologram photoelectron density that, in practice, a FPA records via spatial-heterodyne measurements. Provided Fig. 3, it is important to note that the spatial-heterodyne recording geometry is what ultimately determines where we place the FPA within the analysis. For example, in the off-axis IPRG we must place the FPA in the image plane of the proposed imaging system, whereas in the off-axis PPRG we must place the FPA in the pupil plane (or a plane that is conjugate to the pupil plane). The on-axis PSRG is unique in the sense that we do not have to go to the Fourier plane in order to obtain an estimate. Therefore, we can place the FPA in either the image or pupil plane of our proposed imaging system. In subsequent sections, we will explore the differences and similarities between the various spatial-heterodyne recording geometries. With that said, it is important to acknowledge their subtle differences up front, so that the following background material becomes more tractable.

Hologram Irradiance

In units of Watts per square meter ($\text{W}\cdot\text{m}^{-2}$), we can determine the real-valued hologram irradiance $i_H(x, y)$ that is incident on the FPA as

$$i_H(x, y) = |U_S(x, y) + U_R(x, y)|^2 = |U_S(x, y)|^2 + |U_R(x, y)|^2 + U_S(x, y)U_R^*(x, y) + U_R(x, y)U_S^*(x, y) \quad (13)$$

Here, $U_S(x, y)$ and $U_R(x, y)$ are, respectively, the signal and reference complex fields that are incident on the FPA and the superscript * denotes complex conjugate. It is important to note that in Eq. (13) we have made the assumption that the spatial-heterodyne

Fig. 3 Nominal layout for a focal-plane array or FPA.

measurements are fast enough so that $U_S(x, y)$ and $U_R(x, y)$ do not change significantly over the integration time of the FPA. Consequently, there is no need to include a time-dependent variable within the analysis.

For all intents and purposes, the FPA will convert the hologram irradiance $i_H(x, y)$, which is in an analog form, into a form that is suitable for digital-signal processing. Following the approach taken by Gaskill (1978), let's assume that "digitization" is to take place at sampling intervals of x_p and y_p , which are, respectively, the x - and y -axis pixel pitches of the FPA (cf. Fig. 3). At any particular FPA pixel, we can then obtain an estimate, $\hat{i}_H(x, y)$, of the hologram irradiance, $i_H(x, y)$, by computing its average value over the active area of the FPA pixel, which is centered at $x = nx_p$ and $y = my_p$, where $n = 1, 2, \dots, N$ and $m = 1, 2, \dots, M$. Specifically,

$$\hat{i}_H(nx_p, my_p) = \frac{1}{w_x w_y} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} i_H(x', y') \text{rect}\left(\frac{x' - nx_p}{w_x}\right) \text{rect}\left(\frac{y' - my_p}{w_y}\right) dx' dy' \quad (14)$$

where w_x and w_y are, respectively, the x - and y -axis pixel widths of the FPA, and $\text{rect}(x)$ is a rectangle function (cf. Eq. (78) in Appendix A).

Hologram Mean Number of Photoelectrons

At any particular FPA pixel, the real-valued hologram mean number of photoelectrons $\bar{m}_H(nx_p, my_p)$ results from random photoevents (i.e., when the FPA pixel creates an electron-hole pair or liberates a photoelectron (Saleh and Teich, 2007)). Therefore, over the integration time of the FPA,

$$\bar{m}_H(nx_p, my_p) = \frac{\eta \tau}{h\nu} w_x w_y \hat{i}_H(nx_p, my_p) \quad (15)$$

where η is the quantum efficiency, τ is the integration time, $h\nu$ is the quantized photon energy, and $w_x w_y$ is the active area of the FPA pixel. It is important to note that in Eq. (15) we have made the assumption that the measurements are without noise.

Following the approach taken by Tippie (2012), noise is additive. As such,

$$\bar{m}_H^+(nx_p, my_p) = \mathcal{P}\{\bar{m}_H(nx_p, my_p)\} + \sigma_r n_1(nx_p, my_p) \quad (16)$$

where $\mathcal{P}\{\circ\}$ denotes a Poisson-noise operator, σ_r is the read-noise standard deviation, and $n_k(x, y)$ is the k th realization of real-valued, zero-mean, unit-variance Gaussian random numbers. For most spatial-heterodyne applications, $\bar{m}_H(nx_p, my_p) \gg 1$ because of the use of an LO in creating the reference complex field $U_R(x, y)$. Thus, to a very good approximation, we can rewrite Eq. (16) as

$$\bar{m}_H^+(nx_p, my_p) \approx \bar{m}_H(nx_p, my_p) + \sigma_s(nx_p, my_p) n_2(nx_p, my_p) + \sigma_r n_1(nx_p, my_p) \quad (17)$$

where $\sigma_s(nx_p, my_p)$ is the shot-noise standard deviation. This approximation says that when $\bar{m}_H(nx_p, my_p) \gg 1$, our Poisson-distributed random process becomes a Gaussian-distributed random process with mean $\bar{m}_H(nx_p, my_p)$ and variance $\sigma_s^2(nx_p, my_p)$. Note that for Poisson-distributed random processes, the variance is equal to the mean (Dereniak and Boreman, 1996). In turn,

$$\sigma_s^2(nx_p, my_p) = \bar{m}_S(nx_p, my_p) + \bar{m}_R(nx_p, my_p) + \bar{m}_B(nx_p, my_p) \quad (18)$$

where $\bar{m}_S(nx_p, my_p)$, $\bar{m}_R(nx_p, my_p)$, and $\bar{m}_B(nx_p, my_p)$ are, respectively, the mean-number of photoelectrons associated with the signal, reference, and background illumination that is incident on the FPA. Also note that in Eq. (17), we have made the assumption that pixel to pixel both the shot and read noise result from statistically independent (i.e., delta correlated) random processes (Frieden, 2001). This assumption is a sound one since the sources for the shot noise (e.g., the object, LO, and sun) and read noise (i.e., the read out integrated circuit (ROIC) of the FPA) are physically separated from one another.

Hologram Photoelectron Density

At any particular FPA pixel, a real-valued hologram digital number $d_H(nx_p, my_p)$ results via an analog-to-digital (A/D) conversion (Janesick, 2007). From Eqs. (15)–(18), it then follows that

$$d_H^+(nx_p, my_p) = g_{A/D} \bar{m}_H^+(nx_p, my_p) + \sigma_q n_3(nx_p, my_p) \quad (19)$$

where $g_{A/D}$ is the A/D gain factor in units of digital number per photoelectron (DN-pe⁻¹) and σ_q is the quantization-noise standard deviation. In practice,

$$\sigma_q^2 = \frac{1}{12} \quad (20)$$

and the factor of 12 in the denominator comes from rounding to the nearest integer. Before moving on in the analysis, it is important to note that the effects of dark-current, 1/f, leakage, fano, and fixed-pattern noise are not included in Eq. (19). Under some circumstances, these noise effects might become important (Dereniak and Boreman, 1996; Saleh and Teich, 2007; Janesick, 2007); however, they are beyond the scope of the present analysis.

As previously stated, for most spatial-heterodyne applications, $\bar{m}_H(nx_s, my_s) \gg 1$ because of the use of an LO in creating the reference complex field $U_R(x, y)$ (cf. Eqs. (13)–(15)). For example, given an ideal reference with uniform irradiance, where $|U_R(x, y)|^2 = |A_R|^2$, we can determine the reference mean number of photoelectrons $\bar{m}_R(nx_p, my_p) = \bar{m}_R$ from the following relationship:

$$\bar{m}_R = \frac{\eta \tau}{h\nu} w_x w_y |A_R|^2 \quad (21)$$

Provided Eq. (21), we can then dictate that $\bar{m}_R \gg \bar{m}_S(nx_p, my_p)$, $\bar{m}_R \gg \bar{m}_B(nx_p, my_p)$, and $\bar{m}_R \gg g_{A/D}^{-1} \sigma_q$ within the constraints of the FPA pixel well depth ℓ (i.e., $\ell \geq \bar{m}_H(nx_p, my_p)$, so that the FPA pixels do not saturate). As such, $\sigma_s^2(nx_p, my_p) \approx \bar{m}_R$ (cf. Eq. (18)), and Eq. (19) simplifies, such that

$$d_H^+(nx_p, my_p) \approx g_{A/D} \left[\bar{m}_H(nx_p, my_p) + \sqrt{\bar{m}_R} n_2(nx_p, my_p) + \sigma_r n_1(nx_p, my_p) \right] \quad (22)$$

Dividing both sides of Eq. (22) by the A/D gain factor $g_{A/D}$, we obtain the following relationship:

$$\bar{m}_H^+(nx_p, my_p) \approx \bar{m}_H(nx_p, my_p) + \sigma_n n_4(nx_p, my_p) \quad (23)$$

where

$$\sigma_n^2 \approx \bar{m}_R + \sigma_r^2 \quad (24)$$

is the noise variance. This relationship says that we only have to account for photoelectrons within the analysis.

Neglecting the effects of pixel-edge diffusion in the FPA (Poon and Liu, 2014), the hologram photoelectron density $\rho_H(x_2, y_2)$, in units of pe-m⁻², is simply a sampled version of the analog form of Eq. (23). This declaration leads us to the following relationship:

$$\rho_H^+(x, y) = [\bar{m}_H(x, y) + \sigma_n n_4(x, y)] \frac{1}{x_p} \text{comb}\left(\frac{x}{x_p}\right) \frac{1}{y_p} \text{comb}\left(\frac{y}{y_p}\right) \text{rect}\left(\frac{x}{Nx_p}\right) \text{rect}\left(\frac{y}{My_p}\right) \quad (25)$$

where

$$\bar{m}_H(x, y) = \frac{\eta \tau}{h\nu} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} i_H(x', y') \text{rect}\left(\frac{x' - x}{w_x}\right) \text{rect}\left(\frac{y' - y}{w_y}\right) dx' dy' = \frac{\eta \tau}{h\nu} i_H(x, y) ** \text{rect}\left(\frac{x}{w_x}\right) \text{rect}\left(\frac{y}{w_y}\right) \quad (26)$$

is the analog form of Eq. (15) and $\text{comb}(x)$ is a comb function (cf. Eq. (79) in Appendix A). The reader should note that in Eq. (26), $**$ denotes a 2-D convolution, as defined in Eq. (83) in Appendix B. Moving forward we will use Eq. (25) to explore the differences and similarities between the various spatial-heterodyne recording geometries.

Off-Axis Image Plane Recording Geometry

The goal for the following analysis is to model spatial heterodyne in the off-axis IPRG. With that said, we can represent the signal complex field $U_S(x, y)$ that is incident on the FPA as

$$U_S(x, y) = U_I(x_2, y_2) \quad (27)$$

where again, $U_I(x_2, y_2)$ is the image-plane complex field (cf. Eq. (12)). In addition, if by choice we inject an off-axis LO, then by choice we can represent the reference complex field $U_R(x, y)$ that is incident FPA as

$$U_R(x, y) = U_R(x_2, y_2) = A_R e^{jkz_l} \exp\left[j \frac{k}{2z_l} (x_2^2 + y_2^2)\right] \exp\left(j2\pi x_R \frac{x_2}{\lambda z_l}\right) \exp\left(j2\pi y_R \frac{y_2}{\lambda z_l}\right) \quad (28)$$

where here, A_R is a complex constant and (x_R, y_R) are the coordinates of the off-axis LO. It is important to note that the relationship given in Eq. (28) is the Fresnel approximation to a tilted spherical wave.

Fourier Plane

From Eqs. (1)–(28), we can gain access to an estimate, $\hat{U}_P(x_1, y_1)$, of the pupil-plane complex field (cf. Eq. (10)), $U_P(x_1, y_1)$, by going to the Fourier plane. To go to the Fourier plane, we first let $x=x_2=\lambda z_l v_x$ and $y=y_2=\lambda z_l v_y$. Next, we apply a 2-D inverse Fourier transformation, as defined in Eq. (85) in Appendix B, to the relationship contained in Eq. (25), so that

$$\mathcal{F}^{-1}\left\{\rho_H^+\left(\lambda z_l v_x, \lambda z_l v_y\right)\right\}_{x_1, y_1} = \frac{1}{\lambda^2 z_l^2} \tilde{\rho}_H^+\left(\frac{-x_1}{\lambda z_l}, \frac{-y_1}{\lambda z_l}\right) = \left[\frac{\eta\tau}{h\nu} w_x \text{sinc}\left(\frac{w_x x_1}{\lambda z_l}\right) w_y \text{sinc}\left(\frac{w_y y_1}{\lambda z_l}\right) \mathcal{F}^{-1}\left\{i_H\left(\lambda z_l v_x, \lambda z_l v_y\right)\right\}_{x_1, y_1} \right. \\ \left. + \sigma_n \mathcal{F}^{-1}\left\{n_4\left(\lambda z_l v_x, \lambda z_l v_y\right)\right\}_{x_1, y_1}\right] ** \frac{1}{\lambda^2 z_l^2} \text{comb}\left(\frac{x_p x_1}{\lambda z_l}\right) \text{comb}\left(\frac{y_p y_1}{\lambda z_l}\right) ** \frac{N x_p}{\lambda z_l} \text{sinc}\left(\frac{N x_p x_1}{\lambda z_l}\right) \frac{M y_p}{\lambda z_l} \text{sinc}\left(\frac{M y_p y_1}{\lambda z_l}\right) \quad (29)$$

where $\text{sinc}(x)$ is a sinc function (cf. Eq. (82) in Appendix A). Taking a look at the remaining 2-D inverse Fourier transformations in Eq. (29), we obtain the following relationship with respect to the hologram irradiance $i_H(x, y)$ (cf. Eqs. (12), (13), and (28)):

$$\mathcal{F}^{-1}\left\{i_H\left(\lambda z_l v_x, \lambda z_l v_y\right)\right\}_{x_1, y_1} = \frac{1}{\lambda^2 z_l^2} U_P(x_1, y_1) ** U_P^*(-x_1, -y_1) \\ + |A_R|^2 \delta(x_1) \delta(y_1) + \frac{A_R^*}{j \lambda z_l} U_P(x_1 - x_R, y_1 - y_R) - \frac{A_R}{j \lambda z_l} U_P^*(x_1 + x_R, y_1 + y_R) \quad (30)$$

This relationship contains the desired pupil-plane complex field $U_P(x_1, y_1)$.

To see that this last statement is true, let's analyze the various terms contained in the right-hand side of Eq. (30). The first term is an amplitude-scaled, 2-D autocorrelation. This term is centered on axis and is physically twice the circumference of the exit-pupil diameter d_p . The second term is also centered on axis and contains separable impulse functions (cf. Eq. (80) in Appendix A). These impulse functions are at the strength of the ideal reference with uniform irradiance (i.e., $|A_R|^2$). The last two terms form a complex-conjugate pair and contain the pupil-plane complex field $U_P(x_1, y_1)$, both scaled in amplitude and shifted off axis.

Substituting Eq. (30) into Eq. (29), we obtain the following relationship:

$$\tilde{\rho}_H^+\left(\frac{-x_1}{\lambda z_l}, \frac{-y_1}{\lambda z_l}\right) = \left\{ \frac{\eta\tau}{h\nu} w_x \text{sinc}\left(\frac{w_x x_1}{\lambda z_l}\right) w_y \text{sinc}\left(\frac{w_y y_1}{\lambda z_l}\right) \left[\frac{1}{\lambda^2 z_l^2} U_P(x_1, y_1) ** U_P^*(-x_1, -y_1) + |A_R|^2 \delta(x_1) \delta(y_1) \right. \right. \\ \left. \left. + \frac{A_R^*}{j \lambda z_l} U_P(x_1 - x_R, y_1 - y_R) - \frac{A_R}{j \lambda z_l} U_P^*(x_1 + x_R, y_1 + y_R) \right] + \sigma_n \mathcal{F}^{-1}\left\{n_4\left(\lambda z_l v_x, \lambda z_l v_y\right)\right\}_{x_1, y_1} \right\} ** \text{comb}\left(\frac{x_p x_1}{\lambda z_l}\right) \text{comb}\left(\frac{y_p y_1}{\lambda z_l}\right) \\ ** \frac{N x_p}{\lambda z_l} \text{sinc}\left(\frac{N x_p x_1}{\lambda z_l}\right) \frac{M y_p}{\lambda z_l} \text{sinc}\left(\frac{M y_p y_1}{\lambda z_l}\right) \quad (31)$$

which is in units of pe. This relationship is remarkably physical, as the sampling theorem dictates that a sampled function becomes periodic upon finding its spectrum (Gaskill, 1978). In turn, the 2-D convolution with the separable comb functions causes the terms contained within the squiggly brackets in Eq. (31) to repeat at intervals of $\lambda z_l/x_p$ and $\lambda z_l/y_p$ along the x and y axes, respectively. This periodicity occurs because of the convolution-sifting property of the impulse function (Gaskill, 1978). Lastly, the final 2-D convolution with the separable narrow sinc functions serves to smooth out these repeated terms.

Sampling Quotient

To help simplify the analysis to a case that we can easily simulate using $N \times N$ computational grids, let's assume that the FPA has adjacent square pixels, so that $x_p=y_p=w_x=w_y=p$. In so doing, we can rewrite Eq. (31) in terms of the image-plane sampling quotient q_l , where

$$q_l = \frac{\lambda z_l}{p d_p} \quad (32)$$

For all intents and purposes, q_l is a measure for the number of FPA pixels across the half width of the PSF. Recall that for linear, shift-invariant imaging systems, the PSF is the irradiance associated with an imaged point source (Gaskill, 1978). In turn, the relationship given in Eq. (32) allows us to vary the sampling with the FPA pixels.

Using Eq. (32), we can rewrite Eq. (31) in terms of the image-plane sampling quotient q_l , such that

$$\tilde{\rho}_H^+\left(\frac{-x_1}{\lambda z_l}, \frac{-y_1}{\lambda z_l}\right) = \left\{ \frac{\eta\tau}{h\nu} p^2 \text{sinc}\left(\frac{x_1}{q_l d_p}\right) \text{sinc}\left(\frac{y_1}{q_l d_p}\right) \left[\frac{1}{\lambda^2 z_l^2} U_P(x_1, y_1) ** U_P^*(-x_1, -y_1) + |A_R|^2 \delta(x_1) \delta(y_1) \right. \right. \\ \left. \left. + \frac{A_R^*}{j \lambda z_l} U_P(x_1 - x_R, y_1 - y_R) - \frac{A_R}{j \lambda z_l} U_P^*(x_1 + x_R, y_1 + y_R) \right] + \sigma_n \mathcal{F}^{-1}\left\{n_4\left(\lambda z_l v_x, \lambda z_l v_y\right)\right\}_{x_1, y_1} \right\} ** \text{comb}\left(\frac{x_1}{q_l d_p}\right) \text{comb}\left(\frac{y_1}{q_l d_p}\right) \\ ** \frac{N^2}{q_l^2 d_p^2} \text{sinc}\left(\frac{N x_1}{q_l d_p}\right) \text{sinc}\left(\frac{N y_1}{q_l d_p}\right) \quad (33)$$

Here, $q_l d_p = \lambda z_l/p$ is the side length of the $N \times N$ computational grid in the Fourier plane. Note that as $N \rightarrow \infty$ (cf. Eq. (80) in Appendix A), we can make use of the convolution-sifting property of the impulse function and neglect the final 2-D convolution in Eq. (33). Accordingly, for large N the smoothing caused by the final 2-D convolution in Eq. (33) becomes minimized; however, for small N the smoothing becomes more pronounced. Let's assume that $x_R=y_R=q_l d_p/4$, so that the last two terms within the square brackets in

Eq. (33) shift diagonally. When $q_I \geq 4$, the last two terms no longer overlap with the first two terms which are centered on axis. Correspondingly, when $2 \leq q_I < 4$, the last two terms are still resolvable within the side length of the $N \times N$ computational grid but overlap with the first term. This latter case allows for us to obtain more samples across the exit-pupil diameter d_p which in turn minimizes the smoothing caused by the final 2-D convolution in Eq. (33) but increases the noise sampling. Also note that this functional overlap becomes negligible when the amplitude of the reference $|A_R|$ is dominate (in comparison to the other amplitude terms).

Estimate

Provided Eqs. (32) and (33), we must shift the Fourier-plane data and apply a window function to obtain an estimate, $\hat{U}_P(x_1, y_1)$, of the pupil-plane complex field, $U_P(x_1, y_1)$. Specifically,

$$\hat{U}_P(x_1, y_1) = w(x_1, y_1) \tilde{\rho}_H^+ \left(\frac{-x_1 - x_R}{\lambda z_I}, \frac{-y_1 - y_R}{\lambda z_I} \right) \quad (34)$$

where $w(x_1, y_1)$ is the window function. In using Eq. (34), we must satisfy Nyquist sampling with the FPA pixels (Gaskill, 1978), so that the repeated terms within Eq. (33) do not overlap and cause significant aliasing. As such, the Nyquist rate is $q_I d_p = \lambda z_I / p$ and the Nyquist interval is $1/(q_I d_p) = p/(\lambda z_I)$ when $x_R = y_R = q_I d_p / 4$.

Moving forward let's assume that we satisfy Nyquist sampling. In addition, let's assume that $q_I \geq 2$, $|A_R|$ is dominant, and

$$w(x_1, y_1) = \text{cyl} \left(\frac{\sqrt{x_1^2 + y_1^2}}{d_p} \right) \quad (35)$$

In so doing, Eq. (34) simplifies, such that

$$\begin{aligned} \hat{U}_P(x_1, y_1) \approx q_I^2 d_p^2 \left[\frac{\eta \tau}{h \nu} p^2 \text{sinc} \left(\frac{x_1 + x_R}{q_I d_p} \right) \text{sinc} \left(\frac{y_1 + y_R}{q_I d_p} \right) \frac{A_R^*}{j \lambda z_I} U_P(x_1, y_1) + \sigma_n w(x_1, y_1) \mathcal{F}^{-1} \{ n_4(\lambda z_I v_x, \lambda z_I v_y) \}_{x_1 + x_R, y_1 + y_R} \right] \\ ** \delta(x_1) \delta(y_1) ** \frac{N^2}{q_I^2 d_p^2} \text{sinc} \left(\frac{N x_1}{q_I d_p} \right) \text{sinc} \left(\frac{N y_1}{q_I d_p} \right) \end{aligned} \quad (36)$$

The reader should note that as $N \rightarrow \infty$ (cf. Eq. (80) in Appendix A), we can again make use of the convolution-sifting property of the impulse function and neglect the final 2-D convolutions in Eq. (36). Accordingly, for large N the smoothing caused by the final 2-D convolution in Eq. (36) becomes minimized (and the noise remains delta correlated); however, for small N the smoothing becomes more pronounced (and the noise is no longer delta correlated).

Assuming that N is large, the estimate $\hat{U}_P(x_1, y_1)$ simplifies (cf. Eq. (36)), such that

$$\hat{U}_P(x_1, y_1) \approx \frac{\hat{\eta}_I(x_1, y_1) \tau}{h \nu} p^2 A_R^* U_P(x_1, y_1) + \frac{\sigma_I}{\sqrt{2}} N_1(x_1, y_1) \quad (37)$$

where $\hat{\eta}_I(x_1, y_1)$ is the estimation efficiency in the off-axis IPRG, σ_I is the compressed-noise standard deviation in the off-axis IPRG, and $N_k(x, y)$ is the k th realization of complex-circular Gaussian random numbers with zero mean and unit variance for both the real and imaginary parts (hence the factor of $\sqrt{2}$ in the denominator). It is important to note that by Parseval's theorem (Gaskill, 1978), the total noise power in the windowed Fourier plane is equal to α_I times the original noise power in the image plane, where α_I is the ratio of the pupil area to the Fourier-plane area. Therefore,

$$\sigma_I^2 = \alpha_I \sigma_n^2 = \frac{\pi (d_p/2)^2}{(q_I d_p)^2} \sigma_n^2 = \frac{\pi}{4 q_I^2} \sigma_n^2 \quad (38)$$

which says that the noise variance σ_n^2 (cf. Eq. (24)) is compressed by a factor of α_I when performing spatial heterodyne in the off-axis IPRG.

Signal-to-noise ratio

We can determine the SNR S/N_{IPRG} for the off-axis IPRG as

$$S/N_{\text{IPRG}} = \frac{\mathcal{E}\{|\hat{U}_P(x_1, y_1)|^2\}}{\mathcal{V}\{\hat{U}_P(x_1, y_1)\}} \quad (39)$$

where $\mathcal{E}\{\circ\}$ denotes an expected-value operator and $\mathcal{V}\{\circ\}$ denotes a variance operator. Provided a strong reference, $|A_R|^2 \gg |A_S|^2$ and $|U_S(x, y)|^2 \approx |A_S|^2$. As such, we can determine the signal mean number of photoelectrons $\bar{m}_S(n_x, m_y) \approx \bar{m}_S$ from the following relationship:

$$\bar{m}_S = \frac{\eta \tau}{h \nu} p^2 |A_S|^2 \quad (40)$$

From Eqs. (37) and (38), it then follows that

$$\mathcal{E}\{|\hat{U}_P(x_1, y_1)|^2\} \approx \bar{m}_R \bar{m}_S \quad (41)$$

and

$$\mathcal{V}\{\hat{U}_P(x_1, y_1)\} \approx \sigma_I^2 \quad (42)$$

where $\bar{m}_R$ is the reference mean number of photoelectrons (cf. Eq. (21)). Substituting Eqs. (41) and (42) into Eq. (39), we obtain the following closed-form expression (cf. Eq. (24)):

$$S/N_{\text{IPRG}} \approx \frac{4q_I^2}{\pi} \frac{\bar{m}_R \bar{m}_S}{\bar{m}_R + \sigma_r^2} \quad (43)$$

In writing this closed-form expression, we must assume that the estimation efficiency in the off-axis IPRG is equal to the quantum efficiency (i.e., $\hat{\eta}_I(x_1, y_1) = \eta$) for simplicity in the analysis.

Shot-noise limit

Before moving on in the analysis, it is important to note that if $\bar{m}_R \gg \sigma_r^2$, then the SNR S/N_{IPRG} for the off-axis IPRG simplifies (cf. Eq. (43)), such that

$$S/N_{\text{IPRG}} \approx \frac{4q_I^2}{\pi} \bar{m}_S \quad (44)$$

The open literature often refers to this approximation as the shot-noise limit or as obtaining quantum-limited detection. This limit depends on the constraints of the FPA pixel well depth ℓ . In general, $\ell \geq \bar{m}_H(n x_s, m y_s)$ (cf. Eq. (15)), so that the FPA pixels do not saturate.

Off-Axis Pupil Plane Recording Geometry

The goal for the following analysis is to model spatial heterodyne in the off-axis PPRG. In turn, we can represent the signal complex field $U_S(x, y)$ that is incident on the FPA as

$$U_S(x, y) = U_P(x_1, y_1) \quad (45)$$

where again, $U_P(x_1, y_1)$ is the pupil-plane complex field (cf. Eq. (10)). Furthermore, if by choice we inject an off-axis LO, then by choice we can represent the reference complex field $U_R(x, y)$ that is incident FPA as

$$U_R(x, y) = U_R(x_1, y_1) = A_R \exp\left(-j2\pi \frac{x_R}{\lambda z_p} x_1\right) \exp\left(-j2\pi \frac{y_R}{\lambda z_p} y_1\right) \quad (46)$$

where here, A_R is a complex constant and (x_R, y_R) are the coordinates of the off-axis LO. It is important to note that the relationship given in Eq. (46) is a tilted plane wave.

Fourier Plane

From Eqs. (1)–(26) and Eqs. (45) and (46), we can gain access to an estimate, $\hat{U}_I(x_1, y_1)$, of the image-plane complex field, $U_I(x_1, y_1)$ (cf. Eq. (10)), by going to the Fourier plane. To go to the Fourier plane, we first let $x=x_1$ and $y=y_1$. Then, we apply a 2-D Fourier transformation, as defined in Eq. (84) in Appendix B, to the relationship contained in Eq. (25), so that

$$\begin{aligned} \mathcal{F}\{\rho_H^+(x_1, y_1)\}_{v_x = \frac{x_2}{\lambda z_p}, v_y = \frac{y_2}{\lambda z_p}} &= \tilde{\rho}_H^+\left(\frac{x_2}{\lambda z_p}, \frac{y_2}{\lambda z_p}\right) = \left[\frac{\eta\tau}{h\nu} w_x \text{sinc}\left(\frac{w_x x_2}{\lambda z_p}\right) w_y \text{sinc}\left(\frac{w_y y_2}{\lambda z_p}\right) \mathcal{F}\{i_H(x_1, y_1)\}_{v_x = \frac{x_2}{\lambda z_p}, v_y = \frac{y_2}{\lambda z_p}}\right. \\ &\quad \left. + \sigma_n \mathcal{F}\{n_4(x_1, y_1)\}_{v_x = \frac{x_2}{\lambda z_p}, v_y = \frac{y_2}{\lambda z_p}}\right] * \frac{1}{\lambda^2 z_p^2} \text{comb}\left(\frac{x_p x_2}{\lambda z_p}\right) \text{comb}\left(\frac{y_p y_2}{\lambda z_p}\right) * \frac{N x_p}{\lambda z_p} \text{sinc}\left(\frac{N x_p x_2}{\lambda z_p}\right) \frac{M y_p}{\lambda z_p} \text{sinc}\left(\frac{M y_p y_2}{\lambda z_p}\right) \end{aligned} \quad (47)$$

Taking a look at the remaining 2-D Fourier transformations in Eq. (47), we obtain the following relationship with respect to the hologram irradiance $i_H(x, y)$ (cf. Eqs. (10), (13), and (46)):

$$\begin{aligned} \mathcal{F}\{i_H(x_1, y_1)\}_{v_x = \frac{x_2}{\lambda z_p}, v_y = \frac{y_2}{\lambda z_p}} &= \frac{1}{\lambda^2 z_p^2} \tilde{U}_P\left(\frac{x_2}{\lambda z_p}, \frac{y_2}{\lambda z_p}\right) * \tilde{U}_P^*\left(\frac{-x_2}{\lambda z_p}, \frac{-y_2}{\lambda z_p}\right) + \lambda^2 z_p^2 |A_R|^2 \delta(x_2) \delta(y_2) + A_R \tilde{U}_P\left(\frac{x_2 - x_R}{\lambda z_p}, \frac{y_2 - y_R}{\lambda z_p}\right) \\ &\quad + A_R^* \tilde{U}_P^*\left(\frac{x_2 + x_R}{\lambda z_p}, \frac{y_2 + y_R}{\lambda z_p}\right) \end{aligned} \quad (48)$$

This relationship contains a 2-D Fourier transformation of the pupil-plane complex field $U_P(x_1, y_1)$ which is proportional to the image-plane complex field $U_I(x_2, y_2)$ (cf. Eq. (12)).

Moving forward let's analyze the various terms contained in the right-hand side of Eq. (48). The first term is a 2-D auto-correlation. This term is centered on axis and is physically twice the circumference of the object diameter d_O . The second term is also centered on axis and contains separable impulse functions (cf. Eq. (80) in Appendix A). These impulse functions are at the strength of the ideal reference with uniform irradiance (i.e., $|A_R|^2$). The last two terms form a complex-conjugate pair and contain a 2-D Fourier transformation of the pupil-plane complex field $U_P(x_1, y_1)$, both scaled in amplitude and shifted off axis.

Substituting Eq. (48) into Eq. (47), we obtain the following relationship:

$$\begin{aligned} \tilde{\rho}_H^+\left(\frac{x_2}{\lambda z_p}, \frac{y_2}{\lambda z_p}\right) = & \left\{ \frac{\eta\tau}{h\nu} w_x \text{sinc}\left(\frac{w_x x_2}{\lambda z_p}\right) w_y \text{sinc}\left(\frac{w_y y_2}{\lambda z_p}\right) \left[\frac{1}{\lambda^2 z_p^2} \tilde{U}_p\left(\frac{x_2}{\lambda z_p}, \frac{y_2}{\lambda z_p}\right) * \tilde{U}_p^*\left(\frac{-x_2}{\lambda z_p}, \frac{-y_2}{\lambda z_p}\right) + \lambda^2 z_p^2 |A_R|^2 \delta(x_2) \delta(y_2) \right. \right. \\ & \left. \left. + A_R \tilde{U}_p\left(\frac{x_2 - x_R}{\lambda z_p}, \frac{y_2 - y_R}{\lambda z_p}\right) + A_R \tilde{U}_p^*\left(\frac{x_2 + x_R}{\lambda z_p}, \frac{y_2 + y_R}{\lambda z_p}\right) \right] + \sigma_n \mathcal{F}\{n_4(x_1, y_1)\}_{v_x = \frac{x_2}{\lambda z_p}, v_y = \frac{y_2}{\lambda z_p}} \right\} \\ & * \frac{1}{\lambda^2 z_p^2} \text{comb}\left(\frac{x_p x_2}{\lambda z_p}\right) \text{comb}\left(\frac{y_p y_2}{\lambda z_p}\right) * \frac{N x_p}{\lambda z_p} \text{sinc}\left(\frac{N x_p x_2}{\lambda z_p}\right) \frac{M y_p}{\lambda z_p} \text{sinc}\left(\frac{M y_p y_2}{\lambda z_p}\right) \end{aligned} \quad (49)$$

In units of p , this relationship is physically relevant. Note that the sampling theorem dictates that a sampled function becomes periodic upon finding its spectrum (Gaskill, 1978). In turn, the 2-D convolution with the separable comb functions and the convolution-sifting property of the impulse function causes the terms contained within the squiggly brackets in Eq. (49) to repeat at intervals of $\lambda z_p/x_p$ and $\lambda z_p/y_p$ along the x and y axes, respectively. Also note that the final 2-D convolution with the separable narrow sinc functions serves to smooth out these repeated terms.

Sampling Quotient

To help simplify the analysis to a case that we can easily simulate using $N \times N$ computational grids, let's again assume that the FPA has adjacent square pixels, so that $x_p = y_p = w_x = w_y = p$. In so doing, we can rewrite Eq. (49) in terms of the pupil-plane sampling quotient q_p , where

$$q_p = \frac{\lambda z_p}{p d_O} \quad (50)$$

For all intents and purposes, q_p is a measure for the number of FPA pixels across the half width of the speckle-correlation radius (Goodman, 2007; Spencer, 2014). Recall that for monochromatic light, the speckle-correlation radius is proportional to the size of the speckles. In turn, the relationship given in Eq. (50) allows us to vary the sampling with the FPA pixels.

Using Eq. (50), we can rewrite Eq. (49) in terms of the pupil-plane sampling quotient q_p , so that

$$\begin{aligned} \tilde{\rho}_H^+\left(\frac{x_2}{\lambda z_p}, \frac{y_2}{\lambda z_p}\right) = & \frac{1}{p^2} \left\{ \frac{\eta\tau}{h\nu} p^2 \text{sinc}\left(\frac{x_2}{q_p d_O}\right) \text{sinc}\left(\frac{y_2}{q_p d_O}\right) \left[\frac{1}{\lambda^2 z_p^2} \tilde{U}_p\left(\frac{x_2}{\lambda z_p}, \frac{y_2}{\lambda z_p}\right) * \tilde{U}_p^*\left(\frac{-x_2}{\lambda z_p}, \frac{-y_2}{\lambda z_p}\right) + \lambda^2 z_p^2 |A_R|^2 \delta(x_2) \delta(y_2) \right. \right. \\ & \left. \left. + A_R \tilde{U}_p\left(\frac{x_2 - x_R}{\lambda z_p}, \frac{y_2 - y_R}{\lambda z_p}\right) + A_R \tilde{U}_p^*\left(\frac{x_2 + x_R}{\lambda z_p}, \frac{y_2 + y_R}{\lambda z_p}\right) \right] + \sigma_n \mathcal{F}\{n_4(x_1, y_1)\}_{v_x = \frac{x_2}{\lambda z_p}, v_y = \frac{y_2}{\lambda z_p}} \right\} \\ & * \frac{1}{q_p^2 d_O^2} \text{comb}\left(\frac{x_2}{q_p d_O}\right) \text{comb}\left(\frac{y_2}{q_p d_O}\right) * \frac{N^2}{q_p^2 d_O^2} \text{sinc}\left(\frac{N x_2}{q_p d_O}\right) \text{sinc}\left(\frac{N y_2}{q_p d_O}\right) \end{aligned} \quad (51)$$

Here, $q_p d_O = \lambda z_p/p$ is the side length of the $N \times N$ computational grid in the Fourier plane. Note that as $N \rightarrow \infty$ (cf. Eq. (80) in the Appendix), we can make use of the convolution-sifting property of the impulse function and neglect the final 2-D convolution in Eq. (51). Accordingly, for large N the smoothing caused by the final 2-D convolution in Eq. (51) becomes minimized; however, for small N the smoothing becomes more pronounced. Let's assume that $x_R = y_R = q_p d_O/4$, so that the last two terms within the square brackets in Eq. (51) shift diagonally. When $q_p \geq 4$, the last two terms no longer overlap with the first two terms which are centered on axis. Correspondingly, when $2 \leq q_p < 4$, the last two terms are still resolvable within the side length of the $N \times N$ computational grid but overlap with the first term. This latter case allows for us to obtain more samples across the object diameter d_O which in turn minimizes the smoothing caused by the final 2-D convolution in Eq. (51) but increases the noise sampling. Also note that this functional overlap becomes negligible when the amplitude of the reference $|A_R|$ is dominant (in comparison to the other amplitude terms).

Estimate

Provided Eqs. (50) and (51), we must shift the Fourier-plane data and apply a window function to obtain an estimate, $\hat{U}_l(x_2, y_2)$, of the image-plane complex field, $U_l(x_2, y_2)$. In particular,

$$\hat{U}_l(x_2, y_2) = w(x_2, y_2) \tilde{\rho}_H^+\left(\frac{x_2 + x_R}{\lambda z_p}, \frac{y_2 + y_R}{\lambda z_p}\right) \quad (52)$$

where $w(x_2, y_2)$ is the window function. In using Eq. (52), we must satisfy Nyquist sampling with the FPA pixels (Gaskill, 1978), so that the repeated terms within Eq. (51) do not overlap and cause significant aliasing. Thus, the Nyquist rate is $q_p d_O = \lambda z_p/p$ and the Nyquist interval is $1/(q_p d_O) = p/(\lambda z_p)$ when $x_R = y_R = q_p d_O/4$.

Assuming that we satisfy Nyquist sampling, let's assume that $q_p \geq 2$, $|A_R|$ is dominant, and

$$w(x_2, y_2) = \text{cyl}\left(\frac{\sqrt{x_2^2 + y_2^2}}{d_O}\right) \quad (53)$$

In turn, Eq. (52) simplifies, such that

$$\begin{aligned} \hat{U}_I(x_2, y_2) \approx & \frac{1}{p^2} \left[\frac{\eta\tau}{h\nu} p^2 \text{sinc}\left(\frac{x_2 + x_R}{q_P d_O}\right) \text{sinc}\left(\frac{y_2 + y_R}{q_P d_O}\right) A_R^* \tilde{U}_P\left(\frac{x_2}{\lambda z_P}, \frac{y_2}{\lambda z_P}\right) + \sigma_n w(x_1, y_1) \mathcal{F}\{n_4(x_1, y_1)\}_{v_x = \frac{x_2}{\lambda z_P}, v_y = \frac{y_2}{\lambda z_P}} \right] \\ & * * \frac{N^2}{q_P^2 d_O^2} \text{sinc}\left(\frac{Nx_2}{q_P d_O}\right) \text{sinc}\left(\frac{Ny_2}{q_P d_O}\right) \end{aligned} \quad (54)$$

The reader should note that as $N \rightarrow \infty$ (cf. Eq. (80) in Appendix A), we can again make use of the convolution-sifting property of the impulse function and neglect the final 2-D convolutions in Eq. (54). Accordingly, for large N the smoothing caused by the final 2-D convolution in Eq. (54) becomes minimized (and the noise remains delta correlated); however, for small N the smoothing becomes more pronounced (and the noise is no longer delta correlated).

Assuming that N is large, the estimate $\hat{U}_I(x_1, y_1)$ simplifies (cf. Eq. (54)), such that

$$\hat{U}_I(x_2, y_2) \approx \frac{\hat{\eta}_P(x_2, y_2)\tau}{h\nu} A_R^* \tilde{U}_P\left(\frac{x_2}{\lambda z_P}, \frac{y_2}{\lambda z_P}\right) + \frac{\sigma_P}{\sqrt{2}} N_1(x_2, y_2) \quad (55)$$

where here, $\hat{\eta}_P(x_1, y_1)$ is the estimation efficiency in the off-axis PPRG, σ_P is the compressed-noise standard deviation in the off-axis PPRG, and $N_k(x, y)$ is again the k th realization of complex-circular Gaussian random numbers with zero mean and unit variance for both the real and imaginary parts (hence the factor of $\sqrt{2}$ in the denominator). It is important to note that by Parseval's theorem (Gaskill, 1978), the total noise power in the windowed Fourier plane is equal to α_P times the original noise power in the pupil plane, where α_P is the ratio of the image area to the Fourier-plane area. Therefore,

$$\sigma_P^2 = \alpha_P \sigma_n^2 = \frac{\pi(d_O/2)^2}{(q_P d_O)^2} \sigma_n^2 = \frac{\pi}{4q_P^2} \sigma_n^2 \quad (56)$$

which says that the noise variance σ_n^2 (cf. Eq. (24)) is compressed by a factor of α_P when performing spatial heterodyne in the off-axis PPRG.

Signal-to-noise ratio

We can determine the SNR S/N_{PPRG} for the off-axis PPRG as

$$S/N_{\text{PPRG}} = \frac{\mathcal{E}\{|\hat{U}_I(x_2, y_2)|^2\}}{\mathcal{V}\{\hat{U}_I(x_2, y_2)\}} \quad (57)$$

where again, $\mathcal{E}\{\circ\}$ denotes an expected-value operator and $\mathcal{V}\{\circ\}$ denotes a variance operator. From Eqs. (55) and (56),

$$\mathcal{E}\{|\hat{U}_I(x_2, y_2)|^2\} \approx \bar{m}_R \bar{m}_S \quad (58)$$

and

$$\mathcal{V}\{\hat{U}_I(x_2, y_2)\} \approx \sigma_P^2 \quad (59)$$

Here, $\bar{m}_R$ and $\bar{m}_S$ are the reference and signal mean number of photoelectrons, respectively, assuming a strong reference (cf. Eqs. (21) and (40)). Substituting Eqs. (58) and (59) into Eq. (57), we obtain the following closed-form expression (cf. Eq. (24)):

$$S/N_{\text{PPRG}} \approx \frac{4q_P^2}{\pi} \frac{\bar{m}_R \bar{m}_S}{\bar{m}_R + \sigma_r^2} \quad (60)$$

In writing this closed-form expression, we must assume that the estimation efficiency in the off-axis PPRG is equal to the quantum efficiency (i.e., $\hat{\eta}_P(x_1, y_1) = \eta$) for simplicity in the analysis.

Shot-noise limit

Before moving on in the analysis, it is important to note that if $\bar{m}_R \gg \sigma_r^2$, then the SNR S/N_{PPRG} for the off-axis PPRG simplifies (cf. Eq. (60)), such that

$$S/N_{\text{PPRG}} \approx \frac{4q_P^2}{\pi} \bar{m}_S \quad (61)$$

Again, the open literature often refers to this approximation as the shot-noise limit or as obtaining quantum-limited detection. This limit depends on the constraints of the FPA pixel well depth ℓ . In general, $\ell \geq \bar{m}_H(n_x, m_y)$ (cf. Eq. (15)), so that the FPA pixels do not saturate.

On-Axis Phase Shifting Recording Geometry

The goal for the following analysis is to model spatial heterodyne in the on-axis PSRG. For this purpose, we can represent the signal complex field $U_S(x, y)$ that is incident on the FPA as

$$U_S(x, y) = U_P(x_1, y_1) \quad (62)$$

or

$$U_S(x, y) = U_I(x_2, y_2) \quad (63)$$

where again, $U_P(x_1, y_1)$ is the pupil-plane complex field (cf. Eq. (10)) and $U_I(x_2, y_2)$ is the image-plane complex field (cf. Eq. (12)). Moreover, if by choice we inject an on-axis LO, then by choice we can represent the reference complex field $U_R(x, y)$ that is incident FPA as

$$U_R^{(\delta)}(x, y) = U_R^{(\delta)}(x_1, y_1) = U_R^{(\delta)}(x_2, y_2) = A_R e^{-j\delta} \quad (64)$$

where here, A_R is a complex constant and δ is a real constant. It is important to note that the relationship given in Eq. (64) is an ideal reference with a uniform irradiance and a piston-phase shift (i.e., $|A_R|^2$ and δ , respectively).

Estimate

Provided Eqs. (62)–(64), Eq. (13) becomes

$$I_H^{(\delta)}(x, y) = |U_S(x, y)|^2 + |A_R|^2 + U_S(x, y)A_R^* e^{j\delta} + A_R e^{-j\delta} U_S^*(x, y) \quad (65)$$

This relationship says that via (simultaneous or sequential) piston-phase shifts, we can acquire four hologram-irradiance measurements with the FPA (Poon and Liu, 2014) to obtain an estimate, $\hat{U}_P(x_1, y_1)$ or $\hat{U}_I(x_2, y_2)$, of the desired complex field, $U_P(x_1, y_1)$ or $U_I(x_2, y_2)$. For example, if $\delta=0, \pi/2, \pi$, and $3\pi/2$, then

$$\begin{aligned} I_H^{(0)}(x, y) &= |U_S(x, y)|^2 + |A_R|^2 + U_S(x, y)A_R^* + A_R U_S^*(x, y) \\ I_H^{(\pi/2)}(x, y) &= |U_S(x, y)|^2 + |A_R|^2 + jU_S(x, y)A_R^* - jA_R U_S^*(x, y) \\ I_H^{(\pi)}(x, y) &= |U_S(x, y)|^2 + |A_R|^2 - U_S(x, y)A_R^* - A_R U_S^*(x, y) \\ I_H^{(3\pi/2)}(x, y) &= |U_S(x, y)|^2 + |A_R|^2 - jU_S(x, y)A_R^* + jA_R U_S^*(x, y) \end{aligned} \quad (66)$$

To remove the common terms (i.e., $|U_S(x, y)|^2 + |A_R|^2$), we can perform the following subtractions:

$$\begin{aligned} I_H^{(0)}(x, y) - I_H^{(\pi)}(x, y) &= 2U_S(x, y)A_R^* + 2A_R U_S^*(x, y) \\ I_H^{(\pi/2)}(x, y) - I_H^{(3\pi/2)}(x, y) &= j2U_S(x, y)A_R^* - j2A_R U_S^*(x, y) \end{aligned} \quad (67)$$

so that

$$\left[I_H^{(0)}(x, y) - I_H^{(\pi)}(x, y) \right] + j \left[I_H^{(3\pi/2)}(x, y) - I_H^{(\pi/2)}(x, y) \right] = 4A_R^* U_S(x, y) \quad (68)$$

From Eqs. (1)–(26) and Eq. (68), our estimate, in units of pe, becomes

$$\begin{aligned} \hat{U}_S(x, y) &\approx \frac{4\eta\tau}{S\hbar\nu} A_R^* U_S(x, y) * \text{rect}\left(\frac{x}{p}\right) \text{rect}\left(\frac{y}{p}\right) + 2\sigma_n N_2(x, y) \\ &\approx \frac{4\hat{\eta}(x, y)\tau}{S\hbar\nu} p^2 A_R^* U_S(x, y) + 2\sigma_n N_2(x, y) \end{aligned} \quad (69)$$

with the assumption that the FPA has adjacent square pixels, so that $x_p = y_p = w_x = w_y = p$. In Eq. (69), S is the total number of amplitude splits required to make the four hologram-irradiance measurements with the FPA (Rhoadarmer and Barchers, 2002). It is important to note that since we have four hologram-irradiance measurements with the FPA, the noise variance σ_n^2 (cf. Eq. (24)) is multiplied by a factor of 4 when performing spatial heterodyne in the on-axis PSRG.

Signal-to-noise ratio

We can determine the SNR S/N_{PSRG} for the on-axis PSRG as

$$S/N_{\text{PSRG}} = \frac{\mathcal{E}\{|\hat{U}_S(x, y)|^2\}}{\mathcal{V}\{\hat{U}_S(x, y)\}} \quad (70)$$

where again, $\mathcal{E}\{\circ\}$ denotes an expected-value operator and $\mathcal{V}\{\circ\}$ denotes a variance operator. From Eq. (69),

$$\mathcal{E}\{|\hat{U}_I(x_1, y_1)|^2\} \approx \frac{16}{S^2} \bar{m}_R \bar{m}_S \quad (71)$$

and

$$\mathcal{V}\{\hat{U}_I(x_1, y_1)\} \approx 4\sigma_n^2 \quad (72)$$

where here, $\bar{m}_R$ and $\bar{m}_S$ are the reference and signal mean number of photoelectrons, respectively, assuming a strong reference (cf. Eqs. (21) and (40)). Substituting Eqs. (71) and (72) into Eq. (70), we obtain the following closed-form expression (cf. Eq. (24)):

$$S/N_{\text{PSRG}} \approx \frac{4}{S^2} \frac{\bar{m}_R \bar{m}_S}{\bar{m}_R + \sigma_r^2} \quad (73)$$

In writing this closed-form expression, we must assume that the estimation efficiency in the on-axis PSRG is equal to the quantum efficiency (i.e., $\hat{\eta}(x, y) = \eta$) for simplicity in the analysis.

Shot-noise limit

Before moving on in the analysis, it is important to note that if $\bar{m}_R \gg \sigma_r^2$, then the SNR S/N_{PSRG} for the on-axis PSRG simplifies (cf. Eq. (73)), such that

$$S/N_{\text{PSRG}} \approx \frac{4}{S^2} \bar{m}_S \quad (74)$$

Again, the open literature often refers to this approximation as the shot-noise limit or obtaining quantum-limited detection. This limit depends on the constraints of the FPA pixel well depth ℓ . In general, $\ell \geq \bar{m}_H(n x_s, m y_s)$ (cf. Eq. (15)), so that the FPA pixels do not saturate.

Comparison of the Different Recording Geometries

In this section, we will explore the differences between the various recording geometries (studied in the previous sections) from a visual standpoint. For this purpose, let's assume that we have a point-source object (cf. Eq. (1)), so that the laser-object interaction gives rise to an ideal spherical wave upon propagation. Let's also assume that we have isoplanatic phase aberrations present (i.e., those that exist (or approximately exist) within the pupil plane of our imaging system (cf. Fig. 2)). As such (cf. Eqs. (8) and (10)),

$$\frac{U_P(x_1, y_1)}{A_s} = P(x_1, y_1) \quad (75)$$

and we can neglect the effects of speckle due to an optically rough object. Before moving on in the analysis, it is important to note that example MATLAB[®] code for the off-axis IPRG, the off-axis PPRG, and the on-axis PSRG is included in Appendix C. The readers interested in extended objects (in addition to point-source objects) will be able to visualize the associated physics (cf. Fig. 1) by executing these provided scripts.

To quantify performance, we will use the field-estimated Strehl ratio S_F , such that

$$S_F = \frac{|\mathcal{E}\{U_S(x, y) \hat{U}_S^*(x, y)\}|^2}{\mathcal{E}\{|U_S(x, y)|^2\} \mathcal{E}\{|\hat{U}_S(x, y)|^2\}} \quad (76)$$

where $U_S(x, y)$ and $\hat{U}_S(x, y)$ are the "truth" and "estimated" signal complex fields, respectively, and again, $\mathcal{E}\{\cdot\}$ is the expected-value operator. This performance metric bears some resemblance to a Strehl ratio, which in practice provides a normalized measure for performance (Spencer *et al.*, 2016). In Eq. (76), if $U_S(x, y) = \hat{U}_S(x, y)$, then $S_F = 1$. Else if $U_S(x, y) \neq \hat{U}_S(x, y)$, then $S_F < 1$. Thus, Eq. (76) is in line with the general understanding of a Strehl ratio, and provides a normalized measure for field-estimated performance. The reader should note that Eq. (76) ultimately stems from the following definition of the Strehl ratio:

$$S = \frac{|\mathcal{E}\{U_P(x_1, y_1)\}|^2}{\mathcal{E}\{|U_P(x_1, y_1)|^2\}} \quad (77)$$

Here, we have made use of the fact that the expected value of a pupil-plane field quantity is equivalent to the on-axis DC term of the 2D Fourier transformation of that pupil-plane field quantity.

Off-Axis Image Plane Recording Geometry

Fig. 4 shows the results for the off-axis IPRG. In the left-hand column, $q_I = 2$, whereas in the right-hand column, $q_I = 4$ (cf. Eq. (32)). Note that the computational grids were setup so that the image-plane grid length was set equal to the pupil-plane grid length (which was also set equal to the exit-pupil diameter $d = 0.3$ m) using 256×256 grid points. This setup required that $z_I = q_I d^2 / (N \lambda)$ when solving the Fresnel integral numerically (Spencer *et al.*, 2016). Also note that

- Fig. 4(a) and (b) show the 1 RMS isoplanatic phase aberrations that existed in the simulated pupil plane;
- Fig. 4(c) and (d) show the zero-mean digital holograms recorded with the off-axis IPRG;
- Fig. 4(e) and (f) show the amplitudes associated with the simulated Fourier plane; and
- Fig. 4(g) and (h) show the wrapped phases associated with the estimated complex field.

Here, $S_F = 0.943$ and $S_F = 0.984$ for the left-hand and right-hand columns of Fig. 4, respectively. To calculate the field-estimated Strehl ratio S_F (cf. Eq. (76)), the simulated Fourier plane was zero padded to the appropriate size, so that the windowed Fourier plane (i.e., the estimated complex field) contained 256×256 grid points. This zero padding ensured that the estimated complex field had the same number of grid points as the simulated pupil plane. Given that $\bar{m}_S = 4$ pe, $\bar{m}_R = 0.75\ell$, and $\ell = 100 \times 10^3$ pe, the following SNRs were also calculated for the left-hand and right-hand columns of Fig. 4 (cf. Eqs. (43) and (44)): $S/N = 9$ and $S/N = 18$.

Off-Axis Pupil Plane Recording Geometry

Fig. 5 shows the results for the off-axis PPRG. Here, $q_P = 2$ in the left-hand column and $q_P = 4$ in the right-hand column (cf. Eq. (50)). The computational grids were setup with 256×256 grid points and the pupil-plane grid length was set equal to the exit-pupil diameter $d = 0.3$ m. It is important to note that

- Fig. 5(a) and (b) show the 1 RMS isoplanatic phase aberrations that existed in the simulated pupil plane;
- Fig. 5(c) and (d) show the zero-mean digital holograms recorded with the off-axis PPRG;

Fig. 4 Results for the off-axis image plane recording geometry or IPRG.

Fig. 5 Results for the off-axis pupil plane recording geometry or PPRG.

Fig. 6 Results for the on-axis phase shifting recording geometry or PSRG.

- **Fig. 5(e)** and **(f)** show the amplitudes associated with the simulated Fourier plane; and
- **Fig. 5(g)** and **(h)** show the wrapped phases associated with the estimated complex field.

To calculate the estimated complex field, the windowed Fourier plane was zero padded to 256×256 grid points and was numerically inverse Fourier transformed. This zero padding ensured that the estimated complex field had the same number of grid points as the simulated pupil plane for the purposes of computing field-estimated Strehl ratio S_F (cf. Eq. (76)), where here, $S_F=0.955$ and $S_F=0.986$ for the left-hand and right-hand columns of **Fig. 5**, respectively. Given that $\bar{m}_S = 4$ pe, $\bar{m}_R = 0.75\ell$, and $\ell = 100 \times 10^3$ pe, the following SNRs were also calculated for the left-hand and right-hand columns of **Fig. 5** (cf. Eqs. (60) and (61)): $S/N=9$ and $S/N=18$.

On-Axis Phase Shifting Recording Geometry

Fig. 6 shows the results for the on-axis PSRG. Once again, the computational grids were setup with 256×256 grid points and the pupil-plane grid length was set equal to the exit-pupil diameter $d=0.3$ m. **Fig. 6(a)–(d)** show the four phase-shifted digital holograms, where $\delta=0, \pi/2, \pi$, and $3\pi/2$, respectively. Here, $S=1$, so that $\bar{m}_S = 4/S$ pe, $\bar{m}_R = 0.75\ell$, and $\ell = 100 \times 10^3$ pe. Given these parameters, the following SNR was calculated for the results shown in **Fig. 6** (cf. Eqs. (60) and (61)): $S/N=14$. It is important to note that **Fig. 6(e)** and **(g)** show the wrapped phase and amplitude for the truth complex field, whereas **Fig. 6(f)** and **(h)** show the wrapped phase and amplitude for the estimated complex field. As such, the field-estimated Strehl ratio S_F (cf. Eq. (76)), was calculated as $S_F=0.947$.

Conclusion

Spatial heterodyne, in general, offers a distinct way forward to combat low SNRs that often occur when performing optics and photonics applications. In using spatial heterodyne, we can set the strength of the reference so that it boosts the signal above the read-noise floor of the FPA. As such, we can approach a shot-noise limited detection regime. This last statement is of course dependent on the parameters of the FPA, such as the pixel well depth. With that said, this encyclopedia article provides the toolset needed for future research efforts to use spatial heterodyne in their optics and photonics applications.

Appendix A

This appendix defines the rectangle, comb, impulse, cylinder, and sinc functions as

$$\text{rect}(x) = \begin{cases} 0, & |x| > 0.5 \\ 0.5, & x = 0.5 \\ 1, & |x| < 0.5 \end{cases} \quad (78)$$

$$\frac{1}{|w|} \text{comb}\left(\frac{x}{w}\right) = \sum_{n=-\infty}^{\infty} \delta(x - nw) \quad (79)$$

$$\delta(x) = \lim_{w \rightarrow 0} \frac{1}{|w|} p\left(\frac{x}{w}\right) \quad (80)$$

(where $p(x)$ is a pulse-like function (e.g., the rectangle function)),

$$\text{cyl}(\rho) = \begin{cases} 10 \leq \rho < 0.5 \\ 0.5, \rho = 0.5 \\ 0, \rho > 0.5 \end{cases} \quad (81)$$

(where $\rho = \sqrt{x^2 + y^2}$), and

$$\text{sinc}(x) = \frac{\sin(\pi x)}{\pi x} \quad (82)$$

respectively.

Appendix B

This appendix defines 2-D convolution as

$$V(x, y) * W(x, y) = \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} V(x', y') W(x - x', y - y') dx' dy' \quad (83)$$

(where x' and y' are dummy variables of integration), a 2-D Fourier transform as

$$\mathcal{F}\{V(x, y)\}_{v_x, v_y} = \tilde{V}(v_x, v_y) = \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} V(x, y) e^{-j2\pi(xv_x + yv_y)} dx dy \quad (84)$$

and a 2-D inverse Fourier transformation as

$$\mathcal{F}^{-1}\{\tilde{V}(v_x, v_y)\}_{x, y} = V(x, y) = \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \tilde{V}(v_x, v_y) e^{j2\pi(xv_x + yv_y)} dv_x dv_y \quad (85)$$

Appendix C

This appendix provides the MATLAB[®] code needed to explore the off-axis IPRG, the off-axis PPRG, and the on-axis PSRG.

Listing 1. MATLAB[®] code for the cylinder function.

```
function z = cyl(x, y)
% function z = cyl(x, y)
r = sqrt(x.^2 + y.^2);
z = double(r < 0.5);
z(r == 0.5) = 0.5;
return
```

Listing 2. MATLAB[®] code for the off-axis image plane recording geometry or IPRG.

3D Metrics for Airborne Topographic Lidar

Shea T Hagstrom and Myron Z Brown, The Johns Hopkins University Applied Physics Laboratory, Laurel, MD, United States

© 2018 Elsevier Ltd. All rights reserved.

Introduction

The development and widespread use of airborne topographic lidar systems is one of the most significant changes within the remote sensing field in recent decades. Lidar is now commonly used for production of high-resolution foundation data such as Digital Elevation Models (DEMs) and bare-earth Digital Terrain Models (DTMs) as well as for mapping power lines and discovering ancient ruins under jungle canopy. Community standards for 3D lidar metrics have emerged to set minimum expectations for lidar data quality and to enable objective and quantitative evaluation and comparison of systems and capabilities.

Lidar data quality depends on sensor technology (e.g., well established linear-mode lidar and more recently emerging photon counting lidar), system design, calibration, operating environment, and post-processing such as registration of overlapping swaths and noise filtering. Metrics for assessment of 3D lidar point clouds must be general enough to account for all of these factors. Where possible, metrics should also be general enough to apply to 3D data derived from other sources such as multiple view imagery (Bosch *et al.*, 2016) and synthetic aperture radar (Zhu and Bamler, 2012), though we do not explicitly address these in this article. As lidar system designs continue to evolve, and as lidar technology continues to be applied in new ways, metrics for ensuring acceptable data quality are advancing as well to keep up. This article reviews lidar metrics currently in common use, highlights emerging challenges, and discusses recent work to begin to address those challenges.

Current Lidar Metric Standards

Minimum expectations for topographic mapping lidar metric performance are captured in recent community standards for lidar collection and government specifications for delivered lidar products. The United States Geological Survey (USGS) National Geospatial Program (NGP) released the Lidar Base Specification in 2014 to define minimum metric requirements for the vertical accuracy, data density, and completeness of lidar products for the National interagency 3D Elevation Program (3DEP). Similarly, the American Society for Photogrammetry and Remote Sensing (ASPRS) released the ASPRS Positional Accuracy Standards for Digital Geospatial Data in 2015 to specify vertical and horizontal accuracy requirements for data providers. While other organizations and agencies also independently define metric standards, these documents describe the current state of the industry in metric performance characterization of lidar products. The following discussion draws heavily from these documents to summarize commonly used lidar metrics to assess data density, completeness, and accuracy.

Density and Completeness

Data density is perhaps the most intuitive metric associated with a lidar point cloud, as it indicates what sizes of objects in a scene can be expected to be well represented. The terms nominal pulse spacing (NPS) and nominal pulse density (NPD) are commonly used to indicate lidar point spacing and density respectively on a measured ground surface within the area covered by data of a single flight line or scan. The lidar base specification also defines the terms aggregate nominal pulse spacing (ANPS) and aggregate nominal pulse density (ANPD) to indicate point spacing and density more generally for point clouds that include points from multiple flight lines. Furthermore, to properly characterize point spacing and density for lidar systems incorporating focal plane arrays, even more general terms would be required. The intent of any of these terms is to capture the equivalent of ground sample distance (GSD) in remote sensing digital photography, though lidar point spacing is generally irregular. These metrics are two-dimensional and intended primarily for conventional topographic lidar data collection. In the section on emerging capabilities, a more general three-dimensional metric for data density is discussed that is suitable for lidar collections consisting of multiple off-nadir viewpoints to increase coverage of objects in the scene.

In addition to nominal point density, the completeness and spatial distribution of points are also important in determining the utility of a point cloud. Gaps in lidar coverage are commonly termed data voids. The lidar base specification defines a data void as any area of missing points that is at least as large as $4 \times \text{ANPS}^2$ and indicates that these data voids are unacceptable in delivered lidar products unless caused by water bodies or low near infrared surface reflectivity. Regularity of the spatial distribution of points is also required. This is measured by producing a two-dimensional occupancy grid with cell size $2 \times \text{ANPS}$ and determining if at least 90% of cells are occupied. These metrics are also intended primarily for conventional topographic lidar. A more general discussion of three-dimensional completeness is provided in the section on emerging capabilities.

Absolute and Relative Vertical Accuracy

Absolute vertical accuracy of lidar elevation values is typically estimated by comparison with check point elevation values that have been independently measured in the lidar coverage area. ASPRS recommends that check points be at least three times more accurate than the required accuracy of the product and located in areas with low and uniform slope to avoid interpolation errors.

Highly accurate check points are typically obtained by Global Positioning System (GPS) survey. Control points used for calibration of a lidar system are also typically obtained by GPS survey and should not be included as check points. Absolute vertical accuracy is reported separately in non-vegetated and vegetated terrain and is commonly reported as root mean squared error (RMSE) for non-vegetated terrain, assuming a normal error distribution, or percentile confidence level for vegetated terrain.

Relative vertical accuracy refers to precision or repeatability and internal consistency of elevation measurements in a lidar product. Vertical precision is estimated as the variation in elevation values measured on a flat hard surface such as a building roof. Internal consistency is estimated as the variation in elevation values measured on non-vegetated terrain in overlapping swaths. ASPRS and USGS define standards for repeatability based on the maximum measured difference and for consistency based on both root mean squared difference (RMSD) and maximum difference. Sources of relative vertical error include range precision of the lidar instrument and registration error among overlapping lidar swaths, among others.

Absolute and Relative Horizontal Accuracy

Absolute horizontal accuracy of a lidar product is estimated by comparison with horizontal check points that have been independently measured in the lidar coverage area. Unlike vertical check points described above, horizontal check points must be located at points in the lidar coverage area for which the horizontal position may be very accurately measured independently and which are clearly identifiable in the lidar product itself. These check points are typically obtained by GPS survey and the locations clearly documented with photography. ASPRS defines horizontal accuracy standards for RMSE of X and Y coordinates independently, RMSE of radial accuracy, and percentile confidence level of radial accuracy.

Relative horizontal accuracy refers to point to point horizontal distance measurement accuracy within a geospatial product and may be estimated similarly to absolute horizontal accuracy using check points. ASPRS does not define an explicit standard for relative horizontal accuracy in lidar datasets, and absolute horizontal accuracy standards for lidar collection are sufficiently stringent that independently measuring relative horizontal accuracy would have limited utility. However, in situations for which ground control and GPS accuracy may be limited, such as remote lidar collection for humanitarian purposes, explicitly measuring relative horizontal error may be desirable. Methods for beginning to address these issues are discussed in the following section on emerging capabilities.

Emerging Capabilities and Challenges

Current lidar metrics standards have been developed for use with mature commercial linear-mode lidar technology, fixed nadir viewing angles, and accurate ground survey. New lidar technology, system designs, and use cases may require additional or revised metrics to accurately characterize error. For instance, more emphasis on measuring relative horizontal accuracy may be desirable for recent photon counting lidar systems which require post-processing for photon aggregation and noise filtering that can improve or degrade resolution. Similarly, comprehensive modeling of all error sources may be more desirable for lidar systems that collect from higher altitudes and with significantly off-nadir look angles such that some errors often considered negligible become important. Off-nadir data collection also enables enhanced foliage penetration and true three-dimensional mapping capabilities. Current metrics and conventional wisdom for topographic lidar data collection are insufficient to fully characterize these new collection capabilities. The following sections discuss preliminary efforts within the lidar research community to begin to address some of these recent challenges.

Defining a Lidar Error Model

Inaccuracies in lidar point cloud geospatial coordinates are primarily influenced by uncertainties in sensor position, sensor orientation, and range measurements as described by [Habib et al. \(2010\)](#). These uncertainties are commonly characterized for lidar system error budgets and sensor calibration processing; however, they generally are not readily available to end users of lidar data. While current standards may ensure that products meet minimum performance specifications, additional knowledge of specific uncertainties is desirable for an end user who wishes to merge or compare multiple datasets.

[Rodarmel et al. \(2015\)](#) have proposed a Universal Lidar Error Model (ULEM) that captures sensor-space parameter uncertainties and explains how to mathematically propagate errors into ground plane covariance predictions. The capability of ULEM to predict absolute horizontal and vertical accuracy of air-to-ground lidar data was demonstrated using check points surveyed with GPS combined with standard metric analysis methods. Horizontal or Circular Error at the 90th percentile (CE90) and vertical or linear error at the 90th percentile (LE90) were computed, consistent with National Geospatial-Intelligence Agency (NGA) practices, and approximately 90% of the estimated check point accuracies were determined to be within predicted bounds, indicating the potential utility of this model for practical use. [Fig. 1](#) shows the concept of the ULEM and how the error in horizontal and vertical accuracy leads to position uncertainty following an ellipsoidal shape.

An ongoing challenge in the adoption of a lidar error model is incorporating metadata required to support such models into standard lidar file formats. ULEM metadata variable length records (VLRs) have been developed that are compliant with the ASPRS-developed LAS specification. Similarly, ULEM metadata is defined in an optional header in the BPF3 specification adopted by the National Center for Geospatial Intelligence Standards in 2015. At present, ULEM is used within specialized government

Fig. 1 Universal Lidar Error Model (ULEM) sensor-space error modeling.

communities. With the widespread proliferation of lidar and other 3D data from a variety of sources, development of common standards for metadata used to support error modeling and error propagation is becoming increasingly important.

Measuring Point Cloud Resolution

Horizontal resolution of a lidar point cloud refers to the minimum distance between two adjacent objects that are still resolvable as unique objects. Resolution is often assumed to be equivalent to NPS or GSD, but this is often not the case. For a conventional lidar system, horizontal resolution is largely determined by flight altitude and laser beam divergence. For a system with a focal plane array detector, resolution is also determined by pixel pitch. For photon-counting lidar, the resolution of the point cloud may be degraded by the coincidence processing algorithms used to filter noise. For any point cloud generated by aggregating multiple spatially coincident datasets, resolution may be degraded by sensor calibration error or by registration error. Measuring horizontal resolution explicitly can be an important factor in determining a sensor's capability to produce an interpretable 3D image.

Stevens *et al.* (2011) report methods for estimating resolution achievable by a lidar sensor. Among other methods, horizontal resolution was determined by calculating the contrast transfer function (CTF) based on lidar point densities both on and between pairs of closely spaced reflective panels from an array of panels with varying width and spacing. Visual inspection of panel resolvability in the point clouds was shown to be consistent with the Rayleigh criterion, indicating the utility of this approach. This method for determining resolution requires significant oversampling for reliable calculation and unique targets in the lidar coverage area. While this method provides a useful tool for lidar system calibration and characterization, it is not practical for general use to assess product quality. Methods for calculating the edge spread function (ESF) and line spread function (LSF) were also proposed for estimating horizontal precision using linear features such as building edges which would not require unique calibration targets in the lidar coverage area. However, for reliable calculation these methods also require significant oversampling, and the analytical assumptions associated with these methods do not hold for the broad range of modern lidar system designs. While resolution remains difficult to explicitly measure except in controlled environments, new methods for measuring relative horizontal accuracy are discussed in the next section that may be sufficient to characterize the horizontal precision of lidar point clouds.

Accounting for Relative Horizontal Accuracy

The ASPRS lidar calibration/validation Working Group led by USGS recognizes that current standards are not sufficient to capture the relative horizontal accuracy of lidar data. To address this shortcoming, Sampath *et al.* (2014) define data quality measures

Fig. 2 Relative horizontal and vertical errors with overlapping lidar swaths capture point-to-plane differences for sloped surfaces and flat roof planes and point-to-line differences for roof edges.

(DQM) for determining inter-swath goodness of fit (**Fig. 2**) based on quality control methods proposed by [Habib et al. \(2010\)](#). These measures have been proposed to verify the quality of lidar system calibration and other sources of relative horizontal error in the data. For natural sloped terrain surfaces, a DQM measures the point to plane distance for conjugate points in overlapping swaths. Since a lidar system is unlikely to measure the same exact point in two swaths, a tangential plane is fit to each point in one swath and the point to plane distance is computed rather than point to point distance. For roof planes, conjugate planes are extracted from two swaths, and the distance from the centroid point from one swath to the plane from the other swath is measured. For roof edges, lines are fit to the conjugate edges and the distance from the centroid point in one line is measured to the conjugate line. These metrics do not rely on additional ground control or unique targets in the scene and so can be practically used for routine assessment of relative accuracy; however, they require multiple overlapping swaths which may not always be available. The working group is currently evaluating prototype tools that implement the DQMs before making formal recommendations for their use. Metrics like these will become increasingly important as more complex lidar system designs requiring more careful calibration and post-processing become commercially available.

Characterizing Foliage Penetration Performance

As reviewed by [Wulder et al. \(2012\)](#), multiple-return lidar provides a useful capability for measuring tree height, volume, and biomass for forestry inventory. Federal Emergency Management Agency (FEMA) [Lidar Specifications for Flood Hazard Mapping \(2009\)](#) suggest that high point densities may enable satisfactory data collection under foliage canopy. The USGS lidar base specification requires a minimum ANPD of two pulses per square meter (referred to by USGS as quality level 2) for lidar to be suitable for the 3DEP. For forestry applications requiring canopy penetration, 4–8 pulses per square meter (quality level 1 in the base specification) is commonly recommended in the literature. However, ANPD is insufficient to fully characterize foliage penetration performance.

For high obscuration environments (e.g., multiple layers of foliage canopy), [Burton \(2010\)](#) examines the value of line of sight angle diversity to improve the likelihood of canopy penetration. Both linear mode ([Roth et al., 2007](#)) and photon counting ([Vaidyanathan et al., 2007](#)) lidar systems have been developed that incorporate a gimbal to enable multiple off-nadir line of sight angles that better exploit the nonuniform gap structure in foliage canopy and improve foliage penetration performance. Current rules of thumb based on average point density also do not account for saturation in modern single photon detection lidar systems as described by [Henriksson \(2005\)](#) or the influence of filtering in coincidence processing as discussed in [Stevens et al. \(2011\)](#). To better account for the increasing variety of lidar system designs, explicit measurement of point density on the ground under foliage canopy is desirable to accurately characterize performance and determine data utility.

Defining Density and Completeness in 3D

Current two-dimensional point density metrics are useful for evaluating coverage and finding voids in relatively flat regions, but unfortunately do not work in areas with significant 3D structure because the sample density and completeness of vertical surfaces is ignored. No standard definition of 3D point density exists yet, making evaluation of coverage difficult. In addition, the presence of obscurants means that complete coverage requires sensing from multiple viewpoints, a consequence that is not captured by 2D metrics.

Prior works such as those of [Popescu and Zhao \(2008\)](#); [Pyysalo and Sarjakoski \(2008\)](#) have evaluated 3D point density by using a grid of volumetric cells, known as voxels, and counting the number of points within each cell to derive the density. However, this makes the assumption that the entire volume is evenly sampled by the lidar which is typically not true due to many effects including lidar scan patterns and obscurations. A lack of points within a volume may be due to either an absence of objects or a lidar system being unable to sense certain objects. Ambiguity between those two scenarios makes evaluating 3D completeness and voids difficult, if not impossible, using existing point-based methods.

Fig. 3 Estimating 3D completeness of a dataset. The true surface of the model cannot be well-estimated from the sparse lidar points in (a). The orange unsampled areas in (b), identified using lidar path tracing, estimate the positions of missing surfaces. Given that a complete model should appear as (c), the completeness can be estimated by taking the ratio of the measured surface area to the estimated total surface area.

Several research groups have approached the problem of evaluating density by tracing the path of laser pulses through the dataset volume. The line segment path between the system and each point in the cloud point is computed using the coincident lidar instrument position records. Hagstrom (2014) defines the sampling density for a given voxel as the number of laser pulses intersecting that voxel divided by the voxel's geometric volume, regardless of whether the voxel contains any points itself. This is similar to the ASPRS two-dimensional definitions, where the requirement of using only first returns is effectively counting pulses rather than points.

A byproduct of this volumetric path tracing is that every voxel can be classified into one of three states: full due to containing points, known-empty due to containing no points but having pulses pass through, or unsampled due to being unreachable by the lidar (Fig. 3). This type of classification and knowledge of the unsampled regions has been used to improve methods such as object detection by Yapo *et al.* (2008) and change detection by Haas (2006).

Hagstrom (2014) build on this volumetric analysis idea to estimate completeness of a 3D dataset. Making the assumption that opaque objects always consist of an unsampled interior and known-empty exterior, a completely sampled object would always have at least one layer of full voxels between these two sections. Interfaces between adjacent full and known-empty voxels indicate a known surface, while interfaces between unsampled and known-empty voxels can only appear where surface points are missing. Taking the ratio of the missing surface area to the total surface area gives an estimate of the unsampled surface fraction (USF). While not yet adopted as an official metric, their work shows that 3D completeness can be estimated and that volumetric lidar representations can assist with analysis.

Evaluating 3D density and completeness remains an open problem but one which is increasingly important as lidar becomes more common and datasets increase in density. Though not yet standardized, volume-based metrics are one solution to evaluating 3D dataset quality, and show promise in this regard.

Conclusions

Common standards for metric assessment of lidar data are required to ensure that data quality is sufficient to meet end user needs and to enable objective and quantitative evaluation and comparison of lidar systems and capabilities as well as emerging non-lidar sources of 3D data. As lidar system designs continue to evolve and as lidar data continues to be used in new ways, community standards are also evolving to ensure that metrics continue to accurately characterize data quality. This article has reviewed current industry standards for metric evaluation of lidar data and discussed a few important emerging challenges and preliminary efforts toward addressing them.

Introduction

Weight and space constraints are frequently placed on active EO systems, including lidar systems, but high resolution imaging in cross range requires large optics due to diffraction. Large optics are frequently impractical to use because an imaging system that uses them has to be deeper than a small optical imager to maintain the same $f\#$. This contributes to large monolithic optical systems being heavy and expensive. In order to achieve high resolution at lighter weight and smaller size, methods have been developed to synthesize large apertures either by motion of a single smaller aperture or by an array of smaller apertures (Krause *et al.*, 2011; McManamon and Thompson, 2003).

Using multiple transmitter apertures and multiple receive apertures allows design flexibility not present in monolithic apertures. Synthetic aperture radar is comprised of a single moving aperture, so the transmit and receive apertures both move (Skolnik, 1980, 1990; Soumekh, 1999; Richards, 2005). A synthetic aperture lidar, SAL, uses motion of the single aperture to synthesize a larger effective aperture. For both SAR and SAL the synthetic aperture is almost twice as large as the actual flown distance, due to the angle of incidence being equal to the angle of reflection. This has been experimentally demonstrated over decades in the microwave region, and recently in the optical regime, when SAL, was demonstrated (Krause *et al.*, 2011; Beck *et al.*, 2005). Duncan provides a cross range resolution equation for spotlight-mode SAL:

$$\delta = \frac{R\lambda}{2L + D} \quad (1)$$

where D is the size of the aperture, R is the distance to the object, λ is the wavelength, and L is the distance moved (Duncan and Dierking, 2009). As a result, the effective size of a synthetic aperture based on motion from a diffraction point of view is:

$$D_{\text{eff}} = 2 * L + D_{\text{real}} \quad (2)$$

For RF systems the size of the real aperture is neglected, making the effective aperture twice as large as a monolithic aperture of width equal to the distance flown. The real aperture in RF systems is often on the order of a meter compared to the distance moved, which is multiple kilometers. In an EO system, the real aperture can be a significant fraction of the flight distance, so the D_{real} term is retained. For example, a SAL might have a real beam size of 15 cm and a flight distance of 1 m.

In order to synthesize a large aperture the returned field, including both amplitude and phase, must be measured or estimated. Optical carrier frequencies are much higher than can be measured directly by detectors. For example, a 1.5 μm wavelength has a carrier frequency of 200 THz, orders of magnitude higher than even the highest bandwidth detectors can measure. In order to measure phase as well as amplitude we will need to use a local oscillator, LO, to beat against the return signal. We can choose to have a local oscillator that aligns with the return signal, but uses a different frequency than the transmitter. The two return signals beat against each other to create an intermediate frequency, IF, return. If the LO and the transmitted signal are stable, then the IF return will have the same phase difference as the carrier return. This is called temporal heterodyne, and allows us to measure phase. Alternately we can use spatial heterodyne, sometimes called by the broader term of digital holography, to measure the return phase of the signal. For spatial heterodyne we use an LO that is the same frequency as the transmitter signal, but is offset in angle from the return. This creates a spatial beat, generating fringes across the receive plane, which allows us to measure spatial variations in phase. Both temporal and spatial heterodyne can use either pupil plane or image plane imaging to measure the return fields. When you measure the field, it is possible to convert from image to pupil plane and back, as well as to digitally adjust focus or correct for aberrations.

Conceptual Discussion of Multiple Input, Multiple Output Lidar

Instead of using motion to synthesize a larger effective aperture, such as done in Synthetic Aperture Lidar (SAL), Multiple Input, Multiple Output (MIMO) active EO sensing uses multiple physical sub-apertures to synthesize a larger effective aperture. An array of receive-only sub-apertures can synthesize an effective aperture as large as the receive array if the field across the array can be measured, or estimated. With an array of transmit and receive sub-apertures, even more flexibility is obtained, so long as it is possible on receive to identify which transmitter each photon initially came from. MIMO can be used in both dimensions, or in only one dimension. It can be combined with SAL, with SAL synthesizing a larger pupil plane aperture in one dimension and MIMO in the other dimension.

One effect from multiple transmit and receive sub-apertures is increased angular resolution. This is similar to the angular resolution increase from motion based synthetic aperture sensors. Instead of motion, an array of n sub-apertures that both transmit and receive can be used. Alternately we can have separate arrays for transmitting and for receiving. For 9 sub-apertures in a row, with both transmit and receive from each aperture, the array will have a diffraction limit consistent with a monolithic

aperture that is 1.89 times as large in diameter as the array. This is because 8 sub-apertures are equivalent to the distance moved, L , in Eq. (1) while 1 sub-aperture is equivalent to the real aperture, D_{real} . If transmission occurs from one sub-aperture in the middle of an array, the receive aperture array is effectively in its normal location. If the transmit beam is up one sub-aperture, it is as though the receive aperture were moved down one sub-aperture. If all of the sub-apertures transmit the result is something like what is shown in Fig. 1, where the lighter color linear arrays indicate the perceived location of the linear receive array, depending on which transmit sub-aperture photons are emitted from. The dark color column shows the actual location of the arrays. The lighter columns show the coordinate transformed location of the receive array, based on which aperture is emitting photons. We need to do a coordinate transformation as though all photons are emitted from a single sub-aperture before we can add the fields. The full extent of the linear array is 1.89 times larger, but it is sampled more near the middle of the effective aperture, represented by 9 samples in the middle down to one on either end. This is similar to an apodized aperture.

We could use fewer transmit apertures rather than using them all, and still have the same maximum resolution, but it would reduce the intensity at certain spatial frequencies. The apodizing effect would not be as significant in that case.

An alternate view of the increased resolution is provided in Fig. 2.

The main thrust of Tyler (2012) is to argue that we have multiple ways to obtain the same optical distances because of the multiple receive and transmit apertures. This allows us to solve for the difference in path lengths between the sub-apertures, and to adjust out that optical path difference. This can be done closed form, without iteration.

Fig. 1 Effective receiver aperture placement based on transmit sub-aperture utilized. Dark color shows actual location of the arrays. Light color shows perceived location. The number on the left shows how many received sub-apertures are perceived to be at that location.

Fig. 2 Speckle measurements create a synthetic aperture that is almost twice as large as the array. The diagrams in this figure illustrate the nature of the speckle return from the object. Closed Form MIMO

Rabb *et al.* (2011) only use one receive aperture, but multiple transmit apertures. If transmitters are spaced at distances less than the size of a receive sub-aperture diameter, it provides sampling that can allow a closed form solution to differences in atmospheric path across the sub-aperture array (Fienup, 2000). An example of the resulting effective receiver pupil using transmitter diversity is shown in Fig. 3. Because of the overlap, one can solve in a closed-form manner for the phase between transmit sub-apertures, allowing its use to compensate for atmospheric phase disturbances in the pupil plane.

Rabb showed that he could calculate phase differences between transmit apertures by using multiple closely spaced transmit apertures with a single receive aperture, by using a linear systems of equations in conjunction with three transmit apertures. In this method, they used bivariate expansion to model intra-aperture phase aberrations. Similarly, Gunturk showed closed form phasing to remove intra-aperture aberrations for a single receive aperture using three transmit apertures but he used Zernike polynomials instead of a bivariate expansion (Gunturk *et al.*, 2012). The wave front difference was used to calculate the coefficients of up to seventh order Zernike polynomials to correct for the phase errors. Both of these methods deal with intra-aperture aberrations, but do not address the need for image phasing in a multi-receive aperture imaging system.

Krazcek *et al.* (2016) showed intra and inter-aperture phase aberrations can be solved in a closed form manner similar to Rabb and Gunturk. The intra-aperture aberrations are removed from the field first using an individual receive aperture and an array of three transmit apertures. Krazcek also considered a fourth transmitter widely separated from the three transmitter cluster. This will greatly extend the size of the synthetic aperture and will increase the frequency response cutoff of the system by approximately double, because the fourth transmitter aperture is placed about the width of the aperture array away from the set of 3 transmit apertures. Krazcek analytically calculated the MTF of this MIMO array, and then “experimentally” verified it in simulation using the slant edge MTF approach (Reichenbach *et al.*, 1991).

To perform inter-aperture closed form phasing, intra-aperture phase errors must be removed. The method used by Krazcek closely follows Gunturk’s work, by using three transmit apertures to remove the inter-aperture phase errors.

The left side of Fig. 4 shows an example of a multi-transmitter, single receive aperture system. The receive aperture is light green and the three transmitter cluster is magenta. The cluster is set to the vertices of an equilateral triangle with side lengths equal to the radius of the receive apertures. The right side of 4 shows the measured received fields, referenced to a common coordinate system. This is similar to Fig. 3, taken from Rabb. The overlap regions of the received fields in the pupil plane due to the different transmitter positions are shown in yellow and red. The outer edge of this image is the shape of the synthetic pupil. The synthetic pupil results from all the different fields being referenced to a common coordinate system. This larger synthetic pupil gives rise to a high resolution image. As described in Rabb *et al.* (2010), a shift in the transmitter location has an equal result on the movement of the placement of the received field in the synthetic pupil (Rabb *et al.*, 2010). This necessitates a coordinate change to compensate for different transmitter locations before the pupil plane fields can be coherently added. The synthetic pupil is built from the individual pupil fields being registered into the correct location in post processing. Pupil fields are assembled by Krazcek using known transmitter position since this work was done in simulation.

Fig. 3 Multiple sub-aperture overlap using 3 transmitters in a pattern about half a receive sub-aperture diameter apart. When images are adjusted to account for transmitter location, the receiver sub-aperture pupils overlap as shown. Reproduced from Rabb, D.J., Stafford, J.W., Jameson, D.F., 2011. Non-iterative aberration correction of a multiple transmitter system. *Optics Express* 19 (25), 25048–25056

Fig. 4 Left: Single receive aperture, light green, with three transmitter apertures, magenta. Right: Field overlap due to a single receive aperture and three transmitter cluster.

Fig. 5 Difference between the wave fronts of two overlapped pupil fields. The fringed section in the middle is where the two fields overlap.

The fields incident on the receive aperture can be described by

$$U_i(x, y) = P(x, y) \exp(j2\pi W_e(x, y)) U_b(x - x_i, y - y_i), \quad i = 1, 2 \quad (3)$$

where $P(x, y)$ is the pupil function of the receive aperture, $W_e(x, y)$ is the wave front error over the aperture, $U_b(x - x_i, y - y_i)$ is the received field with the subscript i referring to the i th transmitter. Defining $W_b(x, y)$ to be the wave front of $U_b(x, y)$, the received wave front is

$$W_i(x, y) = W_e(x, y) + W_b(x - x_i, y - y_i), \quad i = 1, 2 \quad (4)$$

The object wave front is not well defined and it is desirable to calculate the wave front aberrations independent of the intended target. As it is necessary to register the different fields based on the field shifts caused by transmitter positions into a synthetic pupil plane, the numerical dependence on the object wave front can be removed. Taking the difference of the overlapping areas in the received wave fronts gives

$$\begin{aligned} \Delta W(x, y) &= W_1(x - x_1, y - y_1) - W_2(x - x_2, y - y_2) = (W_e(x + x_1, y + y_1) + W_b(x, y)) \\ &\quad - (W_e(x + x_2, y + y_2) + W_b(x, y)) = W_e(x + x_1, y + y_1) - W_e(x + x_2, y + y_2) \end{aligned} \quad (5)$$

Due to the coordinate shift, the wave front difference is a difference between the wave front errors, which can be calculated and removed. [Fig. 5](#) shows the difference of the wave front of two overlapped pupil plane fields. The fringed area is where the two field overlap. Notice that this also removes speckle within the region of overlap.

Using the wave front difference, Gunturk is able to remove the intra-aperture phase errors using a set of over-determined linear equations, solving for the Zernike polynomials describing the phase errors across a circular pupil. His method does not work for inter-aperture phase errors because the Zernike coefficients are not necessarily the same between two apertures. The zeroth and first order, piston, tip, and tilt, cannot be solved for in the method describe above because they do not show up in the wave front difference using the same receive aperture. This is because piston is a flat phase and there is no difference in that term across the aperture. Tip and tilt terms have constant slopes across the aperture and therefore also cancel out when taking the difference of the two wave fronts in the same aperture.

A different method must be developed to correct for the inter-aperture tip-tilt-piston aberrations. The top of 6 shows a three transmitter and five aperture array. This is an example of a MIMO system that can be used for inter aperture closed form phasing. The bottom of 6 shows the pupil plane overlap pattern for the system shown in the top 6. Each individual receive aperture provides coverage in the same pattern as shown in 4. There is significantly less overlap between each aperture, but it still exists. The receive apertures should be located as close together as is physically permitted to allow for greater inter-aperture overlap. This greater overlap is beneficial in the registration process. We will define the wave front difference as the wave front error across the overlapped apertures. Assuming that the intra aperture phase errors have been removed, the wave front difference is now defined as

$$\Delta W(x, y) = W_{e,i1,j1}(x, y) - W_{e,i2,j2}(x, y) \quad i1 \neq i2, j1 \neq j2 \quad (6)$$

where $i1$ and $i2$ are different transmit apertures and $j1$ and $j2$ are different receive apertures (Fig. 6).

The left side of 7 shows an example of the wave front difference between two receive apertures. The wave front difference shows only the relative difference between the phase errors on the two apertures. On the left is the wave front difference after intra-aperture corrections have been made and on the right is the same wave front difference after tip-tilt corrections have also been made, resulting in just piston remaining. The gradient can be used on the area between phase wraps to gain an estimate of the tip and tilt between the two apertures. This estimate can then be used to correct tip and tilt. At this point, all that is left is piston. The right side of Fig. 7 shows an example of the wave front difference after all other phase errors are removed, resulting in just piston phase error being left. The value of the dark section is the piston phase. In a noise free environment both the piston and the tip and tilt corrections can be calculated with very few pixels. In a noisy system more pixels will need to be used. When correcting for these inter-aperture phase errors, one aperture is set as a reference to which all others are corrected. The corrections are daisy chained from the reference field to the field farthest away. As seen in 7, only two transmit apertures are required for inter-aperture phasing. Three transmit apertures are still used for intra-aperture phasing and to facilitate inter-aperture phasing with 2D receive aperture arrays.

Adding a fourth transmitter can increase the size of the synthetic pupil significantly, depending on the location of the fourth transmitter. The top of 8 shows a four transmitter, five receive aperture system. The bottom of 8 shows the shape of the synthetic pupil. The set of five circles on the left hand side comes from the fourth, widely separated, transmitter. Those fields do not need to be overlapped since they come from the same apertures that already had the intra and inter-aperture phase aberrations removed. The exception is that there needs to be overlap between at least one pupil field from the fourth transmitter with one of the pupil

Fig. 6 Top: Example of a three transmitter and five aperture array. The red circles are unfilled receive apertures, the light green circles are filled receive apertures and the magenta circles are transmit apertures. Bottom: Example of the field overlaps from the three transmitter and five aperture array shown on top. The light blue areas are where only one field is present, the yellow are areas of two fields overlapping, and the red is where three fields overlap.

Fig. 7 Wave front difference between two pupils coming from two different apertures. Left: A Piston, tip, and tilt error remains. Right: Piston error remains.

Fig. 8 Top: Example of a four transmitter and five aperture array. The red circles are unfilled receive apertures, the light green circles are filled receive apertures and the magenta circles are transmit apertures. Bottom: Example of the field overlaps from the four transmitter and five aperture array shown on top.

fields from the initial three transmitter cluster. In this example, the farthest left field from the fourth transmitter and the farthest right field from the transmitter cluster are overlapped. This overlap is used to obtain an additional piston correction for all pupil fields from the fourth transmitter and allow for field registration. Sub-pixel registration on the speckle in the pupil plane is used. It is assumed exact positions of all transmit apertures are known but overlap is maintained. An additional piston correction will be necessary to account for the different position of the fourth transmitter fields from where the initial inter-aperture measurements were made; movement of the pupil fields cause an additional piston term in the wave front difference, due to tip-tilt, that needs to be corrected (Fig. 8).

Fig. 9 shows the theoretical modulation transfer function (MTF) in the horizontal dimension for the synthetic aperture in 6 on the left and the synthetic aperture in 8 on the right. Notice that the cutoff frequency for the three transmitter and five aperture array is about half the cutoff of the array with four transmit apertures and five apertures. This is because the synthetic pupil size is about half as large in that dimension.

Trade Space of Current MIMO

MIMO techniques as described here can be implemented either using temporal or spatial heterodyne (digital holography) techniques. It will however be much easier to tag the emitted transmitter signals, allowing simultaneous transmission, if high bandwidth temporal heterodyne is used, since high bandwidth tagging schemes can then be used. RF MIMO techniques that use multiple simultaneous phase centers have been developed (Coutts *et al.*, 2006).

The angular resolution of an array of sub-apertures can be almost twice the resolution of the diffraction limit for a monolithic aperture. In addition, atmospheric turbulence between the object imaged and the sensor can be very quickly and accurately compensated because we do not need to use an iterative approach to finding the required optical path correction to compensate for the turbulence. This compensation is relatively straightforward for turbulence in the pupil plane, but will be more difficult for

Fig. 9 MTF plots for the arrays shown in 5 and 7. The X-axis is in cycles per mm. Left: Horizontal MTF for array shown in 6. Right: Horizontal MTF for array shown in 7.

volume turbulence. A significant limitation is that the received signal is captured in a smaller receive aperture area. The required laser power will increase by the ratio of the area of the monolithic aperture to the received aperture array area. Also, if the angular resolution is greater than a monolithic aperture of the same size, the cross section of each pixel is lower because of the increased resolution. This results in either more required power, or lower signal to noise. Since each new transmit aperture adds power this can balance out.

Arrays of high temporal bandwidth detectors will be very helpful in implementing MIMO techniques for EO imaging. The papers cited sequenced through the multiple transmitters because they implemented MIMO using a digital holography/spatial heterodyne approach to imaging, using low bandwidth framing detector arrays. If high bandwidth detector arrays and a temporal heterodyne approach to imaging are used then it should be possible to simultaneously emit multiple tagged transmitter beams, and to have each receiver be able to distinguish the transmit aperture any photon came from. High-bandwidth detectors can allow high bandwidth modulations to be imposed on each transmitted beam, and sorted on receive. Temporal heterodyne arrays will need to be AC-coupled, or have high dynamic range, or have high sensitivity such that temporal heterodyne can be implemented using a relatively weak LO.

A second technical hurdle to overcome is volume turbulence. Techniques for calculating, and compensating for, volume turbulence still need to be developed.

MIMO technology will allow imaging with high angular resolution using a much lighter and more compact aperture arrays than a monolithic aperture. An array of small sub-apertures can be much thinner and lighter than a monolithic aperture. Also, a MIMO approach can achieve almost twice the diffraction limited angular resolution of a monolithic aperture.

To be really useful in freezing the atmosphere, MIMO should be implemented using high bandwidth detector arrays, which still need to be further developed. There will be a digital implementation requirement to conduct the required calculations. There will be a need to have many different optical trains, complicating the optical system. Also, narrow line lasers will need to be used to do either spatial or temporal heterodyne. Higher power lasers will be required to image a given area using a MIMO array compared with imaging with a monolithic aperture because the spatial frequency cutoff of the measured signal is being increased more rapidly than the area of the pupil plane receive aperture.

Conclusion

This technology is well suited for long range imaging applications from air or space. MIMO could be used in the cross range dimension along with motion-based synthetic aperture imaging.

In summary, MIMO approaches for active EO sensing can, at a minimum, increase the effective diameter of an aperture array by almost a factor of two, and can allow multiple sub-apertures on receive to be phased using a closed-loop calculation of the phase difference between sub-apertures. This can compensate for atmospheric turbulence at least at some locations between the sensor and the imaged object.

Nomenclature

a	Random variable for the number of primary photoelectrons injected into a multiplier	NEP	Photoreceiver noise expressed as an equivalent input optical power level
a_{bg}	Random variable for the number of primary background photoelectrons	NEPh	Photoreceiver noise expressed as an equivalent number of input photons
a_{dark}	Random variable for the number of primary dark current electrons	n_h	Count of holes within the depletion region of a junction
a_{signal}	Random variable for the number of primary signal photoelectrons	N_Q	Photoreceiver noise expressed as an equivalent number of electrons at the APD output
BW	A modulation frequency bandwidth in Hz	n_{th}	Detection threshold expressed as an equivalent number of electrons at the APD output
F	Excess noise factor by which APD output variance exceeds the deterministic gain case	P_{RX}	Photoreceiver output distribution scaled to electron count at APD output
I_{bg}	Background photocurrent measured at the APD's terminals	q	Elementary charge
I_{dark}	Dark current measured at the APD's terminals	QE	Quantum efficiency
$I_{primary}$	Primary current injected into a multiplier	Q_{signal}	Output signal charge in units of electrons
I_{signal}	Signal photocurrent measured at the APD's terminals	R	Responsivity
k	Impact ionization rate ratio for electrons and holes (slower rate over faster rate)	$S_{I\ TIA}$	Input-referred noise current spectral intensity of an amplifier in units of $A^2\ Hz^{-1}$
M	Mean avalanche gain factor	$S_{I\ total}$	Total noise current spectral intensity of a photoreceiver
m	Random variable for the per-electron gain factor	S_I	Noise current spectral intensity
n	Random variable for the total number of electrons output by a multiplier	t	Time
N_{CTIA}	Input-referred charge noise of an amplifier in units of electrons	Γ	Euler gamma function
n_e	Count of electrons within the depletion region of a junction	v_{se}	Electron saturation drift velocity
		v_{sh}	Hole saturation drift velocity
		w	Junction depletion width
		λ	Optical signal wavelength

Introduction

Linear-mode (LM) avalanche photodiodes (APDs) are used to preamplify signal photocurrent in photoreceivers where amplifier circuit noise is the dominant noise component. Since amplifier noise is a fixed quantity that is independent of the APD's gain, the photoreceiver's signal initially increases faster as a function of APD gain than its total noise, improving measures of sensitivity such as the signal-to-noise ratio (SNR). However, LM APDs amplify the shot noise associated with charge carrier generation in the diode junction and also generate excess shot noise associated with the stochastic gain process itself. Since an APD's shot noise increases faster with gain than the amplified signal photocurrent, optimal photoreceiver sensitivity occurs at some finite gain that is determined by factors such as the intensity of the amplifier noise, the magnitude of the APD's dark current, the intensity of the optical signal, and the statistics of the APD's gain process. The interplay of photoreceiver noise components leading to optimal sensitivity at finite gain is illustrated in Fig. 1.

InGaAs LM APD Structure and Manufacturing

Several binary and ternary III–V compound semiconductor alloys are plotted in Fig. 2 according to their crystal lattice parameters and their bandgaps at room temperature. In the diagram, the binary alloys are plotted as points, connected by arcs representing the range of ternary alloy compositions which result from blending pairs of binary alloys. $In_{0.53}Ga_{0.47}As$ is the alloy composition aligned vertically with the triangle representing InP, which means they share the same lattice parameter. $In_{0.53}Ga_{0.47}As$ is favored for use in short-wavelength infrared (SWIR) detectors because its direct and relatively narrow (~ 0.74 eV) bandgap results in efficient light absorption out to a cutoff wavelength near $1.7\ \mu m$ and because comparatively thick ($\sim \mu m$) single-crystal light absorption layers can be grown with very low defect density, lattice-matched to InP substrates. Although non-lattice-matched InGaAs alloy compositions can be grown on InP substrates to push spectral response further into the SWIR, the use of non-lattice-

Fig. 1 Total noise, noise components, and signal-to-noise ratio of an avalanche photodiode (APD) photoreceiver vs. mean avalanche gain.

Fig. 2 Room temperature band gap vs. crystal lattice parameter for technologically important III-V compound semiconductor alloys.

matched alloys in APDs is not common, owing to the sensitive dependence of APD dark current on defect density. Dark current considerations also constrain selection of the alloys used for avalanche multiplication layers in InGaAs APDs to either InP itself or the lattice-matched ternary $\text{In}_{0.52}\text{Al}_{0.48}\text{As}$. Wider-bandgap alloys like InP or InAlAs are preferred for use in APD multiplication layers because their use minimizes dark current generation by band-to-band tunneling.

The single-crystal thin films from which InGaAs APDs are fabricated are grown on (100)-oriented or (100)-vicinal InP substrates by molecular beam epitaxy (MBE) or metal-organic chemical vapor deposition (MOCVD). Most InGaAs APDs share a common epitaxial structure in which an InGaAs light absorption layer and a charge carrier multiplication layer are separated by a space charge layer. Also called a field control layer, the charge layer assures that during operation, the electric field in the narrower-bandgap absorber will remain weak enough to limit dark current generation by tunneling when the electric field in the wider-bandgap multiplier is strong enough to generate a useful amount of avalanche gain. The charge layer of an InGaAs APD is the most critical to its function, and calibration of the charge layer's thickness and active doping concentration is the most difficult aspect of InGaAs APD manufacturing. Too many active dopant ions between absorber and multiplier result in an APD that reaches

avalanche breakdown at a reverse bias lower than that required to render it sensitive to optical signals, whereas too few result in excessive dark current generation by tunneling at reverse bias lower than that required to achieve useful avalanche gain. Common methods of doping calibration used in crystal growth labs, such as Hall effect measurements or electrochemical capacitance–voltage (ECV) profiling, typically do not have sufficient precision to calibrate InGaAs APD charge layers. Instead, prior to growth of production wafers, charge layer calibration is commonly accomplished by growth of complete APD layer stacks followed by quick-turn fabrication and current–voltage (I – V) characterization of test structures.

The separate absorption, charge, and multiplication (SACM) layer stack is sandwiched between anode and cathode layers. It is common to grow InGaAs APDs with the cathode side down, and often n-type InP substrates are selected so that electrical contact to the APD's cathode can be made through the wafer substrate. The ordering of the SACM layer stack between anode and cathode is determined by which alloy is selected for the multiplication layer. Because the absorption layer is physically separate from the multiplication layer, and because electrons drift toward the cathode and holes drift toward the anode of a reverse-biased diode, only one carrier polarity can be injected into the multiplier. The impact ionization rate of holes is higher in InP than that of electrons, but lower than that of electrons in InAlAs. Consequently, InP multipliers are grown on the anode side of the absorber, whereas InAlAs multipliers are grown on the cathode side of the absorber. The two common SACM stack orderings are illustrated in Fig. 3.

Detector elements are formed from the epitaxial thin film either by patterned diffusion to define the active area of each element, or by etching away the film surrounding each element. In the most common implementation of the diffused junction design, the anode layer of the APD thin film is not doped during crystal growth. Instead, the p-type dopant species – typically zinc – is introduced during wafer fabrication by diffusion through openings patterned in a dielectric mask layer that is deposited over the thin film. The maximum electric field strength inside the junction of a diode formed by patterned diffusion tends to occur at the edge of the diffusion because charge neutrality requires that the donor ions on the cathode side of the junction be balanced by an equal number of acceptor ions on the anode side. The upward curvature of the depletion region at the edge of the anode diffusion results in ionized acceptors facing ionized donors along a narrower frontage, concentrating the electric field (Fig. 4, left). Shallower anode diffusions result in tighter radii of curvature with higher maximum electric field strength. Multilevel diffusions or diffused guard rings surrounding the central anode can be used to minimize crowding of electric field lines at the perimeter of a

Fig. 3 Typical layer orderings for InP- and InAlAs-multiplier InGaAs avalanche photodiodes (APDs).

Fig. 4 Sketch of electric field lines in diffused junction photodiodes with (right) and without (left) guard rings.

diffused anode by reshaping the depletion region along the edge of the detector element, preventing edge breakdown (Fig. 4, right).

APDs fabricated by etching are made from thin films in which the top contact layer (typically the anode) is doped during crystal growth. Instead of defining the junction area by patterning the anode doping, the thin film outside the detector element area is etched away down to the substrate, leaving behind a mesa. Whereas the principal concern with diffused junction APDs is managing the electric field intensity at the perimeter of the patterned diffusion, it is sufficient that the sidewalls of an etched mesa APD be smooth, and slope gradually inward from the base of the mesa. Physical irregularities on the mesa sidewall – and especially notches where the slope of the mesa sidewall reverses, creating an overhang – can locally enhance the electric field and create a weak point at the junction perimeter. However, in general, the chemical cleanliness of the mesa sidewall is the principal manufacturing challenge for mesa APDs.

Most of an APD's dark current is generated in its InGaAs absorption layer because, having the narrowest bandgap in the structure, it presents the lowest energetic barrier to generation of charge carrier pairs, and because it is depleted during operation of the APD. In a diffused junction APD the InGaAs layer is safely buried under a wider-bandgap material like InP, and the depletion region intersects the wafer surface along a narrow band of wider-bandgap material at the anode perimeter. In contrast, a swath of depleted narrow-bandgap InGaAs is exposed along the sidewall of an etched mesa APD. Interruption of a crystal lattice by a surface creates a high density of mid-bandgap trap states. When the surface is of a narrow-bandgap semiconductor alloy and lies within the depletion region of a photodiode, a high dark current generation rate results. Chemical formation of materials with higher conductivity than the depleted diode junction is another problem at the mesa sidewall, as this can form a conductive path that shunts the diode. Both issues are addressed during mesa APD manufacturing by preparing mesa sidewalls that are as chemically clean – and devoid of sub-surface damage to the lattice – as possible, and then encapsulating the clean sidewall surface under an impermeable dielectric coating to protect it from environmental degradation. In some cases, chemical passivation treatments – often involving sulfide compounds – are applied to the mesa sidewall prior to encapsulation. Chemical passivation works by forming bonds at the semiconductor surface, the molecular orbitals of which lie outside the semiconductor bandgap, such that the resulting energy states do not behave as traps. The passivation treatment replaces trap states with inactive states and prevents traps from forming by tying up potentially reactive surface sites.

Fabrication of APDs also includes deposition of anode and cathode metal contact pads, and usually deposition of an anti-reflection coating. Different APD shapes and configurations are possible. The most common APD configuration is designed for illumination normal to the wafer surface, with light absorption occurring in a single pass through a comparatively thick ($\sim \mu\text{m}$) absorption layer. APDs of this class are commonly fabricated with active area diameters ranging from about 25 to 500 μm . Larger InGaAs APDs are seldom fabricated because detector capacitance, dark current, and manufacturing yield loss all scale linearly with junction area. However, hemispherical immersion lenses are sometimes affixed to APDs to increase their effective light-gathering area. APDs with thick single-pass absorbers may be top- or bottom-illuminated, depending upon whether the optical signal is delivered from the side of the wafer on which the epitaxial thin film was grown, or through the InP substrate. Top-illuminated InGaAs APDs tend to have superior responsivity at wavelengths shorter than the InP absorption band edge at about 950 nm, although the short-wavelength response of bottom-illuminated InGaAs APDs can be enhanced by physically removing the InP substrate. Bottom-illuminated APDs can be bump-bonded directly to application-specific integrated circuits (ASICs) to achieve lower interconnect parasitics than is possible with front-illuminated APDs of equal active area, and the bottom-illuminated configuration is always used for dense two-dimensional imaging arrays of APD pixels. A cross section through an example 25- μm diameter, bottom-illuminated, etched mesa APD pixel is sketched in Fig. 5 to illustrate the major structural parts of such a device. In Fig. 5 a ring-shaped cathode contact around the base of the APD mesa is connected to a pad on top of an adjacent inactive mesa for easy of bump-bonding of both anode and cathode connections. It is common for all the APD pixels of a multielement array to share a small number of common cathode connections.

Fig. 5 Cross-sectional sketch of a representative etched mesa InGaAs avalanche photodiode (APD) pixel.

APDs designed for high-bandwidth operation (greater than a few GHz) must minimize their junction thickness in order to cut down the junction transit time. Minimizing the junction thickness minimizes the thickness of the InGaAs absorption layer, so alternative APD configurations like resonant cavity and waveguide designs are necessary to maintain high quantum efficiency (QE). Resonant cavity APDs are illuminated normal to the wafer surface but include mirrors above and below the standard SACM layer stack in order to create a vertical optical cavity that increases the effective number of passes an optical signal takes through the thin absorption layer. In waveguide APDs, the optical signal propagates in the plane of the thin film, so the absorption path length can be increased without increasing the junction transit time. Resonant cavity APDs have the advantage of comparatively easy optical coupling at the resonant wavelength, since the signal may be focused onto the surface of the wafer. Resonant cavity APDs can also be built with very small junction area, which limits capacitance. In comparison, waveguide APDs present the challenge of coupling the optical signal into an edge-facing facet of the in-plane waveguide, and potentially have higher capacitance owing to the larger footprint of the waveguide structure. However, the lattice-matched alloys from which epitaxial distributed Bragg reflectors (DBRs) can be formed for resonant cavity APDs do not provide very much refractive index contrast, necessitating gratings with a large number of periods which are difficult to manufacture. Also, resonant cavity APDs only work well at a single wavelength, since the DBR through which the signal enters is reflective at nonresonant wavelengths. Although these high-bandwidth APD configurations are potentially of interest for light and compact optical free space communications transceivers, APDs are not generally used for very high-bandwidth terrestrial telecommunications because erbium-doped fiber amplifiers (EDFAs) paired with gain-less photodiodes provide superior speed and sensitivity.

Some manufacturing issues have a bigger impact on dense APD pixel arrays than on single-element detectors. Localized morphological defects originate from thin film growth over dust or patches of native oxide remaining on imperfectly cleaned substrate surfaces, or from growth over regions on the substrate surface inadvertently damaged during the thermal desorption process that removes the native oxide. Fig. 6 is an amplitude mode atomic force microscope (AFM) image of an unusually large dust-related defect. Other morphological defects may be introduced during thin film growth as a metal droplet spat from an effusion cell, or as a patch of non-stoichiometric material created by a local temperature or pressure excursion outside the growth window for the compound semiconductor. When one of these defects occurs within the footprint of an APD's active area it can provide a current path that shunts the diode junction, causing the detector element to fail short. The area density of these defects on an APD wafer is usually on the order of 100 cm^{-2} , and APD active areas are small, so shorted single-element detectors can be screened out and rejected with very modest manufacturing yield loss. However, even when the probability is very low that any given detector element is defective, the likelihood of yielding large format APD arrays with 100% operable pixels drops rapidly with array format. For example, if the likelihood any given $30\text{-}\mu\text{m}$ -diameter pixel is defect-free is about 99.93%, the likelihood that every one of the 1024 pixels in a particular 32×32 -format array is defect-free is only about 48.5%; for 64×64 -format arrays the estimated yield of completely defect-free array die is only about 5.5%. Insofar as InGaAs APDs operate at voltages that greatly exceed the damage threshold of most CMOS processes and a shorted APD pixel drops most of that high voltage across the readout integrated circuit (ROIC) to which it is connected, it is usually necessary to engineer into the interconnect between APD and ROIC pixels a means of isolating shorted APD pixels.

Limited optical fill factor is another issue particular to APD arrays. Arrays of etched mesa pixels have the advantage of extremely good inter-pixel isolation but cannot make use of the portion of the optical signal which falls between pixel active areas. The dimensional tolerance of the semiconductor process used to pattern and etch pixel mesas determines some minimum separation between adjacent mesas. As the pixel pitch decreases, the dead area consumed by this minimum inter-mesa gap becomes a larger fraction of the total pixel footprint. The ratio of active area to pixel footprint defines an optical fill factor by which the signal is attenuated. Optical fill factor can be recovered by aligning a microlens array to an APD array, such that light incident on the footprint of each microlens element is reimaged onto the active area of the corresponding APD pixel. However, practical implementation can be challenging for finer pixel pitches when the array is to be compatible with small f -number external camera

Fig. 6 Amplitude mode atomic force microscope (AFM) image of a large dust-related defect on an avalanche photodiode (APD) wafer surface.

optics of the sort commonly used in compact sensor systems. APD and microlens wafers thinner than about $300\text{ }\mu\text{m}$ – and, depending on size, die which are thinner than about half that – cannot be safely handled as independent pieces without high risk of breakage. Depending on pixel pitch, pixel size, and the f -number of external camera optics, a microlens focal length less than $100\text{ }\mu\text{m}$ may be required, necessitating use of special techniques such as substrate removal and attachment of temporary mechanical handling wafers during fabrication.

InGaAs LM APD Device Characteristics

Example current–voltage (I – V) and capacitance–voltage (C – V) characteristics for a $500\text{-}\mu\text{m}$ -diameter InGaAs LM APD are overlaid in Fig. 7, with reverse current plotted logarithmically against the left-hand axis and capacitance plotted linearly against the right-hand axis. The InGaAs APD in question is one of the larger to be produced commercially. APDs of smaller junction area have proportionally lower dark current and capacitance, although these parameters also depend somewhat on details of structure and manufacture. However, the characteristics in Fig. 7 exhibit features that are common to all InGaAs LM APDs.

Both the current and capacitance characteristics undergo an abrupt step at approximately 22 V reverse bias. This step occurs because the junction’s growing depletion region has finished penetrating the doped space charge layer which separates the APD’s multiplication and absorption layers. Prior to “punching-through” the charge layer, the junction’s depletion region does not extend into the narrow-bandgap InGaAs absorption layer, and a potential energy barrier prevents charge carriers generated in the absorber from reaching the junction and contributing to the diode’s reverse current. Reverse current jumps at punch-through because with the potential barrier pulled down, the junction abruptly becomes able to collect the charge carriers generated in the absorption layer. Capacitance drops abruptly at punch-through because the junction’s depletion region is able to widen into the substantially undoped absorption layer.

The vertical asymptote in the reverse current characteristics of Fig. 7 occurs at the APD’s avalanche breakdown voltage, the critical reverse bias at which the impact ionization process inside the APD junction becomes self-sustaining. Breakdown occurs because secondary charge carriers generated by impact ionization can themselves initiate further impact ionization in a branching chain reaction which need never terminate if the propensity to impact-ionize is high enough. A notional chain of impact ionization events is diagrammed in Fig. 8, where time progresses downward on the page and – because of their opposite electric charge – electrons are depicted drifting to the right and holes drift to the left. The starburst symbols from which both the initiating carrier and a new electron–hole pair emerge represent impact ionization events. The fact that impact ionization is a stochastic process is represented in Fig. 8 by the starburst outlines which do not result in additional secondary carriers – these are impact ionization events which might have happened but didn’t in the eventuality sketched. Because the multiplication layer is of finite width, carriers can drift out of the multiplier without triggering impact ionization. Below the APD’s breakdown voltage, every impact ionization chain eventually terminates in this way, so the avalanche gain is finite. Increasing the reverse bias applied to the APD’s terminals exponentially increases the impact ionization rate until, at the breakdown voltage, chains which never terminate become possible. When an APD is biased above its breakdown voltage it behaves like a low value resistor, and the current through the diode is limited by what its bias circuit can supply rather than by the APD junction characteristics. It is advisable to use

Fig. 7 Current–voltage (I – V) and capacitance–voltage (C – V) characteristics of a representative $500\text{-}\mu\text{m}$ InGaAs Linear-mode (LM) avalanche photodiode (APD).

Fig. 8 Diagrammatic sketch of notional impact ionization chains inside an avalanche photodiode's (APD's) multiplier.

current-limited supplies when operating or testing APDs near breakdown, because most InGaAs LM APDs burn out under direct currents in the 1–10 mA range.

QE, avalanche gain (M), and spectral responsivity (R) are usually calculated from direct current (DC) I - V characteristics of the sort plotted in Fig. 7. Responsivity, the APD's ratio of output photocurrent to input optical power, expresses the linear relationship alluded to by the terminology LM APD, and contains factors of gain and QE:

$$R = 8.065544 \times 10^5 \times M \times QE \times \lambda \text{ (AW}^{-1}\text{)} \quad (1)$$

where λ is the optical wavelength in m.

Of the three parameters QE, gain, and responsivity, only responsivity can be measured directly and unambiguously for every InGaAs LM APD. DC responsivity measurements are made by using an optical power meter with a reference photodiode to calibrate the optical power delivered from a monochromatic, continuous-wave (CW) source such as a stabilized diode laser or a monochromator. The DC photocurrent characteristic is found by subtracting the dark I - V characteristic from the light I - V characteristic, so that at any given reverse bias the responsivity is the photocurrent divided by the optical power delivered to the APD's active area.

When operated at a fixed reverse bias, gain saturation causes an InGaAs LM APD's responsivity to drop if the optical signal intensity is increased beyond a certain level. Gain saturation occurs when the photocurrent density is high enough that the mobile charges carrying the current partially compensate the ionized dopant atoms of the APD junction. The impact ionization rate in the APD multiplier is an exponential function of the local electric field strength. Partial compensation of the ionized dopants weakens the electric field, reducing the ionization rate, and therefore the avalanche gain. Different APD designs exhibit gain saturation to different degrees, but in general, the onset of gain saturation occurs at lower optical signal levels when a given APD is operated at higher avalanche gain. This is because the space charge compensation mechanism depends on the charge density carried by the multiplied photocurrent, whereas the optical signal power only determines the primary photocurrent prior to multiplication. Fig. 9 illustrates this point with responsivity data from a 75- μm -diameter InGaAs LM APD. The APD was operated at different reverse biases under 1550 nm illumination at different optical power levels. The lowest operating point depicted, 67.5 V reverse bias, corresponds to an avalanche gain of about $M=10$. Very little gain saturation is observed for the 67.5 V responsivity curve from 1 nW through 10 μW of optical signal power, whereas the responsivity curve at 70.35 V reverse bias drops from nearly 80 A W^{-1} ($M \approx 80$) for a 1 nW signal to close to 10 A W^{-1} ($M \approx 10$) for a 100 μW signal.

InGaAs LM APDs are usually used to sense weak optical signals, but gain saturation has practical bearing on optical overload behavior and special situations such as optical heterodyne systems in which a weak signal is coherently mixed with a strong optical local oscillator. Gain saturation can also affect the accuracy of APD experiments meant to isolate some property of the

Fig. 9 Avalanche gain saturation as a function of optical power for a representative 75- μm InGaAs linear mode (LM) avalanche photodiode (APD).

photocurrent, in which a measurement taken in the dark is subtracted from the same measurement under strong optical illumination. Spurious measurements can result if the test signal is bright enough to saturate the APD's gain because then the APD's gain operating point is higher for the dark measurement than for the illuminated measurement, and not all of the light-versus-dark difference results from the photocurrent.

Although the DC responsivity of an APD is a commonly reported parameter, APDs are almost always used to detect rapidly modulated or pulsed optical signals. APD responsivity to modulated optical signals decreases with increasing modulation frequency because of the APD's fundamental impulse response, and because of low-pass filtering related to the APD's capacitance in combination with the characteristics of the amplifier which operates the APD. According to the Shockley–Ramo theorem, the instantaneous terminal current of an APD depends upon the instantaneous drift velocities of the electrons and holes in its junction, but can be approximated based on the instantaneous count of electrons and holes present in the junction (n_e and n_h), average electron and hole saturation drift velocities (v_{se} and v_{sh}), and the junction width (w):

$$i(t) \approx \frac{q}{w} [v_{se} n_e(t) + v_{sh} n_h(t)] \quad (\text{A}) \quad (2)$$

where q is the elementary charge.

The fundamental impulse response of an APD has a finite rise time because it takes a finite amount of time for the instantaneous population of secondary carriers in the junction to reach its maximum value. It takes time for primary photocarriers generated in the absorber to reach the multiplier, and once there, carriers which lack sufficient kinetic energy to impact ionize must move through a minimum displacement in the local electric field – the carrier's dead space – in order to pick up the ionization threshold energy. Once energetically active, carriers do not instantly impact ionize. Instead, active carriers travel a variable distance through the multiplier before ionizing – if they ever ionize – based on alloy composition and field-dependent impact ionization rates. Following impact ionization, both the original primary carrier and the newly generated secondary carriers must again pick up the ionization threshold energy before they can trigger new ionizations.

The fall time of an APD's fundamental impulse response is determined by how long impact ionization continues in its multiplier after the peak instantaneous carrier population is reached, and how far secondary carriers must travel from their point of generation in the multiplier to exit the junction. Electrons exit the junction at the cathode and holes exit at the anode, so depending upon the APD's epitaxial stack order (Fig. 3), one carrier type has a short distance to travel to exit the junction and the other carrier type must cross the absorption layer. The carrier type with further to travel carries most of the current. When an APD is operated at low gain, generation of secondary carriers may end before any of the secondary carriers of the type with further to travel have exited the junction, in which case the peak of the impulse response coincides with the end of impact ionization and the fall time is determined by the absorber transit time. However, when an APD is operated at higher gain, impact ionization may continue after the peak of the impulse response, extending the fall time of the APD.

Monte Carlo simulations of the impulse response of an APD operating at $M=12.3$ and $M=44.0$ are compared in Fig. 10. The APD that was simulated has a 1.5- μm -thick InGaAs absorber and a 0.3- μm -thick InAlAs multiplier; including various spacer layers and the charge layer, the total junction width of the simulated APD was 2.25 μm . Saturation drift velocities typical of electrons and holes in these alloys – respectively 10^5 m s^{-1} for electrons and $5 \times 10^4 \text{ m s}^{-1}$ for holes – were assumed. The spatial distribution of

Fig. 10 Monte Carlo simulation of an InGaAs avalanche photodiode's (APD's) photocurrent impulse response.

primary photocarrier generation within the absorber, the dead space effect, and the stochastic nature of impact ionization are treated in this model, but with the approximation of a hard dead space and local field-dependent rather than carrier energy-dependent impact ionization rates, meaning that a carrier's propensity to impact-ionize is treated as abruptly assuming a value that depends on the local field strength once it picks up the ionization threshold energy, as opposed to gradually increasing as it accumulates kinetic energy in excess of the threshold. The approximation that all carriers travel at the average saturation drift velocity at all times is also made, rather than tracking the velocity of individual carriers as they are accelerated by the electric field and lose energy through scattering. These approximations – especially the values chosen for the saturation drift velocities – affect the scaling of the simulated impulse response, but **Fig. 10** illustrates the qualitative features that the carrier type which takes longest to leave the junction dominates the total current, and the fall time is extended at higher avalanche gain. The increase of impulse response duration with gain places a fundamental limit on APD gain-bandwidth product.

The impulse response of an InGaAs LM APD can be measured by exciting it with a laser pulse that is very short compared to the APD's junction transit time, and observing the resulting photocurrent pulse with an oscilloscope, but the input impedance of the scope in combination with the APD's junction capacitance low-pass filters the voltage waveform measured by the oscilloscope. InGaAs LM APD capacitance varies with junction area from less than 0.1 pF for small APD pixels to greater than 10 pF for the largest detector elements. Whereas smaller InGaAs LM APDs typically have sub-nanosecond impulse response, **Fig. 11** illustrates how the 12.3 pF capacitance of a 500- μm -diameter APD leads to much longer impulse response durations.

Similar low-pass filtering effects occur when an APD is connected to an amplifier circuit, and any given amplifier design provides gain over a limited frequency band, so the frequency response of an APD photoreceiver depends as much on the characteristics of the amplifier as on those of the APD. The highest gain-bandwidth products reported for experimental waveguide (Kinsey *et al.*, 2001) and resonant cavity (Lenox *et al.*, 1999) InGaAs LM APDs as individual components is about 300 GHz, but most commercially available InGaAs LM APD photoreceivers have 3 dB bandwidths in the range from tens of megahertz to a few gigahertz. Example plots of photoreceiver responsivity in unit of V W^{-1} (i.e., including a factor of the amplifier's transimpedance gain) versus modulation frequency are shown in **Fig. 12** for a photoreceiver assembled from a 75- μm -diameter InGaAs LM APD and a transimpedance amplifier (TIA) chip designed for 2.125 Gbps optical communications.

The photocurrent gain of an APD is the ratio between the photocurrent measured at its terminals to the primary photocurrent generated in its absorber. Avalanche gain is a critical input to APD sensitivity calculations because it affects both signal level and the intensity of excess multiplication noise. APD dark current is also commonly benchmarked to a particular reference gain, and empirical measurement of the APD's excess noise factor requires knowing the gain at which noise power measurements are collected. It is therefore unfortunate that the gain of an InGaAs LM APD often cannot be measured unambiguously.

Although terminal photocurrent is directly measured by subtracting dark from light I - V characteristics, measurement of the primary photocurrent can be ambiguous because photocarriers generated in the APD's absorber cannot contribute to the terminal current until the APD is biased above its punch-through voltage. Since the electric field in the APD's multiplier strengthens with increasing reverse bias regardless of whether or not punch-through has yet occurred, it is often the case that at the APD's punch-through voltage, when it first becomes possible to observe photocurrent, impact ionization is already generating avalanche gain in the multiplier.

Bias-dependent collection efficiency of primary photocarriers by the junction is a second factor which can make gain measurements ambiguous. Although the APD abruptly becomes sensitive to light at its punch-through voltage, the collection efficiency of primary photocarriers increases with increasing reverse bias until the InGaAs absorption layer is fully depleted. Since avalanche

Fig. 11 Measured impulse response of a 500- μm InGaAs linear mode (LM) avalanche photodiode (APD).

Fig. 12 Measured frequency response of an InGaAs linear mode (LM) avalanche photodiode (APD) photoreceiver assembled from a 75- μm APD and a transimpedance amplifier (TIA) designed for 2.125 Gbps telecommunications.

gain also increases with increasing reverse bias, both the supply of primary photocarriers reaching the multiplier and the gain factor by which they are multiplied increase as the reverse bias is raised past the APD's punch-through voltage. In order to avoid confusing increasing collection efficiency for avalanche gain, gain measurements based on the terminal photocurrent must be made relative to a reference point for which collection efficiency is already at its maximum value. Maximum collection efficiency is usually reached within a few volts of punch-through and is recognizable as a local minimum of the slope of the photocurrent characteristic above the punch-through voltage. The point of minimum photocurrent slope above punch-through can be attributed to the collection efficiency nearing its maximum because any contribution to the slope from avalanche gain increases monotonically with reverse bias. The photocurrent characteristic of an APD for which the primary photocurrent is directly observable has a slope above punch-through that approaches zero where collection efficiency is maximized and increases gradually thereafter as avalanche gain turns on. The point of minimum photocurrent slope above punch-through is also used as a reference point for relative gain measurements in APDs where avalanche gain is already active in the multiplier at punch-through, but in this case, the minimum slope is nonzero and an absolute measurement of the primary photocurrent cannot be made. [Fig. 13](#) replots on linear

Fig. 13 Photocurrent characteristic of a representative 500-μm InGaAs linear mode (LM) avalanche photodiode (APD).

axes the photocurrent characteristic derived from Fig. 7. The minimum slope reference point occurs near 23 V reverse bias but is nonzero, from which one can infer that the multiplier is already generating some avalanche gain at punch-through.

If an InGaAs LM APD's primary photocurrent cannot be directly measured, that prevents exact measurement of its avalanche gain. In that circumstance, measurement of QE is similarly ambiguous, because the gain must be known in order to find the QE from a responsivity measurement. In this common circumstance, physical arguments or measurements on physically analogous photodiodes which lack a charge layer can be used to bound the plausible QE and gain, based on responsivity measurements. For instance, the bottom-illuminated 500-μm-diameter APD whose I - V characteristics were plotted in Figs. 7 and 13 has a 1.5-μm-thick InGaAs absorption layer. Ellipsometric measurements on pure InGaAs films give an absorption coefficient of 6700 cm^{-1} at 1500 nm. The minimum plausible QE at 1500 nm, when this APD is operated at 23 V reverse bias, can be estimated by assuming an antireflection coating that transmits 99% of the incident optical power, transmission losses of about 15% through the doped substrate, and absorption of about 63.4% of the optical signal in a single pass through the InGaAs layer, calculated from the known absorption coefficient under the assumption of near perfect collection efficiency. This results in a lower bound estimate of $\text{QE} = 53.3\%$. On the other hand, in this design the optical signal is intended to back-reflect from the underside of the APD's anode contact, passing through the absorber a second time. In the best case scenario the substrate absorption is only 5% and the back-reflection is lossless, giving a high estimate for the plausible QE of about $\text{QE} = 81.4\%$. Eq. (1) gives unity-gain responsivities at 1500 nm of $R = 0.64 \text{ A W}^{-1}$ in the worst case QE scenario and $R = 0.98 \text{ A W}^{-1}$ in the best case. In comparison, an empirical spectral responsivity measurement at 1500 nm with the APD biased at 23 V finds a responsivity of $R = 0.99 \text{ A W}^{-1}$, implying that at 23 V the APD is actually operating with a gain between $M = 1.0$ and $M = 1.5$. The continuous increase of photocurrent with reverse bias observed in Fig. 13 shows that by 23 V some avalanche gain is already occurring, which is consistent with the range estimated for the gain. Example responsivity and QE spectra for this APD that reflect the gain calibration ambiguity are plotted in Fig. 14.

Multiplied shot noise is the dominant noise source in an InGaAs LM APD. Because InGaAs LM APDs are exclusively used to sense fast optical signals, any significant $1/f$ noise generated by an InGaAs LM APD is usually at frequencies below the low-frequency cutoff of its amplifier. Some references include a Johnson–Nyquist noise term in their analysis of LM APD noise but this is unnecessary because diodes only have Johnson–Nyquist noise near zero bias, and because the series contact resistance of an APD is typically too low to contribute measureable noise. Sometimes noise is attributed to a hypothetical load resistor connected in parallel to the APD, but this circuit configuration is practically never employed. Instead, photoreceiver sensitivity analysis should consider the multiplied shot noise of the APD and an input-referred amplifier circuit noise term that is particular to the amplifier design.

An APD's multiplication noise results from the random variation of its avalanche gain. Analysis of APD noise is based on the counting distribution derived by Robert J. McIntyre (McIntyre, 1972). The probability that an APD multiplier operating at some average gain (M) will output a certain number of electrons (n) given an input of a certain number of primary electrons (a) is

$$P_{\text{McIntyre}}(n) = \frac{a \Gamma\left[\frac{n}{1-k} + 1\right]}{n(n-a)! \times \Gamma\left[\frac{nk}{1-k} + 1 + a\right]} \times \left[\frac{1+k(M-1)}{M}\right]^{a+\frac{n-k}{1-k}} \times \left[\frac{(1-k)(M-1)}{M}\right]^{n-a} \quad (3)$$

where k is the ratio of impact ionization rates for the two carrier types (the slower rate over the faster rate) and Γ is the Euler gamma function.

Fig. 14 Measured responsivity and upper and lower bounds on quantum efficiency (QE) for a representative 500- μm InGaAs linear mode (LM) avalanche photodiode (APD).

Fig. 15 Output count distributions for linear mode (LM) avalanche photodiodes (APDs) operating at $M=20$ and responding to 10 primary photoelectrons, but differing in terms of k .

McIntyre distributions for APDs operating at the same average gain ($M=20$) and illuminated by the same signal strength ($a=10$ primary photoelectrons) but differing in k are plotted in Fig. 15. These distributions illustrate the practical meaning of different values of k . For the same input signal strength and the same average gain, an APD with lower k will have a higher probability of detecting a signal and a lower probability of generating a false alarm.

These statements assume that the APD is employed in a photoreceiver equipped with a binary decision circuit that rejects inputs below a certain detection threshold, and that the mean signal photocurrent is larger than the mean dark current. In this common scenario, a single detection threshold is simultaneously in the high-output tail of the dark current distribution but comfortably lower than the bulk of the photocurrent distribution's probability density (Fig. 16), such that the longer tail of the high- k distribution increases the probability of false alarm but reduces signal detection probability by decreasing the distribution's median output value. The detection threshold is employed to reject false alarms arising from total photoreceiver noise, of which the APD's dark current is one component. At the same time, the detection threshold must not be set so high that it also rejects outputs arising from valid photocurrent signals. An output distribution with a higher median for a given input is desirable because

Fig. 16 Illustration of signal and noise distributions for an avalanche photodiode (APD) photoreceiver equipped with a thresholded decision circuit.

Fig. 17 Comparison of false alarm rate vs. detection threshold profiles for avalanche photodiode (APD) photoreceivers with different values of k .

the high median will allow one to set the detection threshold higher without sacrificing signal detection efficiency. On the other hand, a reduced likelihood of very high-output events will help minimize the false alarm rate (FAR) arising from “lucky” dark current electrons that happen to individually experience very high avalanche gain.

Photoreceiver performance actually depends upon the convolution of the APD’s output distribution with the amplifier’s Gaussian circuit noise and not just the APD’s output distribution, but the general observations about how k relates to signal detection and false alarm performance illustrated for the APD output distributions of Fig. 15 still hold in a more rigorous analysis. Fig. 17 is an empirical demonstration of the advantage a low- k APD conveys from the standpoint of FAR performance. FAR measurements are plotted in Fig. 17 for two otherwise identical APD photoreceivers, both operated with similar low-frequency responsivities to 1550 nm light (marked in V W^{-1} because of the TIA’s transimpedance), which employ 75- μm -diameter InGaAs LM APDs respectively characterized by $k=0.2$ (red square; orange rectangle) and $k=0.02$ (blue and green triangles). The FAR versus detection threshold behavior of the two receivers is similar at low threshold but diverges sharply at higher threshold, giving the photoreceiver with a $k=0.02$ APD a significant sensitivity advantage in applications that are intolerant of high FARs.

The exact McIntyre distribution often must be used to calculate quantities like FAR or bit error rate (BER) because those photoreceiver characteristics depend on the shape of the tail of the APD's output distribution, and the McIntyre distribution has positive skew. In most cases, the standard FAR and BER formulas which apply to photodiode-based receivers do not provide accurate results when applied to APD-based receivers – even when the standard deviation is adjusted to account for the APD's excess multiplication noise – because those formulas assume the probability density of false alarms falls off as a function of output amplitude with a Gaussian profile. In general, the only circumstances in which the Gaussian approximation provides accurate results are when APDs operate at low gain or with very low k . The FAR of InGaAs LM APD photoreceivers is better modeled by

$$\text{FAR} = \sqrt{\frac{2\pi}{3}} N_Q \text{BW} P_{\text{RX}}(n_{\text{th}}) \text{ (Hz)} \quad (4)$$

where N_Q is the noise of the photoreceiver (APD and amplifier) referenced to the output of the APD in units of electrons, BW is the bandwidth in Hz of the signal chain into the threshold comparator, and $P_{\text{RX}}(n_{\text{th}})$ is the McIntyre distribution of the APD's multiplied dark current convolved with the amplifier's input noise, evaluated at an electron count corresponding to the detection threshold.

The most common measures of photoreceiver sensitivity such as SNR and NEP define noise based on the standard deviation of an APD's output distribution, and so are not affected by the divergence of the tail of the McIntyre distribution from the Gaussian approximation, which normally becomes an issue a few standard deviations beyond the mean. For this type of analysis, it is sufficient to compute the variance of the APD's output. In units of electrons the APD output variance is found using the Burgess variance theorem:

$$\begin{aligned} \text{var}(n) &= M^2 \text{var}(a) + \langle a \rangle \text{var}(m) \\ &= M^2 F \langle a \rangle \text{ (e}^{-2}\text{)} \end{aligned} \quad (5)$$

where the excess noise factor (F) is defined as:

$$F \equiv \frac{\langle m^2 \rangle}{M^2} \quad (6)$$

In Eq. (5) the symbol m is a per-electron gain random variable, and the symbols a , M , and n have the same meaning as in Eq. (3). The noise factor of Eq. (6) is deemed “excess” because if APD gain was deterministic, Eq. (5) would simply read $\text{var}(n) = M^2 \langle a \rangle$. Eq. (5) assumes that the primary photocarrier count represented by a is generated by a Poisson process, so the substitution $\text{var}(a) = \langle a \rangle$ can be made.

For most linear-mode APDs, including InGaAs APDs, the excess noise factor has the gain-dependence derived by McIntyre for thick, uniform junctions (McIntyre, 1966):

$$F = M \left[1 - (1 - k) \left(\frac{M - 1}{M} \right)^2 \right] \quad (7)$$

In Eq. (7), the parameter k is the same ratio of impact ionization rates appearing in Eq. (3). When $k > 0$, k is the slope of the excess noise curve as a function of gain, in the limit of high gain. For single-carrier multiplication, $k = 0$, and $F \rightarrow 2$ in the limit of high gain. Another feature of single-carrier $k = 0$ multiplication is that avalanche breakdown cannot occur because the only carriers capable of impact ionizing all drift in the same direction across the junction. The gain curve of a $k = 0$ APD does not exhibit the vertical asymptote shown in Fig. 7, enabling stable operation at higher gain than a $k > 0$ APD. Different InGaAs LM APDs vary with respect to the value of k that characterizes their multiplication noise. Holes ionize more readily than electrons in InP, and InGaAs APDs with comparatively thick ($\sim \mu\text{m}$) InP multipliers typically have $k = 0.4$. The impact ionization rate of electrons is higher than that of holes in InAlAs; APDs with thick ($\sim \mu\text{m}$) InAlAs multipliers are characterized by $k = 0.3$ whereas those with InAlAs multipliers thinner than about $0.3 \mu\text{m}$ have $k < 0.2$ (Lenox *et al.*, 1998). InGaAs LM APDs with multipliers engineered to suppress hole multiplication have been reported in which $k = 0.04$ (Williams *et al.*, 2013).

In many applications it is common to work in units of current rather than electron count. The noise spectral intensity theorem for APDs that is equivalent to Eq. (5) is

$$S_I = 2 q M^2 F I_{\text{primary}} \text{ (A}^2\text{Hz}^{-1}\text{)} \quad (8)$$

where I_{primary} is the total unmultiplied current (the sum of signal and background photocurrent and dark current) prior to injection into the APD's multiplier. In principle, there can be dark current leakage paths in an APD which bypass the multiplying junction which would not be multiplied and therefore which would not be part of I_{primary} in Eq. (8). Also, in some exotic InGaAs LM APDs a substantial portion of the total dark current is generated inside the multiplier by tunneling rather than originating in the absorber, and so – because of a different path length through the multiplier – experiences a different amount of avalanche gain and contributes a different amount of multiplied shot noise than the photocurrent. However, in practice, dark current which originates in the absorber and which experiences the APD's full multiplication dominates in most commercially available InGaAs LM APDs, and the noise on that dark current is well modeled by Eq. (8).

As explained in connection to gain and QE measurements, unambiguous measurements of primary photocurrent cannot be made on an InGaAs LM APD if avalanche gain in its multiplier turns on at a lower reverse bias than its punch-through voltage. For APDs where I_{primary} is not observable, the best practice when making APD photoreceiver sensitivity calculations with Eq. (8) is to

use the terminal current in place of the quantity $M \times I_{\text{primary}}$, and to use the best estimate of the gain for the second factor of M . Uncertainty about I_{primary} also affects the accuracy of experimental measurements of the excess noise factor, because the most common method of measuring F involves measuring noise power spectral intensity, S_p , with a noise figure meter, converting S_p to S_i using an impedance that is characteristic of the test system but which must be measured, and then applying Eq. (8) to find F from S_i (which requires an estimate of M). For this reason, the most accurate measurements of F are made on special test structures which lack charge layers, and which do not include InGaAs absorbers. Instead, photocarriers are generated by illuminating the test structure with a short-wavelength laser, and both the primary current and the avalanche gain can be unambiguously measured because there is no charge layer to prevent collection of photocarriers at low reverse bias.

Eqs. (5) and (8), respectively, calculate multiplied shot noise variance expressed in units of electrons or in units of current; the square root gives the standard deviation, which is the most common measure of noise. The total noise of an APD photoreceiver assembled from a charge-integrating capacitive-feedback transimpedance amplifier (CTIA) is

$$\begin{aligned} N_Q &= \sqrt{N_{\text{CTIA}}^2 + (\langle a_{\text{dark}} \rangle + \langle a_{\text{bg}} \rangle + \langle a_{\text{signal}} \rangle) M^2 F} \\ &= \sqrt{N_{\text{CTIA}}^2 + \left[\frac{\tau}{q} (I_{\text{dark}} + I_{\text{bg}}) + Q_{\text{signal}} \right] M F} \quad (\text{e}^-) \end{aligned} \quad (9)$$

where N_{CTIA} is the input-referred charge noise of the CTIA in units of electrons, τ is the effective DC current integration time of the CTIA, I_{dark} and I_{bg} are, respectively, the dark current and background photocurrent as measured at the APD's terminals, and Q_{signal} is the product of the APD's QE and gain factor (M) with the optical signal level in units of photons.

The total noise current spectral density of an APD photoreceiver assembled from a resistive-feedback transimpedance amplifier (RTIA) is

$$\sqrt{S_{I_{\text{total}}}} = \sqrt{S_{I_{\text{TIA}}} + 2 q M F (I_{\text{dark}} + I_{\text{bg}} + I_{\text{signal}})} \quad (\text{AHz}^{-1/2}) \quad (10)$$

where $S_{I_{\text{TIA}}}$ is the input-referred noise current spectral intensity of the RTIA and I_{signal} is the product of the APD's spectral responsivity and the optical signal power. If the optical signal intensity is rapidly modulated rather than being quasi-CW, the RMS optical signal power is used.

The total noise calculated in Eq. (9) can be referred to the photoreceiver input, expressed in units of noise-equivalent photons, by dividing N_Q by the product of QE and M :

$$\text{NEPh} = \frac{Q_N}{\text{QE} \times M} \quad (\text{photons}) \quad (11)$$

Similarly, the total noise calculated in Eq. (10) can be referred to the photoreceiver input, expressed in units of noise-equivalent power, by dividing $S_{I_{\text{total}}}^{1/2}$ by the responsivity, R :

$$\text{NEP} = \frac{\sqrt{S_{I_{\text{total}}}}}{R} \quad (\text{W Hz}^{-1/2}) \quad (12)$$

The spectral density forms of current noise and NEP can be converted to in-band figures by multiplying either by $\text{BW}^{1/2}$.

Optical SNR, such as plotted in Fig. 1, is calculated as the ratio of the optical signal in photons to NEPh or in units of power to the in-band NEP.

Very High Range Resolution Lidars

Introduction

Light detection and ranging (lidar) or laser radar (ladar) technologies have already made high impacts in wide range of industrial, construction, scientific, and defense fields, and future applications of lidar will multiply as performance and cost improve. Consumer lidars already exist in the form of laser rangefinders for golfers and hunters, but the push toward autonomous vehicles and robots will increase the proliferation of lidar technology to unprecedented levels (Ackerman, 2016; Khoshelham and Zlatanova, 2016; see Section Relevant Websites). An important performance metric for all lidars is the resolution of the range measurement, which determines the suitability for different applications. Range resolution at the level of a meter to a few centimeters are the most common and are good for general range finding, mapping, and outdoor navigation applications. With very high range resolution lidar technology (as small as a few tens of micrometers) based on coherent frequency modulated continuous wave (FMCW) (De Groot and McGarvey, 1992) or concepts such as dual-comb coherent optical sampling (Coddington *et al.*, 2009); very different classes of applications are enabled. These include: noncontact metrology, high resolution 2D and 3D imaging, and coherent synthetic aperture imaging. This article focuses on very high resolution lidar technologies that enable range measurements with resolution of less than 1 cm. This is a convenient threshold as generally the lidar and ladar technologies required to achieve this level of range resolution are significantly different than more common brief-pulse, direct-detect lidars due to the difficulty of achieving sub-70 ps (~ 1 cm range difference) timing resolution.

Range Resolution Versus Range Precision

Before describing very high range resolution lidar technology, it is important to clarify the definition of range resolution. The definition of range resolution used in this article is consistent with that used in the radar community (see Section Relevant Websites). Namely, resolution is defined as the minimum range separation that two point targets of equal power can have and still be resolved (see Fig. 1). As all lidars and ladars are based upon measuring the round-trip time-of-flight of light between the ladar system and the target, range resolution is then fundamentally limited by the temporal bandwidth of the optoelectronics as $\Delta R \geq c/2B$, where B is the bandwidth and c is the speed of light. This definition is directly analogous to the Rayleigh resolution criterion used in optical imaging, where the image resolution is fundamentally limited by the spatial bandwidth of the imaging system. For example, in brief-pulse, direct-detection lidar, the fundamental timing (range) resolution is just set by the temporal duration, $\Delta\tau$, of the optical pulse (assuming the detector and electronics are sufficiently fast). For a Fourier limited Gaussian pulse the temporal width is just the inverse of the bandwidth as, $\Delta\tau = 1/B$. Given this temporal pulse width, if two targets are separated by less than $\Delta\tau$ in delay then echo pulses from each target merge into a single slightly wider return pulse and the targets are unresolved.

Unfortunately, this definition of range resolution is not used consistently throughout the literature or in manufacturer specifications. Often metrics better described as range precision (σ_R in Fig. 1) or the range grid/bin size (dR in Fig. 1) are specified as resolution. Range precision measures the statistical spread of multiple ideally identical range measurements of a single target. Using signal processing and estimation on a lidar signal with sufficient signal-to-noise ratio (SNR) the range precision achieved can be significantly better than the range resolution supported by the bandwidth. Part of the confusion of range resolution and range precision is that many lidars for 3D imaging are designed to only return a single range for each measurement, which blurs the

Fig. 1 Graphical definitions of range resolution – minimum separation to resolve two targets, and range precision – deviation of range estimates from a constant target.

distinction as the lidar can measure range displacements or differences in range to targets with precision much smaller than the resolution with sufficient SNR. However, the distinction is important as range resolution is an intrinsic property of the lidar system independent of the return power, while range precision is an extrinsic property dependent on the return power and resulting SNR. Therefore, when comparing different lidar technologies, range resolution provides a more fundamental comparison.

An advantage of resolving power in lidar is the ability to reduce the effect of range pulling from weaker nearby scatterers. An extreme example of range pulling can be observed with a common type of time-of-flight based ranging based on phase measurements of periodic intensity modulated optical signals (Fujima *et al.*, 1998). In these systems, the range to a target can be inferred by the period of the modulation and the amount of phase lag on the received light induced by the time-of-flight to the target and back. This type of time-of-flight distance measurement method has been used in surveying and metrology equipment for a long time and is now being used for 3D imaging (Iddan and Yahav, 2001) using special photonic mixing device, complementary metal-oxide-semiconductor (CMOS) cameras also known as “time-of-flight” cameras that are now provided by many vendors (see Section Relevant Websites). With a modulation frequency of 50 MHz (in the range common for these type of systems) and 12 bit resolution of the phase, the range could potentially be measured with a very good precision of $\sigma_R = c / (2f_{\text{mod}} \cdot 2^N) = 0.73$ mm. However, the drawback with this method is that there is essentially no range resolution whatsoever. The return phase of the received light is just the radio frequency (RF) coherent sum of all the scatterers in the scene. This means that if there are multiple returns in the range dimension (e.g., imaging through a window, screen, or foliage; or in a scene with a strong specular reflections which generates multiple path returns) the range will be a weighted average and very sensitive to stray scattering. Additionally, the range is only unambiguous out to one half of a wavelength of the modulation frequency (~ 3 m for 50 MHz), which limits the performance of the systems. In surveying and metrology applications these issues are resolved by using retro-reflecting targets to ensure the target of interest dominates the return signal reducing range pulling, and changing the modulation frequency slightly to implement a Vernier effect to resolve ambiguities.

Finally, range resolution is defined analogous to the Rayleigh criterion because many applications of interest require imaging, i.e., resolving multiple returns in the range dimension. For these applications, the resolving power of the lidar system is most important. A good example is the use of lidar in foliage and camouflage penetrating 3D imaging. In order to range gate out the cover, the lidar system must be able to resolve the return from the cover from the object beneath, which means the minimum distance between the cover and the object is proportional to the range resolution. Another example is the use of very high resolution lidar for optical metrology, where reflections from multiple surfaces need to be resolved to measure thicknesses and positions. However, the best example is the use of coherent lidar in synthetic aperture imaging lidar (SAIL or SAL) (Beck *et al.*, 2005). Here the Rayleigh analogy is complete as the image resolution in one dimension is directly set by the range resolution.

Very High Range Resolution Lidar Techniques

Brief-Pulse, Direct-Detect Lidar

For a lidar system to meet a threshold of 1 cm range resolution (timing resolution less than 66.7 ps), the corresponding bandwidth must be in excess of 15 GHz. To achieve this level of resolution with the straightforward brief-pulse, direct-detect lidar approach is very challenging, in particular if one is to simultaneously achieve high sensitivity (i.e., equivalent to longer ranges). Several type of pulsed laser sources with sub-100 ps pulse width exist to support the range resolution including microchip passively Q-switched lasers (Spühler *et al.*, 1999) and modulated master oscillator/fiber power amplifier (MOPA) systems. However, high energy lasers needed for long range lidar applications are less available due to the high peak powers this entails. On the detection side, bandwidths exceeding 50 GHz is achievable with modern optoelectronics developed for the telecommunication industry, however, these components meet severe trade-offs between sensitivity and bandwidth. Typically, these very fast linear PIN detectors are fiber coupled and use a 50 Ω load, which limits the NEP to approximately 10 pW/rHz when dark current and a 3 dB noise figure (NF) low noise amplifier are included. For a 15 GHz bandwidth pulse this translates to a unity SNR sensitivity of about 1 μ W, which is the equivalent of over 500 return photons per pulse. Linear avalanche photodiode (APD) based receivers can achieve a factor of 10 better, but rarely achieve bandwidth greater a few GHz. Operating APDs in Geiger mode can achieve single photon sensitivity and timing resolution of sub-50 ps (Butera *et al.*, 2016) and are the preferred approach for achieving the highest sensitivity and resolution for brief-pulse, direct-detect lidars. Yet, in general, approximately 70 ps/1 cm range resolution is the limit for brief-pulse, direct-detect lidar and prospects for further improvement are not promising due to electronic bandwidth limitations.

Streak Cameras

The use of streak cameras with brief-pulse laser illumination has been used with success for high resolution lidar (Gelbart *et al.*, 2002; Knight *et al.*, 1989; Yang *et al.*, 2012). Streak cameras are optical detectors that use time-to-space mapping mechanism to allow high time resolution. The most common type of streak cameras use a photocathode to generate free-electrons which are accelerated and deflected in space using time varying electric fields. Streak cameras can achieve very high timing resolution (as low as 200 fs; Hamamatsu, 2008) and sensitivity as low as a single photoelectron. However, there are trade-offs with high temporal resolution. This includes timing errors dominated by trigger jitter against the electric field sweep waveform. The timing jitter can be

significantly worse (> 50 ps) than the timing resolution of the streak camera reducing absolute ranging capability and making it difficult to average low-level signals to increase sensitivity. Another problem that arises with high timing resolution and sensitivity is reduced dynamic range caused by the need to run at high photomultiplier gain. Finally, as the range window/range resolution ratio is set by the spatial resolution of the camera, the range window to range resolution ratio (i.e., time bandwidth product) can be much smaller than with other approaches. However, a significant benefit of many streak cameras is the ability to use the second spatial dimension of the camera for line imaging or other modalities such as spectroscopy.

Coherent Mode-Locked Lasers

Coherent mode-locked lasers have emerged as a powerful tool for a large range of applications including various forms of lidars. For very high resolution lidar applications several different techniques (Coddington *et al.*, 2009; van den Berg *et al.*, 2015; Delfyett *et al.*, 2012) have been developed that utilize the coherence of the mode-locked laser rather than just relying on the mode-locked laser's ability to make short pulses of light. The key difference is that these methods utilize interferometric or coherent detection methods to resolve time differences much smaller than the timing resolution of the optical detector.

Mode-locked laser based multi-wavelength interferometry

This class of mode-locked laser based very high resolution lidar combines the spectral comb structure of the mode-locked laser with interferometry and spectrally resolving elements (van den Berg *et al.*, 2012, 2015; Wu *et al.*, 2016). The basic operation utilizes a Michelson interferometer to coherently interfere the mode-locked laser with itself. The output port of the interferometer is then spectrally dispersed in space to resolve each comb line (see Fig. 2). Each resolved comb line in this interferogram then becomes an individual CW interferometer obeying Michelson interference rule of $I(\lambda) = I_0 \{ \frac{1}{2} + \frac{1}{2} \cos(4\pi R/\lambda) \}$. If the repetition rate of the comb is not large (i.e., < 1 GHz) individually resolving each comb line with an optical grating spectrometer can be difficult, so some researchers have utilized an etalon based dispersive element known as a virtually imaged phased array (VIPA) (Shirasaki, 1996) that provides a high, but periodic, dispersion in another dimension to fully resolve the comb. Fully resolving the comb is important to eliminate the pulse structure of the mode-locked laser on the optical detector, without which the pulses would also need to be temporally overlapped to see the spectral interference.

The reason why this technique can be classified under the category of lidar ranging is that with a large number of comb lines a range profile can be constructed by a fast Fourier transform (FFT) of the interferogram. The range resolution is set by the bandwidth $\Delta R = c/(2N f_{\text{rep}})$, where N is the number of resolved comb lines. However, due to the equally spaced comb structure, the interferogram is discretely sampled at the repetition rate which forms a frequency domain Nyquist limit. The range profile is then ambiguous with a period of $\tau_{\text{max}} = 1/f_{\text{rep}} \Rightarrow R_{\text{max}} = c\tau_{\text{max}}/2 = c/2f_{\text{rep}}$. For example, a 1 GHz repetition rate leads to a 15 cm ambiguity period. These ambiguities can be resolved by changing the repetition rate of the laser to sample with a different repetition rate.

It is important to note that this technique relies on the coherence of the mode-locked laser to maintain contrast of the interferogram. This means the coherence length of each individual comb lines must be larger than the range to the target. However, this technique does not require coherence between the comb lines. A laser made-up of many independent lasers with tight tolerance of the line frequencies would work as well. This also means that the technique is robust to the temporal shape of the transmitted mode-locked laser pulse, however relative dispersion and/or line-to-line relative phase errors between the Tx/Rx path and the reference path are important. In addition to the laser coherence, this technique utilizes coherent detection which means the target must maintain holographic stability with the Tx/Rx system during the integration time of the camera.

Dual-comb interferometry based distance measurement

A second method of mode-locked laser based very high resolution lidar is based on an innovative detection method that uses a second mode-locked comb as a local oscillator rather than a copy of the signal laser (Coddington *et al.*, 2009; Wu *et al.*, 2016; Durán *et al.*, 2016; Zhang *et al.*, 2014). The second comb has a slightly different repetition rate so that the relative pulse delay on

Fig. 2 A schematic of one possible realization of a mode-locked laser based multi-wavelength interferometric lidar system. Many-wavelength interferometry with thousands of lasers for absolute distance measurement. *Physics Review Letters* 108, 183901. doi:10.1103/PhysRevLett.108.183901.

the detector scans with a period equal to the inverse of the difference in the repetition rates ($T_{\text{meas}} = 1/\Delta f_{\text{rep}}$). If balanced homodyne detection is used the output is zero unless the pulses overlap in time. When the pulses do overlap in time the coherent interference determines the strength of the homodyne signal (see Fig. 3(a)). If the detector output is digitized with a sample rate synced to the local oscillator (LO) comb, then the output is a sampled version of the optical field of the signal laser with very high time resolution. Lidar ranging is simply accomplished by using one of the combs as a transmitter (see Fig. 4). The range profile then is a series of echo pulses in the dual-comb heterodyne output (or nonlinear sampling (Zhang *et al.*, 2014)), which not only provides the envelope of the pulse but also the pulse phase. The sampling resolution of the range profile is related to the repetition rates as $\Delta t = \Delta f_{\text{rep}} / (f_{\text{rep, sig}} \cdot f_{\text{rep, LO}})$. For example, with ~ 100 MHz repetition rates with an $\Delta f_{\text{rep}} = 1$ kHz the sampling resolution is 100 fs or effectively a 10 THz sampling rate. This time sampling condition sets the range resolution, but also must satisfy Nyquist criteria on the bandwidth of the comb to prevent aliasing. The Nyquist condition is $\Delta t \leq 1/2B$, where B is the bandwidth of the combs. This then sets the fundamental trade-offs between range resolution, unambiguous range window, and measurement rate (Wu *et al.*, 2014). These trade-offs often necessitate the use of long measurement periods and/or use of optical bandpass filters to limit the optical bandwidth.

In addition to the time domain description of this dual-comb approach, as shown in Fig. 3(b), the frequency domain description reveals it also as a massively multi-heterodyne detection technique (Coddington *et al.*, 2010). The difference in the repetition rate of the two combs causes the heterodyne beat frequency of adjacent comb modes to increase linearly with mode

Fig. 3 Graphical description of the dual-comb approach in (a) the time domain as a cross-correlation and (b) the frequency domain as a multi-heterodyne signal showing how the optical comb translates to a radio frequency comb including individual line amplitudes. Coherent dual-comb spectroscopy at high signal-to-noise ratio. *Physical Review A* 82, 043817. doi:10.1103/PhysRevA.82.043817.

Fig. 4 Simple schematic setup used to perform dual-comb very high resolution ranging approach.

number. This effectively translates the phase and amplitude of the optical frequency comb onto a fine resolution RF comb with spacing equal to Δf_{rep} . Therefore if the amplitude of an optical comb line is reduced, for example, by a molecular absorption in the path, this will be observed on the corresponding RF comb line. While this RF comb can be obtained by use of an RF spectrum analyzer, an FFT of the time domain dual-comb signal provides a phase coherent spectrum. From this perspective the dual-comb approach is similar to Fourier transform infrared red (FTIR) spectroscopy, where the scanned delay between the signal and reference paths is provided by Δf_{rep} rather than the physical motion of an interferometer mirror.

Dual-comb interferometry has relatively strict requirements on the mutual coherence of the mode-locked lasers. The technique was originally demonstrated using highly stabilized mode-locked lasers (also known as optical frequency combs), where both the repetition rate and carrier offset degrees of freedom are locked to stable RF sources. This ensures that the relative phases of all the mode-locked lines are well defined during the measurement time and allows one to simply time average the interferogram on an oscilloscope to achieve improved SNR. An additional benefit of using highly stabilized comb lasers is that the optical phase of the return pulses in the interferogram allows interferometric distance measurement along-side the time-of-flight range measurement provided by the envelope. As demonstrated in Liu *et al.* (2011) high resolution lidar ranging can be achieved using free-running mode-locked lasers as long as the linewidth of the individual comb lines are less than the difference in the repetition rate, Δf_{rep} . However with this technique, the absolute phase of the pulse drifts with time necessitating more advanced signal processing techniques to perform averaging of the signal envelope which provides the time-of-flight lidar measurement. Other difficulties of this technique include: (1) The large optical pulse amplitudes, which can lead to nonlinearities in the photodetector and limited dynamic range of the measurement. This has been mitigated by using large fixed fiber dispersion to spread the pulse in time then using digital pulse compression in the signal processing stage. (2) The range ambiguity caused by the periodic pulse structure. This can be mitigated by making Vernier type measurements by changing the repetition rates of the lasers (Nakajima and Minoshima, 2015).

FMCW Lidar

The final very high range resolution lidar method that will be described is coherent FMCW lidar. FMCW ranging techniques have long been utilized in the RF domain for radar applications (Stove, 1992). The benefits of FMCW techniques include: continuous wave (as opposed to pulsed) output that provides higher energy per measurement at low peak powers which is also a better match to continuous waveform (CW) amplifiers, shot-noise-limited single-photon sensitivity, and high dynamic range. While many types of frequency modulated waveforms have been investigated, the dominant waveform type in use for both the radar and lidar domains is the linear frequency chirp (LFC). The LFC waveform is a linear ramp of the frequency versus time that provides a unique linear correspondence of time and frequency (see Fig. 5). Combined with coherent detection against a local copy of the LFC waveform (i.e., a LO), this structure produces a coherent beat signal, the frequency of which indicates the delay between the two LFC waveforms as $f(\tau) = \kappa\tau$, where κ is the chirp rate. Extending this to multiple range returns as in a radar or lidar system, the full range profile can be obtained from the spectrum of the coherently detected signal (generally in the form of an FFT of the digitized time domain signal). This procedure, known as stretched processing, makes a simple and bandwidth efficient signal processing system as compared to other coded waveform ranging techniques.

The main benefit of this stretched processing approach is that when the maximum relative delay of the signal versus the LO is small compared to the chirp time, T_c , the bandwidth of the coherent beat note is much less than the overall chirp bandwidth, B . This allows the use of relatively low bandwidth photodetectors and analog-to-digital converters (ADCs) while maintaining the full range resolution provided by the chirp bandwidth. Low bandwidth detectors have higher dynamic range and make it easier to achieve shot-noise-limited detection, while high speed ADCs are expensive and are improving only slowly (Walden, 1999) and the best speed versus dynamic range performance of ADCs are currently in the couple hundred megasample per second (MS/s) regime (see Section Relevant Websites). The trade-off with this bandwidth compression is to limit the maximum delay and/or range

Fig. 5 Diagram of the time-to-frequency mapping performed by the coherent mixing of linear frequency chirps as in frequency modulated continuous wave (FMCW) lidar.

window. For very long range lidar applications this can be a significant issue. As an example, assume an LFC with $B = 100$ GHz of bandwidth and a chirp duration of $T_c = 1$ ms, which translates to a chirp rate of $k = 100$ MHz/ μ s. At this chirp rate, a 2 km range ($\tau = 13.3$ μ s round-trip delay) produces a frequency of ~ 1.33 GHz. This is much smaller than the 100 GHz chirp bandwidth, but still relatively large compared to the < 100 MHz regime in which one would like to operate. Additionally, to sample this high frequency signal at more than Nyquist requires significant memory and signal processing requirements. Assuming 3 GS/s sampling rate for the full T_c would produce 3 million samples that need to be processed with an FFT. For these reasons long range FMCW lidar systems may utilize hardware based range shifting mechanisms such as frequency shifters or multiple chirp sources to limit the bandwidth requirements of the photodetector, ADC and digital-signal-processing system.

A second issue with FMCW lidar that has not been brought up with the other coherent techniques is the relative motion of the target and Tx/Rx system which create Doppler shifts ($f_D = v_l/\lambda$) where v_l is the line-of-sight velocity. In direct-detect lidar systems only the optical power is detected and the optical frequency shifts caused by the Doppler shift are too small to greatly affect the measurement. For coherently detected systems, however, the Doppler shift translates in to RF frequency shifts (~ 645 KHz/(m/s) for 1550 nm light) of the detected signal. This has effects in all coherent lidar systems, but they are most consequential in FMCW lidar with LFC's because the frequency shift of the coherently detected signal directly translates to a shift in apparent range. This range-Doppler ambiguity can be resolved by making measurements at different chirp rates. One common method is to make measurements on both the up frequency chirp and the down frequency chirp of a triangle type chirp waveform as in Fig. 5. By changing the sign of the chirp rate, the relative sign of the Doppler frequency shift and range delay are reversed and the range-Doppler ambiguity can be resolved from the two measurements.

Very High Resolution FMCW Lidar

The rest of this article focuses on FMCW very high resolution lidar with discussion of the technical aspects of the technique, laser sources, and its application to imaging and metrology.

Chirp Nonlinearity

To take advantage of the bandwidth compressing ability of FMCW lidar in the very high resolution regime requires chirped laser sources with large frequency tuning range. While microwave photonic methods of generating optical chirps using microwave chirps and external modulators has been used successfully for resolutions of about 1 cm, the most successful demonstrations of very high resolution lidar to date have relied on the use of chirps created by directly tuning the output frequency of a CW laser. The main difficulty with this approach is that widely tunable lasers are generally not very stable and often do not tune linearly. An important aspect LFC based FMCW lidar is that the linear chirp enables the use of a simple FFT to compress the pulse and obtain a high resolution range profile. If the chirp is nonlinear then the linear mapping of frequency-to-time is not perfect and, as illustrated in Fig. 6, the time domain FMCW signal is no longer a single frequency sinusoid that can be compressed with a simple FFT. If the nonlinear form of the chirp is well-behaved and known it can be possible to compensate for the nonlinearities in the FMCW signal with additional signal processing. However, often the nonlinearities are unknown or vary from chirp-to-chirp, which means that some method is required to measure and correct the nonlinearities on each chirp.

The most common method for measuring the nonlinearities of a chirp from a tunable laser is to simply measure the FMCW signal from a single fixed delay, often from a fiber based reference interferometer. If the delay is fixed and not wavelength dependent (Barber *et al.*, 2010) then the FMCW signal should be a single sinusoid and the phase of the time domain signal should

Fig. 6 Resulting FMCW signal from a nonlinear chirp. The blue and red lines represent the frequency of the imperfect chirp waveform vs. time. The dotted lines represent the relative phase of the interference signal in the time (along horizontal axis) and frequency domain (along the vertical axis).

advance perfectly linearly in time (ignoring phase wraps). Deviations from a single frequency sinusoid indicate local variations in the chirp rate with advancing phase indicating locally higher chirp rate and retarding phase indicating lower chirp rate. By tracking the phase of the FMCW signal the nonlinearities of the chirp can be determined. As illustrated in Fig. 6, with a fixed delay the relative phase of the two chirps referenced in the frequency domain is consistent because the relative phase (up to a constant overall offset phase) is just $\Delta\phi(f) = 2\pi f' t$, where f' is the instantaneous frequency. However, due to the chirp nonlinearities the time domain signal is not consistent with the frequency domain signal. An important aspect of this reference delay approach that should not be overlooked is that the interferometer signal is ambiguous to the sign of the chirp rate. This means that if the chirp is not monotonic there can be errors in tracking the phase when the chirp rate goes through zero. One way to break this ambiguity, is to add an acousto-optic modulator (AOM) to one arm of the interferometer. This shifts the beat note away from DC so that positive chirp rates show up as a positive frequency shift from the AOM frequency and negative chirp rates show up as negative shifts.

Active Chirp Laser Stabilization for FMCW Lidar

While this delay based chirp referencing method is common, how it is used varies. In very short range applications such as swept source optical coherence tomography (SS-OCT) (Huber *et al.*, 2005) the reference interferometer output is often just used to trigger samples of the ADC in the signal path at every zero phase crossing. This forces the time domain samples to be regular in frequency. Other works use the reference output to determine the chirp nonlinearities and use digital signal processing to correct the FMCW signal in post-processing (Beck *et al.*, 2005; Ahn *et al.*, 2005; Cabral and Rebordão 2007). The last approach – and what will be described in further detail here – is to use the reference interferometer output as an error signal in a phase-locked loop (PLL) to actively stabilize the frequency of the chirp (Roos *et al.*, 2009; Satyan *et al.*, 2009; Greiner *et al.*, 1998). In general, the sweep rate of most tunable lasers can be actively stabilized to achieve a linear frequency chirp suitable for lidar range measurements. However, the frequency tuning, free-running linewidth, and feedback characteristics of the particular laser will determine the details of the stabilization approach and the resulting chirp properties.

Broadband (5 THz) chirp stabilization

A first example of active chirp stabilization is that described in Roos *et al.* (2009). The laser used was developed for telecommunications test and measurement and is able to tune mod-hop free over an extremely large range (up to >80 nm from 1525 to 1605 nm). The relatively long external cavity and tunes mechanically by changing the angle of the feedback grating and so has a slow frequency sweep period, >500 ms, with a maximum chirp rate of ~10 THz/sec. Around this relatively slow sweep there are faster frequency tuning mechanisms including: a piezoelectric actuator that provides a few kHz bandwidth and 1 GHz of frequency tuning range; and direct feedback to the current of the laser diode which provides about 1 MHz feedback bandwidth. To stabilize this laser to a 70 m reference fiber interferometer required several layers of passive feedforward linearization and active stabilization using both the piezoelectric actuator for larger, slower deviations from linearity and direct current feedback for fast, small fluctuations from the finite linewidth of the laser. With both active and passive linearization a 5 THz chirp from this laser was linearized to less than 100 kHz rms (Barber *et al.*, 2011). This bandwidth provides less than 50 μm resolution at large ranges (several hundred meters limited by the rms deviations). In addition, one of the important results of this work was the realization that over this large of bandwidth (~40 nm) the wavelength dispersion of the fiber interferometer had a great effect on the linearity of the chirp. Therefore, dispersion compensating fiber was used in the reference interferometer to minimize the wavelength dispersion. Without dispersion management, the ability to perform pulse compression with a simple FFT for longer range (greater than a couple meters) FMCW lidar was compromised (Barber *et al.*, 2010).

For use in metrology applications where high accuracy distance measurements are needed, in addition to linearizing the chirp, the chirp rate also must be accurately calibrated. To provide calibration independent of a distant standard, the chirp rate of the laser could be calibrated by measuring the time versus optical frequency against a fixed set of widely separated frequency references. Two examples that were performed on this laser were: (1) The use of the NIST calibrated hydrogen cyanide (HCN) absorption lines as absolute frequency references as in Fig. 7, and (2) using the comb lines of a stabilized mode-locked laser as a frequency ruler (Barber *et al.*, 2011; Giorgetta *et al.*, 2010). The former method can achieve sub part per million calibration, and the latter could achieve part per billion calibration. The optical frequency comb based method was adapted in Baumann *et al.* (2014a,b, 2013) to provide dynamic high accuracy chirp nonlinearity measurements that could be used for post-processing based correction in high range resolution FMCW lidar based 3D metrology.

80 GHz distributed feedback based chirp stabilization

A second example of an actively linearized chirp laser is one based on a distributed feedback (DFB) laser (Satyan *et al.*, 2009). DFB lasers are common in the telecommunications industry due to their robust single-mode, narrow linewidth, and stable wavelength operation. While stable relative to other diode laser types, DFB lasers can be frequency tuned relatively rapidly and reliably using the laser current with a tuning rate on the order of 1 GHz/mA. A schematic for the active linearization and stabilization of a DFB chirp laser is shown in Fig. (8a). This setup is similar to that used in Ref. Roos *et al.* (2009) for the 5 THz tunable chirp laser except that the fiber delay line is shorter to better match the relatively larger linewidth of the DFB laser (~500 kHz) versus that of the external cavity diode laser (<50 kHz). However, this setup is more advanced in that the RF reference of the phase and frequency

Fig. 7 (a) The transmission of a wideband chirp laser from 1530 to 1570 nm region through 10 Torr hydrogen cyanide (HCN) fiber coupled cell; (b) shows the measured HCN absorption peaks vs. chirp time use to calibrate the chirp rate and residual quadratic chirp of the 5 THz chirp laser; and (c) the residuals of the fit in (b). The error bars are the absolute frequency uncertainty provided by NIST (Gilbert *et al.*, 2005).

Fig. 8 (a) A schematic of a distributed feedback (DFB) chirp linearization system and center frequency stabilization based on an optical absorption line in hydrogen cyanide (HCN); and (b) a timing diagram representing how the different frequencies and voltages are used to stabilize the up-chirp, down-chirp, and the center frequency of the laser. A full description is provided in Section 80 GHz distributed feedback based chirp stabilization. DDS, direct digital synthesizer; PFD, phase and frequency detector; PI, proportional integral amplifier.

detector (PFD) used to generate the error signal for the PLL is derived from a highly controllable direct digital synthesizer (DDS) signal source. As in Roos *et al.* (2009) both the up-chirp and the return down-chirp of the laser are actively stabilized by switching the frequency of the reference to be shifted above or below the AOM frequency, respectively. However, instead of rapidly switching from one frequency to the other, here the reference frequency makes a controlled sweep between the two settings (see the f_{DDS2} line in Fig. 8(b)). This controlled sweep allows the PLL loop to remain locked at the turn-around point. This has the effect of making the center frequency of the chirp also stabilized to the fiber interferometer. This is in great contrast to the 5 THz laser chirp where the laser came completely unlocked at the turn-around points, leading to >100 MHz level jumps of the center frequency from chirp-to-chirp. Further investigations of the DFB laser, showed that while this locking around the corner provided good short term stability, drifts in the fiber length and possible timing instabilities in the triggering of the up and down sweeps could lead to slow drift of the center frequency of the laser. This long term drift could be controlled by slight (1 Hz level) adjustments of the

AOM frequency, but to provide truly long term absolute stability this setup implemented a slow digital feedback loop using an absorption line in a HCN spectroscopic cell as a frequency reference. The feedback loop was implemented using a microcontroller that measured the time difference, τ_{HCN} , between the start of the chirp and incidence of the absorption peak using a simple threshold comparator circuit. The AOM frequency is then adjusted through f_{DDS1} to stabilize the time difference. This stabilized center frequency is beneficial for SAL imaging or other interferometric applications that require the frequency of the chirps to be stable.

Applications of Very High Range Resolution Lidar

Aspherical optical metrology

The ability to perform lidar with resolutions at smaller than $50\ \mu\text{m}$ over large distances (greater than $10\ \text{m}$) lends itself very naturally to think about length metrology as an application. What is more, because FMCW lidar has the ability to resolve multiple range returns, new metrology concepts can be explored. In particular, if one applies the FMCW lidar system to an optical system the distance to every surface (even if buried inside) can be measured. This is similar to optical time domain reflectometry (OTDR) systems that are used in the fiber telecommunications industry to diagnose and find faults, but on a much finer scale of microns instead of meters. Additionally, while the range resolution of the FMCW lidar system is $50\ \mu\text{m}$, the range precision and accuracy on the measurement of distance can be much smaller due to the ability to find the center of a range peak much better than its width. Fig. 9(a) shows the range profile of a microscope slide placed in a slightly focused beam at about $2.8\ \text{m}$ of total range delay. The two peaks are well resolved by the $\approx 50\ \mu\text{m}$ range resolution at about $1.5\ \text{mm}$ apart, which is the optical thickness of the microscope slide. Both peaks have high SNR of greater than $35\ \text{dB}$. This high signal to noise allows a fit of the peaks to determine their centers to high precision. This can be confirmed by taking a series of measurements of the range profile. While the individual standard deviation of the fit to the individual range peaks is approximately $700\ \text{nm}$ (not shown), the thickness as measured by subtracting the two individual range measurements show less than $50\ \text{nm}$ standard deviation, which is approximately 1000 times less than the range resolution of an individual peak.

Extending this to three-dimensional metrology shows a potential application of very high resolution lidar to optical metrology.

Fig. 10 shows work performed to characterize highly aspherical optics. This work used an X-Y stage to make a grid of range profile

Fig. 9 (a) Range profile of the front and back surface of a microscope slide placed at about $2.8\ \text{m}$ range delay using FMCW lidar with an $\sim 5\ \text{THz}$ chirp and (b) series of optical thickness measurements taken by subtracting the range of the back and front surface. This series of measurements shows less than $50\ \text{nm}$ standard deviation.

Fig. 10 (a) X-Y scanning setup to perform multi-surface profilometry and (b) 3D surface profile (vertical dimension exaggerated to show range precision) of complex aspheric optic provided by Wavesource Inc.

measurements on an optical flat whose surface was machined with a strong Zernike aberration function profile. This complex surface was machined by Wavesource Inc. as part of a research project to test the potential of FMCW lidar for optical metrology and as confirmation and testing of Wavesource Inc.'s diamond turning capability. The profile had steep slopes (nearly 50% grade at points), which make standard interferometric methods of characterization difficult. In addition to the reflection on the top surface, the high range resolution allows both the top and bottom surface to be measured simultaneously. To improve the precision and accuracy of the measurement a reference reflection near to the sample is used to remove any path length fluctuations that occur in the measurement chain. As it can be seen from Fig. 10(b) the $\sim 50\ \mu\text{m}$ surface elevations are highly resolved. Comparison with the predicted surface profile from the diamond turning process showed good quantitative agreement.

Noncontact 3D metrology

In addition to shorter range optical metrology, very high resolution lidar is also suited to 3D metrology applications over larger distances and volumes. In the 3D metrology space the highest accuracy volume metrology systems utilize interferometric based optical distance measurements that require some type of retro-reflective target to achieve high precision and accuracy ($\sim 25\ \mu\text{m}$) desired by the most demanding applications. The use of a retro-reflective targets forces the operator to manually contact the target to the part under measurement reducing productivity. The use of very high resolution FMCW lidar that can achieve high SNR from diffuse surfaces could allow noncontact and unsupervised metrological scanning. Indeed, 3D architectural and terrestrial lidar scanners (Petrie and Toth, 2008) have become one of the largest markets for lidars. Utilizing high resolution lidars in these systems to make more precise and accurate range measurements is an obvious application space.

In the area of 3D metrology with FMCW lidar, investigations have been made into the fundamental limits of precision when measuring the range to a diffuse surface (Baumann *et al.*, 2014a,b). One difficulty that was discovered was the influence of surface roughness and laser speckle on the FMCW ranging process that can lead to unpredictable range pulling with size on the order of the range resolution. A similar effect also can lead to pseudo-Doppler range pulling when the measurement beam moves rapidly across a surface. Despite these limits it was shown that with a 1 THz bandwidth laser these effects could be held to less than $10\ \mu\text{m}$ (Baumann *et al.*, 2014a,b).

Improving the range measurement in a 3D lidar scanner also necessitates that the transverse precision and accuracy of the laser scanner is commensurate with the range measurement. While angular scanning mechanisms can be made quite accurate, difficulties still arise when making precise noncontact measurements due to the size of the incident laser beam on the target. With the high precision and accuracy available with very high resolution FMCW lidar, researchers have investigated 3D metrology methods that utilize only distance measurements to position points in 3D space (Warden *et al.*, 2015; Warden, 2014; Mateo and Barber, 2015). These approaches use similar techniques to GPS where the distance between the point of interest and a few (or several) known points in 3D space is used to determine the position of the unknown point. One difficulty with these techniques is being able to provide measurement coverage in a large volume while maintaining sufficient SNR to make precise and accurate range measurements.

Advanced coherent imaging with FMCW lidar

One of the most exciting applications for coherent FMCW lidar is in the area of coherent imaging including Synthetic Aperture (Imaging) Lidar or Ladar (SAL or SAIL; Beck *et al.*, 2005; Bashkansky, 2002; Krause *et al.*, 2011; Crouch and Barber, 2012), holographic aperture lidar (HAL; Duncan and Dierking, 2009), sparse aperture imaging, digital holography, or combinations of these (Crouch *et al.*, 2015; Krause *et al.*, 2012). These coherent imaging methods seek to exploit the phase information obtained with coherent detection methods to improve the ability to image a scene and/or reduce resource requirements in an imaging system. As a direct optical analog to common radar methods, FMCW lidar is ideal for translating synthetic aperture radar (SAR) imaging methods to the optical domain. In fact, SAL was one of the motivations for the development of the 5 THz chirp laser described in Section Broadband (5 THz) chirp stabilization. An earlier investigation into SAL (Beck *et al.*, 2005), described the lack of suitable chirp laser sources as an impediment to the development of the technique. The benefit of very high resolution lidar FMCW lidar is that relatively high resolution images, i.e., large number of pixels, can be made with table-top sized experimental setups, making the investigation of SAL technique easier (Crouch and Barber, 2012).

SAL is a 2D range/cross-range imaging technique that provides imaging resolution within the diffracted limited beam of the transmitter. In one dimension the image resolution is provided by the range resolution of the lidar system, which does not depend on diffraction and means that high range resolution provides better image resolution. It also means that the target/scene must present range diversity to the lidar receiver, usually accomplished by illuminating the target at an angle. In the other dimension, the image resolution is provided by exploiting relative motion between the target/scene and the lidar transmitter/receiver. Relative motion perpendicular to the line-of-sight provides different points of view of the target and traces out a larger effective synthetic aperture for imaging. To successfully use this synthetic aperture, the system must coherently combine the information from the many range profile measurements. This necessitates the use of coherent lidar.

A basic design and simplified signal processing architecture for strip-map SAL is shown in Fig. 11. In strip-map SAL the motion of the Tx/Rx aperture, which is perpendicular to the ranging direction, also scans the Tx/Rx beam across the target. This limits the maximum size of the synthetic aperture in strip-map to the size of the beam on target. The data collection and signal processing system is relatively simple. At each aperture position the coherent FMCW lidar signal, before processing with an FFT to give a range profile, is stored in a 2D matrix called the phase history data. Because no lenses or range dimension FFT is used, this phase history data is a Fourier domain projection of the scene in the range dimension and the cross-range dimension (along the direction of motion or track). In the far-field limit, the SAL image can then be formed by a 2D FFT of the phase history data. In more physical

Fig. 11 Simple schematic of SAL setup and signal processing architecture.

Fig. 12 Two SAL images made at $\sim 2\text{m}$ range using a 5 THz chirp laser (a) is a RAM memory chip and (b) is a dried dragonfly specimen. Republished with permission from Crouch, S.C., 2012. Synthetic aperture LADAR techniques. Master's Thesis, Montana State University – Bozeman, College of Letters & Science. situations, some phase compensation of the phase history data is needed first to account for not being infinitely far away. **Fig. 12** shows two high resolution images made on a table-top setup with the laser described in Section Broadband (5 THz) chirp stabilization.

An important aspect of SAL imaging is that it is a coherent process, which means that the phase of the phase history data is crucial. Yet, the phase of the FMCW signal is sensitive to the relative motion of the Tx/Rx aperture and the scene on the wavelength scale, i.e., holographically sensitive. While this would seem to make the SAL data collection task near impossible over any kind of distance or time, there are methods to compensate for the non-ideal motions. First, if there are known bright points in a scene these can be used as a phase reference. Second, algorithms developed for SAR such as the phase gradient autofocus (PGA) algorithm show remarkable ability to estimate and correct piston motion phase errors using the correlation of phase errors in the range dimension (Wahl *et al.*, 1994). The PGA algorithm has also shown to work quite well in the low SNR regime where the image signal less than an order of magnitude larger than the shot-noise background (Barber and Dahl, 2014). The proof of the feasibility for real-world SAL imaging is that air-to-ground SAL imaging has actually been demonstrated from an aircraft (Krause *et al.*, 2011), however work is still required for practical applicability.

Conclusions

The objective of this article was to introduce the reader to technologies, techniques, and applications in the area of very high range resolution (< 1 cm) lidar. In general, these techniques are not brief-pulse, direct-detection lidars. They do, however, often utilize coherent lidar techniques with lasers that have unique spectral domain coherence. Clever exploitation of this spectral coherence reduces the requirements for high speed optoelectronics allowing range resolution of tens of microns – the equivalent of THz bandwidths which is far beyond current electronics. The article then focused on coherent FMCW lidar to introduce interesting applications for very high resolution lidar in metrology and coherent imaging. While precision optical distance measurement techniques for metrology have been around for a long time, the difference between these older methods and the newer lidar techniques is the ability to fully resolve a range profile, not just single ranges. With the ability to resolve range profiles, multiple returns in the path of the lidar can be measured simultaneously, which provides unique capabilities in the area of optical metrology. In addition, the high sensitivity of these coherent lidar techniques provide the ability to measure distances to diffuse surfaces precisely and accurately. Lastly, very high resolution coherent FMCW lidar has been used to demonstrate coherent imaging modalities such as synthetic aperture lidar (SAL).

Acknowledgments

This article represents my understanding of the state of the field of very high resolution lidars. I have been working in this field for only 8 years and a lot of great work had been performed before I entered the field and continues to this day. About once a month I receive peer-review requests for articles in the area of coherent lidar and the field only seems to be growing. As one person, it is difficult to keep up to date on all the advances in even this relatively narrow field, and I am sure that I overlooked much excellent work in high resolution lidar. While I decided to heap all the errors, omissions, and opinions contained in this article onto myself as sole author, none of my knowledge of the field could have been gained without the help and assistance of many people including current and former students, colleagues and coworkers, industry and government collaborators, and acquaintances.

In particular I need to acknowledge: My former students Stephen Crouch and Ana Baselga Mateo who performed the work for their thesis research that led to my understanding of the issues and applications of very high resolution FMCW lidar. My colleagues at Bridger Photonics and Blackmore Sensors and Analytics, Dr. Peter Roos and Dr. Randy Reibel who introduced me to FMCW lidar and helped me earn my first research grants in the area and much sub-award funding over the years. Wavesource Inc. for collaborating on initial optical metrology measurements by providing samples and sub-award funding. My collaborators at NIST in Boulder, CO Ian Coddington, Esther Baumann, Fabrizio Giorgetta, and Nathan Newbury for showing initial interest in this area and then by greatly pushing the field of precision metrology with very high resolution FMCW lidar. Finally, I would like to thank collaborators in the AFRL/Rymm – LADAR Technology Branch.

Additional acknowledgment must go to Nate Newbury for providing permission to adapt Figure 3 from their excellent paper on dual-comb measurement methods. Thanks is required for Dr. Steven van den Berg of the Dutch Metrology Institute for giving permission to adapt Figure 2 from an article on his excellent work in mode-locked laser based multi-heterodyne interferometry.

Parts of this work were supported by grants through the Montana Board of Research and Commercialization Technology (MBRCT), also by the National Science Foundation through GOALI grant #1031211, and by the United States Air Force through a Young Investigator Program Award.

Multi-Dimensional Laser Radars

Vasyl V Molebny, Academy of Technological Sciences of Ukraine, Kiev, Ukraine

© 2018 Elsevier Ltd. All rights reserved.

Introduction

Despite the word “ranging” in the term “laser detection and ranging” implies acquiring the information on range, the other parameters measured by laser radar can have its own dimensionality, for example, object orientation in space and its velocity, light scattering in the media, refraction of the media, temperature, humidity, gases concentration, etc. Some of them are single-dimensional, like temperature. Some can have several dimensions, like temperature distribution in space or temperature dependence on time. Other types of examples are combinations of several parameters distributed in space and time, like 3D velocity of an object having its 3D position and 3D orientation in space, both changing in time, thus climbing up to a hypothetical ten-dimensional (10D) laser radar system. Extending the popular term “3D (three-dimensional)”, Molebny and Steinvall (2014) introduced the term “multi-dimensional” meaning that the laser radar outputs the information defined by three or more independent descriptors, which can be regarded as dimensions. This publication will serve as a canvas for our article. Examples of information delivered by three-dimensional laser radars are illustrated in Table 1.

Examples of multi-dimensional laser radar systems are illustrated in Table 2.

Measurement of any of the dimensions can be provided with a single transmitter and a single receiver or with several of each of them. Moreover, there could be a combination of different laser radar systems or even a combination of laser radars with passive infrared systems or with microwave radars. Last decade brought hundreds of studies and corresponding publications on a variety of designs, applications, theories, experiments and field tests. We report here some representatives of them.

Stepping up the Dimensionality

The number of dimensions acquired by laser radar can be increased when adding new functions. For example, scanning the optical axis of a simple rangefinder and storing the measured range at different positions of the optical axis one can reconstruct the profile of the target thus getting its three-dimensional image.

The range information for reconstruction of the 3D image can be got not only by changing the direction of the optical axis sequentially in time (scanning), but by illuminating (flashing) the space in a wide field of view and receiving the information from all directions simultaneously.

In the first case, the range dimension is supplemented with two new dimensions (x, y) or (α, ϵ). In the second case, the two-dimensional image is supplemented with the range information. Here are the examples of these two approaches.

Table 1 Three-dimensional description of the parameters acquired by a laser radar

D_1	D_2	D_3	Comments
x	x	R	Range (R) in orthogonal (x, y, R) system of co-ordinates
x, α	y, ϵ	R, d	Range (R) or depth (d) in orthogonal (x, y, R), (x, y, d), or spherical (α, ϵ, R), (α, ϵ, d), system of co-ordinates
α	ϵ	V_r	Radial velocity in spherical (α, ϵ, V_r) system of co-ordinates
x, α	y, ϵ	A, f	Distribution of amplitude (A) or frequency (f) of vibrations on the target surface
f	t	A	Frequency (f) and amplitude (A) of vibrations of a point on the target surface in time (t)
x, α	y, ϵ	β, c, h, n, T, p	Distribution in space of scatter (β), gas concentration (c), humidity (h), refraction (n), temperature (T), polarization (p)

Table 2 Examples of multi-dimensional description of laser radar information (4D and more)

D_1	D_2	D_3	D_4	D_5	D_6	D_7	D_8	D_9	D_{10}	Comments
α	ϵ	V_r	t							Radial velocity varying in time
x	y	T	V_x	V_y						Temperature and velocity distribution in a plane
x	y	z	V_x	V_y	V_z					Velocity distribution in a volume
x	y	z	V_x	V_y	V_z	t				Velocity distribution in the volume varying in time
α	ϵ	R	V_α	V_ϵ	V_R	α_x	ϵ_η	$(\varphi)_\zeta$	t	Range, velocity and object orientation varying in time

Ranging Supplemented by Two-Dimensional Scanning

One of the very first 3D laser radars developed under NASA contract used two-axis piezoelectric driven mirror scanners providing 350×350 resolvable scan elements (Flom, 1972). These elements, for both the transmitter and the receiver, were aligned and their positions were electronically controlled, thereby creating a synchronously scanned transmitter-receiver in a total search field of view 30×30 degrees. The wavelength of the GaAs laser was $0.9 \mu\text{m}$. Pulse repetition rate was controlled depending on the range to the target.

In 1960s, the antimissile defense (AMD) was a strategic problem at both sides of Atlantic. To improve the precision of the AMD radars, an experimental laser radar was built and tested (Molebny *et al.*, 2010) with impressive dimensions and parameters. It consisted of 196 lasers and the same number of range-gated photomultipliers (4 groups of 7×7 arrays, totaling a 14×14 array). Initial target designation from microwave radar was got with an error ± 3.5 arc. min. Therefore, the total field of view (7×7) arc. min. was split into (100×100) arc. sec. sub-zones, to be illuminated in sequence. Each ruby laser pulse had energy of 1 J pulse repetition frequency 10 Hz, pulse duration 30 ns.

In 1980s, an imaging CW heterodyne ladar was tested (Wang *et al.*, 1984). The CO_2 laser produces a 5 W beam at $10.6 \mu\text{m}$. The beam is split into a signal beam and a local oscillator beam. The signal beam is frequency shifted, intensity modulated at 15 MHz, and scanned across the field of view by a galvanometer scanner controlled by a microcomputer. The scanner covers 512 lines in a (12×12) -deg. field of view. From the received signal, 15 MHz is filtered, amplified, and detected to produce amplitude and phase data. These data are then recorded on a magnetic tape. The recorded data are read by a computer in the laboratory and presented on a video monitor. Reflectance has a speckled appearance, horizontal stripes in the range images represent 10 m ambiguity steps produced by the amplitude modulated ranging system. Range resolution was about 0.3 m at a range of 50 m.

Two-Dimensional Imaging Supplemented by Scanning in z Direction

The technology of scanning in z direction can be implemented by range gating – a technique widely used in microwave radars. In the case of laser radar, pulses of picosecond duration allow to section the space in very thin “slices”. High-speed cameras with a highly sensitive CCD and short gate times provide gated viewing with automatic gain control versus range, whereby foreground backscatter can be suppressed. Compensation can be automated for decreasing reflection with range as z (Flom, 1972), or an exponential damping of the light in absorbing media. A 3D laser radar prototype implementing this technology was reported (Busck and Heiselberg, 2004). The system uses a picosecond Q-switched Nd:YAG laser at 532 nm with a 32 kHz pulse repetition frequency, which triggers a (752×582) -pixel CCD camera.

Developing the idea of cutting the range in slices, a set of image slices at different distances can be reconstructed. Some of these slices can be removed (e.g., obscuring objects, camouflage, clutter, etc.). In one of the approaches of such processing, the first step consists in selecting the distances of interest in the histogram, for example, distances around the ranges of 2.5, 7.5, and 16.0 m (Fig. 1), where maximal numbers of pixels are concentrated. Additional processing can be made involving a 3D mesh to analyze the cloud points both in (x, y) and z directions. Processing for laser gated viewing was developed by TNO Defence, Security and Safety (Netherlands) (Bovenkamp and Schutte, 2010) based on Intevac laser gated viewer. 1.5- μm eye safe laser was used and a CMOS camera for gated viewing (minimum gate shift was 1.0 m, minimum gate width – 20 m). The results of image processing are demonstrated in Fig. 2.

Intevac’s Electron Bombarded Active Pixel Sensor (EBAPS) technology is based on a III-V semiconductor photocathode in proximity-focus with a high resolution, backside-thinned, CMOS chip anode. The electrons emitted by the photocathode are

directly injected in the electron bombarded mode into the CMOS anode, where the electrons are collected, amplified and read-out to produce digital video directly out of the sensor (Electron Bombarded Active Pixel Sensor (EBAPS)) (Fig. 3).

It is the further development of the hybrid photomultiplier tube sensitive from 900 to 1300 nm referred to as an intensified photodiode (Bradbury *et al.*, 1997). It uses an active electron photocathode and a GaAs Schottky avalanche photodiode as an anode. Its first stage amplification consists of a very low noise electron-hole multiplication. This is then followed by traditional APD multiplication. These two processes are sufficient to overcome preamplifier noise, and the photodetector is therefore capable of photon counting.

Another option of 3D imaging with laser radar is the illumination of the whole field of view with one or small number of short pulses. This technology called "flash ladar" is based on range-gated imaging. Fig. 4 illustrates the time "slices" 1, 2, 3, ..., 20 operated by a (128×128) FPA (focal plane array) with a ROIC (read out and integration circuit). This flash ladar was developed by Northrop Grumman Aerospace Systems (Wong *et al.*, 2010). It can store an image every 0.5 ns. The ROIC captures 20 time lapsed images for each pulse which are then used to calculate the range estimates of the target area. Laser flash lamp pumps Nd: YAG OPO, 1.57 μm , 50 mJ, 6.7 ns, 30 Hz. Time per slice is 2.2 ns.

Advanced Scientific Concepts (ASC) developed the TigerEye flash 3D ladar video camera and DragonEye space camera (Stettner, 2010) that can assist almost any manned or unmanned vehicle with collision avoidance, navigation, etc. Each of 128×128 pixels is "triggered" independently, allowing capture of 16,384 range data points to generate a 3D point cloud image up to 30 frames per second.

Selex developed advanced infrared detectors for multimode active and passive imaging applications (Baker *et al.*, 2008) that can be electronically switched from a thermal imaging function to a laser gated imaging function so that passive thermal imaging, solar flux imaging and laser-gated imaging can be designed into one electro-optic system. The wavelength sensitivity of these detectors (APD arrays in HgCdTe) ranges from 1 μm to 4.5 μm which is promising for active multispectral imaging in the SWIR and MWIR regions.

Another promising technology of 3D imaging developed at Lincoln Lab (Albota *et al.*, 2002a,b), is photon counting. The technique is based on a 2D detector array. Rather than measuring intensity, these detectors measure the photon time-of-arrival.

Fig. 4 Image building in a flash ladar. Reproduced from Wong, C.M., Logan, J.E., Bracikowski, C., Baldauf, B.K., 2010. Automated in-track and cross-track airborne flash LADAR image registration for wide-area mapping. Proc. SPIE7684, 768427.

Fig. 5 Ladar reconstructed image of a missile model with a 32×32 APD array, 16 kHz repetition rate. Reproduced from Cho, P., Anderson, H., Hatch, R., Ramaswami, P., 2006. Real-time 3D ladar imaging. Lincoln Lab. J.16 (1), 147–164.

With each pixel coded in range, the ladar produces a 3D image (angle-angle-range). The illuminator is a passively Q-switched laser. The electro-optical receiver is a 4×4 array of avalanche photodiodes (APDs) that is passively quenched and gated to operate in photon-counting (Geiger) mode. Each of the 16 APD pixels in the detector array is linked to timing circuitry. The field of view of the 4×4 array is scanned to generate larger images with up to 128×128 pixels.

Doubled Nd:YAG laser microchip generates 250 ps pulses at 532 nm. It is pumped with 1.2 W at 808 nm. Repetition rate is 1 kHz, output energy per pulse is $3 \mu\text{J}$. This energy is enough to image the targets nearer than 1 km. 3D images at ranges beyond 1 km with a $30 \mu\text{J}$ per pulse source were also reported. In response to a single photoelectron, Geiger-mode APDs yield a fast, high-amplitude electrical pulse that triggers the timing circuitry. The next step at Lincoln Lab was designing a 32×32 APD array with 16 kHz repetition rate (Cho *et al.*, 2006). Single photon counting and linear mode photon counting made great progress in the last decade. An example of 3D imaging is demonstrated in Fig. 5.

For operation in the short-wavelength infrared (1.06 μm), arrays of InP-based avalanche photodiodes were developed in the 128×32 format (Verghese *et al.*, 2009).

One of the perspective applications of laser radar is identification capability based on measuring the range profiles reconstructed in the form of histograms from a combination with a detection sensor. The detection sensor gives the location of the threat, while the laser range profiler (LRP) can identify the target based on high range-resolution data. Heuvel van den *et al.* (2008) tested the LRP with the Infrared Search and Track (IRST) sensor on board of a naval vessel.

It was shown that range profiles of ships can be obtained up to a range of 10 km. The range profiles have a good correspondence with the geometry of the ship and do not vary rapidly with aspect angle like microwave radar range profiles. Fig. 6 shows the LRP prototype used for the MCG/8 NATO trial in Stavanger, Norway. Fig. 7 shows the 3D model of a frigate illuminated from the front side. The model was used to calculate the range profile. An example of the reconstructed range profile at a distance 3.6 km is shown in Fig. 8.

The profiler gives the range and can discriminate between false alarms and potential threats. False alarms that can limit IRST usefulness like birds, cloud edges, and sun glints can be easily discriminated from real targets by a laser range profiler.

Fig. 6 Laser Range Profiler for the MCG/8 trial. Reproduced from Heuvel van den, J.C., Pace, P., Bekman, H.H., *et al.*, 2008. Experimental validation of ship identification with a laser range profiler. Proc. SPIE 6950, 69500V.

Fig. 7 Plot of data points used to generate a range profile. Reproduced from Heuvel van den, J.C., Pace, P., Bekman, H.H., *et al.*, 2008. Experimental validation of ship identification with a laser range profiler. Proc. SPIE 6950, 69500V.

Fig. 9 Marine target sensing testbed with 1550-nm laser and two receivers. Below is optics for two cameras and Celestron telescope. Reproduced from Steinvall, O., Tulldahl, M., 2017. Laser range profiling for small target recognition. *Opt. Eng.* 56 (3), 031206.

The LRP has the favorable properties of a good range resolution in combination with low sea-surface clutter. These properties have been validated by experiments: a range resolution of 0.6 m has been achieved. Sea-surface reflection was negligible.

Steinvall and Tulldahl (2017) described similar technique for identification of small targets. They used an LRP based on a laser with a pulse width of 6 ns. They showed both experimental and simulated results for laser range profiling of small boats out to a 6–7-km range and a unmanned aerial vehicle (UAV) mockup at close range (1.3 km). The naval experiments took place in the Baltic Sea using many other active and passive electro-optical sensors in addition to the profiling system (Fig. 9). The UAV experiments showed the need for a high-range resolution, thus a photon counting system in addition to the more conventional profiler was used in the naval experiments. The typical resolution of 0.7 m obtainable with a conventional range finder type of sensor can be used for target classification with a depth structure over 5–10 m or more, but for smaller targets such as an UAV a high resolution (in the described case 7.5 mm) is needed to reveal depth structures and surface shapes. Fig. 10 shows an example of range profile from the boat at 0-deg course. The large peak is attributed to the fore and the next to the front of the cabin at a 2.5-m distance from the fore. The extent of the pulse shows a boat length exceeding 7 m.

Fig. 10 The waveform referred as the pixel number when sweeping along the line of sight. Reproduced from Steinvall, O., Tulldahl, M., 2017. Laser range profiling for small target recognition. *Opt. Eng.* 56 (3), 031206.

Fig. 11 Subsonic advance cruise missile AGM 129A. Reproduced from Directory of U.S. Military Rockets and Missiles. Raytheon (General Dynamics) AGM-129 ACM. Available at: <http://www.designation-systems.net/dusrm/m-129.html>.

Adding the Velocity as a Dimension

Precision navigation to the designated target or to any other landing site on Earth or extraterrestrial objects, rendezvous and docking with orbiting spacecraft require more information than range and/or altitude. The solutions for navigation can be flying on a preprogrammed route, via image recognition of a series of radar photographs of the terrain or surface altitude profile. Early variants of the Tomahawk (Brigety, 2007) are equipped with an inertial navigation system (INS), Terrain Contour Mapping (TERCOM), and the Digital Scene Matching Area Correlator (DSMAC). TERCOM uses a highly sensitive radar altimeter embedded in the missile to identify surface features by their height. In the terminal phase, the weapon requires even more accurate guidance than TERCOM can provide. For this reason, Tomahawk relies on DSMAC which uses an optical sensor to scan the ground over which the missile is flying. The on-board computer compares the acquired image to the stored one and adjusts the missile's course so it is following the preplanned route. The missile uses also inertial navigation to update the navigation points.

A modified approach was implemented in the subsonic advance cruise missile (ACM) AGM 129A (Fig. 11). Its external shape was optimized for low observable characteristics. To provide a low detectability, the microwave radar was excluded from the set of sensors. For guidance, the AGM 129A uses an inertial navigation system together with a TERCOM enhanced by highly accurate speed updates from laser Doppler velocimeter. The accuracy is quoted between 30 and 90 m.

For the extraterrestrial applications, a Doppler lidar was developed by NASA under the Autonomous Landing and Hazard Avoidance Technology (ALHAT) project (Pierrottet *et al.*, 2009; Amzajerdian *et al.*, 2012). The lidar precision vector velocity data enable the navigation system to continuously update the vehicle trajectory toward the landing site. The ALHAT project included

tests on the Morpheus lander (Fig. 12) developed not to fly in space but to demonstrate technologies that could support future human or robotic exploration (Morpheus lander).

The prototype of Doppler lidar in ALHAT project measures three components of the velocity of which the velocity vector is calculated. A fiber laser is used to generate a very narrow line width, which is frequency modulated and amplified. The output is split into three components in order to distribute the power to three optical channels corresponding to the velocity vector components (Fig. 13).

Using the laser waveform modulated linearly with time the lidar obtains high-resolution range and velocity information. Fig. 14 shows the waveform's frequency content versus time, and the resulting intermediate frequency that contains the range and velocity information. The lidar design uses an optical homodyne receiver configuration, in which a portion of the transmitted beam serves as the reference local oscillator for the optical receiver. The prototype was preliminary tested on the Eurocopter AS350D helicopter. Its optical head is mounted inside a gimbal spherical shroud, pointing in the nadir position while collecting the data.

Interference of oppositely chirped pulses was exploited for simultaneous, range and Doppler velocity measurements (Henderson *et al.*, 1993). In this instrument, echo signals are Doppler shifted in frequency and are also delayed in time relative to

the reference pulse trains. This results in the generation of up and down beat tones. Sub millimeter resolution ranging was performed and simultaneous, range and Doppler velocity measurements were experimentally demonstrated using a target moving faster than 330 km/h.

Vibrations

The detection of vibrations at long range is of interest in a number of applications: different kinds of operating mechanisms (civil and military), civil infrastructure (bridges, dams, etc.), security (detection of acoustic signals induced in objects nearby), medicine, and so on.

Laser vibrometers typically use the Doppler effect and the coherent detection at any optical wavelength (1.5 μm , 2 μm , 10.6 μm). To get spatially resolved vibrational information, scanning and even multi-beam lasers are used. The review papers of Lutzmann *et al.* (2011), (2017) are focused on works at Fraunhofer IOSB target classification and identification, including camouflaged or partly concealed targets, detection of buried land mines, remote sensing of human breathing, some other applications. Authors used an in-house-developed coherent laser radar (Fig. 15). The sensor is all-fiber-based and operates at a wavelength of 1.5 μm . With an output power of almost 1 W, a spectral line width smaller than 1 kHz and a field of view of 75 μrad , this system is optimized for performing long-range measurements at distances of up to several kilometers.

One of the applications of the developed vibrometer was monitoring the wind turbines. Turbines tend to vibrate strongly, and laser Doppler vibrometry can usefully supplement the existing on-board sensors. The measurements were done on a medium-size wind turbine with a hub height of about 70 m with a rotor diameter of 25 m. The laser Doppler vibrometer was placed about 270 m away from the base point of the wind turbine. The aim was to measure the vibration characteristics of the mast and the nacelle. Fig. 16 shows the wind turbine with indication of points on the mast where the measurements were done and an example of a spectrogram of the signal recorded from a point in the upper point of the mast. Following the time axis one can see the first natural frequency which is about 0.33 Hz. To study the turbine in multiple points simultaneously, a multi-beam vibrometry system would shorten the measuring time.

It is of great interest to the security and military forces, to use remote vibration sensors to detect and assess human state of health or activity. Typical targets are battlefield or earth-quake casualties, and also humans perceived as potential threats. The LDV can give important hints about human activity and health.

The data from 1.5- μm vibrometer were collected from stationary subjects the laser beam being mostly directed on their bare necks at a distance of about 90 m. Fig. 17(a) displays strong pulse beat spikes recorded immediately after a short run with a pulse rate of 110 beats per minute, where the breathing is weakly overlaid by a rate of ~ 43 breaths per minute. The lower part (b) displays the signal sequence a little later, where a deep breathing is dominant (breathing rate: 25 breaths per minute) and the body has partly recovered.

An example (Lutzmann *et al.*, 2000) of the visualized distribution of vibrations of a functioning engine is shown in Fig. 18. Fig. 19 illustrates (Polytec 2006) the vibrations of a car's door (left) and of a turbine's blades (right).

Understanding the characteristics of the vibration of musical instruments is important in studying the acoustic characteristic and improving their manufacture technique. Fig. 20 demonstrates the acoustic vibrations of the violin acquired with the (Polytec 2006) vibrometer using the Doppler principle.

The drumhead has been studied using various methods. Zhang and Su (2005) used the method of Fourier Transform Profilometry (FTP) introduced by Takeda and Motoh (1983). The method is particularly requiring only one image of the deformed fringe pattern to reconstruct the 3D shape of the measured dynamic object. A sinusoidal structured pattern, which is projected onto the surface of a measured drum, is dynamically deformed with the vibration of the membrane. The sequence of the deformed fringe images is grabbed by a high-speed CCD camera, and then a series of wrapped phase maps are produced after the processing with Fourier transform, filtering and inverse Fourier transform. Fig. 21 shows two different phases of drum vibration.

Compared with the vibration pattern measurement by laser Doppler vibrometry, this method has lower accuracy, but has an obvious advantage that all the data of the whole membrane at one sampling instant can be obtained simultaneously, furthermore its information recording time can last along with the whole vibration process to demonstrate the whole vibration from uncreated to fade away.

To get a spatial distribution of vibrations on the surface of the investigated object, a scanning vibrometry is applied. It allows analysis of the structure with a very fine spatial resolution, not modifying its dynamic behavior, decreasing the testing time if a

large number of measurement points is requested, and allowing measurement of vibrations even on hot surfaces. In some applications, laser vibrometry has also been coupled with laser excitation to develop a complete noncontact and nonintrusive modal analysis procedure.

Revel *et al.* (2011) investigated the problem of noise in the cabin of Agusta A109MKII. They described the use of a scanning laser Doppler vibrometer to measure vibrations inside the helicopter using its mock-up, and demonstrated the applicability of the technique for in-flight tests. The whole area was 430×315 mm. In the scanning tests, a 30×20 grid (corresponding to a spatial resolution of about 14×15 mm) was used. An additive mass was used in order to lower the center of mass of the vibrometry system and to gain stability. The comparison was also made with the vibrograms measured when the vibrometer was placed outside the mock-up. Fig. 22 is a summary of the tests at different resonances. They all refer to instantaneous amplitude of the velocity component at a certain frequency orthogonal to the surface with the bandwidth ± 10 Hz for the frequencies up to 1000 Hz and ± 30 Hz for the frequencies up to 5000 Hz.

Perea and Libbey (2016) demonstrated a laboratory system for measurement of three degrees of vibrational freedom simultaneously (Perea and Libbey, 2016). Heterodyne speckle imaging was exploited in which the optical speckle pattern was mixed with a coherent reference. From these data, three dimensions of surface motion are extracted. Axial velocity is measured by demodulating the received time-varying intensity of high amplitude pixels. Tilt, a gradient of surface displacement, is calculated by measuring speckle translation following extraction of the speckle pattern from the mixed signal.

Media Parameters as Dimensions

The diversity of laser radar applications for media investigation is impressive. Many of them use detection and processing of signals scattered in the medium of propagation, that can be not only the atmosphere of planets, but also the water and any other

Fig. 22 Resonance vibration frequencies registered in the cabin of the helicopter mock-up. Summary of images reproduced from Revel, G.M., Castellini, P., Chiariotti, P., *et al.*, 2011. medium of organic or non-organic origin. Examples could be like airborne atmospheric remote sensing (Palm *et al.*, 1994), cloud top remote sensing by airborne lidar (Spinhirne *et al.*, 1982), airborne high spectral resolution lidar that provides measurements of aerosol backscatter and extinction coefficients and aerosol depolarization at two wavelengths (Hair *et al.*, 2008), nanostructure and defect analysis using a simple 3D light-scatter sensor (Herffurth *et al.*, 2013), refraction distribution in the human eye (Molebny, 2013). Even a military rangefinder can be used for atmosphere sensing (Steinvall *et al.*, 2014). There are also many other applications.

Retro-scattering based on interaction of laser light with medium components brings another amount of information. Examples are as follows: Raman lidar for water vapor, temperature, aerosol, and cloud measurement (Reichardt *et al.*, 2012), dual field-of-view Raman lidar measurements for the retrieval of cloud microphysical properties (Schmidt *et al.*, 2013), lidar measurements of the Eyjafjallajökull ash cloud over the Netherlands (Donovan and Apituley, 2013), spectrally resolved Raman lidar measurements of gaseous and liquid water in the atmosphere (Liu and Yi, 2013), using Raman and elastic backscatter for measurement of temperature, density, pressure, moisture, and particle backscatter coefficient (Fraczek *et al.*, 2012).

Philbrick *et al.* (2010) experimentally showed how multi-wavelength backscatter measurements from Rayleigh and Raman lidar techniques can provide signals to be used to profile the properties of the atmospheric column. Rayleigh lidar signals provide backscatter coefficients, and Raman lidar signals backscattered from the major molecular components provide extinction profiles. The ratio of these simultaneous extinction and backscatter measurements are used to classify the aerosol type. In addition, a laser beam can be used to make bistatic and multistatic measurements of the polarization ratio of the scattering phase function. Analysis of multistatic measurements can be used to determine profiles of the aerosol number density, size, size distribution, and type. These parameters can be determined for spherical particles in the size range between about 20 nm and 20 μm . Information on aerosol type and shape can be supposed from determining the approximate refractive index of the scattering aerosols and by measuring the depolarization of the scattered radiation.

In a later publication, Philbrick and Hallen, (2017) discussed the Raman lidar measurements that provide profiles of several different tracers of spatial and temporal variations, which are excellent signatures for studies of dynamical processes in the atmosphere. An examination of Raman lidar data collected during the last four decades clearly showed signatures of atmospheric planetary waves, gravity waves, low-level jets, weather fronts, turbulence from wind shear at surfaces and at the interface of the boundary layer with the free troposphere. Water vapor profiles are important as a tracer of the sources of turbulence eddies associated with thermal convection, pressure waves, and wind shears, which result from surface heating, winds, weather systems, orographic forcing, and regions of reduced atmospheric stability. Examples of these processes were selected to show the influence of turbulence on profiles of atmospheric properties.

Fluorescence is one of physical phenomena successfully used in the today's laser radars for remote detection of oil spills (Sato *et al.*, 1978), for remote sensing of vegetation (Matvienko *et al.*, 2006), for fluorescence imaging of the ocean bottom (Sitter and Gelbart, 2001). High-repetition-rate three-dimensional OH imaging using scanned planar laser-induced fluorescence system allows for multiphase combustion control (Cho *et al.*, 2014). Combinations of several physical phenomena (elastic scattering, fluorescent scattering, and differential absorption) were the basics of the developed airborne lidar for observations of atmospheric tracers (Utke, 1991). Some examples of acquiring the media parameters and data 3D presentation are given hereinafter.

Wind and Flow Velocity

The need for remote sensing of atmospheric winds is well established, be it from ground-based sites, air-, or space-borne equipment. Lidar systems observe large volumes of atmosphere with high spatial and temporal resolution, making these data important for many applications. Doppler lidars can use incoherent or coherent techniques. In the incoherent system, to isolate

the laser line from the day light influence, a Fabry-Pérot étalons (interference narrow-band filters) are used. The laser is typically Nd-doubled 532 nm, 3 W average power (Fischer *et al.*, 1995). The field of view of the receiving telescope is of the order of 0.5 mrad that is somewhat larger than the laser divergence of 0.2 mrad to collect all of the laser light, which may be outside the divergence angle because of different factors like pointing jitter, scanning instability, or similar. The collected light is focused by the telescope onto an optical fiber with the diameter of 3.5 mm. The spatial scrambling of the collected light is necessary to remove the effects of inhomogeneity in the scattering aerosol volumes and of changes in normalization degree in detectors, and to avoid systematic offset errors in measured wind velocity. Fig. 23 shows a time series of the horizontal wind field at the altitude of 100 m. The velocity vectors are scaled as shown in the diagram. Complete profiles were generated every 5 min.

Low altitude wind profile measurements with a laser rangefinder were demonstrated using a simple balloon tracking system, with small (0.25 m diameter) lightweight balloons (Wilkerson *et al.*, 2009). Experiments on balloon trajectories demonstrate that laser range detection (± 0.5 m) combined with azimuth and elevation measurements is a simple, accurate, and inexpensive alternative to other wind profiling methods. To increase the maximum detection range to 2200 m, a retroreflector tape was attached to the balloons. Nighttime tracking was facilitated by low power LEDs.

Wind speed and direction results are compared with simultaneous sodar measurements (Fig. 24). The profiling resolution is greatly improved using a laser rangefinder with automatic coordinate and time recording. However, balloon tracking is still man-in-the-loop. Improvements should include automation of the tracking system to collect trajectory points automatically at 1 Hz or faster.

Windshear poses the greatest danger to aircraft during takeoff and landing due to its abrupt change of direction (Fig. 25) (Targ *et al.*, 1991), when the plane is close to the ground and has little time or room to maneuver (Molebny and Steinvall, 2013) (Fig. 26). During landing, the pilot has already reduced engine power and may not have time to increase speed enough to escape the downdraft. During takeoff, an aircraft is near stall speed and thus is very vulnerable to windshear. Microburst windshear often occurs during thunderstorms. But it can also arise in the absence of rain near the ground. Pilots need 10–40 s of warning to avoid windshear.

The first airborne measurements of winds used a pulsed CO₂ laser (Bilbro and Vaughan, 1978; Bilbro, 1984). The lidar was oriented in the fore and aft directions in order to obtain the horizontal vector wind field. Another coherent lidar system Coherent Lidar Airborne Shear Sensor (CLASS) was developed in two versions: with a 10.6 μm CO₂ laser (CLASS-10) and with a solid state 2.02 μm Tm: YAG laser (CLASS-2). Both lidars showed a wind measurement accuracy better than 1 m/s (Targ *et al.*, 1996). Coherent airborne wind lidar system Wind INfrared Doppler lidar (WIND) was developed later in French-German cooperation (Werner *et al.*, 2001).

NASA's Langley Research Center tested three airborne predictive windshear sensor systems (NASA, 2017): microwave radar detecting the raindrop scattering, Doppler laser radar detecting the aerosol scattering, and infrared detector measuring the temperature changes ahead of the airplane. The system was manufactured by Lockheed Corp.'s Missiles and Space Co.; United Technologies Optical Systems Inc., and Lassen Research.

In the wind infrared Doppler lidar (WIND) project, airborne conically scanning CO₂ Doppler lidar was used. Spatial resolution requirements were 250 m in height with a grid size of 10×10 km. The radiation of the local oscillator is mixed with outgoing pulse and with the Doppler-shifted backscattered signal. A locking loop connects both lasers. The laser pulse with a pulse duration

of 2.5 μs and 100–300 mW of per-pulse power is sent out via the transceiver telescope into the region of investigation with a repetition frequency 10 Hz. The wind-shifted Doppler frequency directly determines the line-of-sight component of the wind vector. At CO_2 laser wavelength 10.6 μm , a velocity component of 1 m/s corresponds to a frequency shift of 189 kHz. Ground-based tests, airborne tests and a validation flight were performed. An example of polar wind map is shown in Fig. 27.

Lockheed Martin Coherent Technologies developed a system called WindTracer (Lockheed Martin, 2015), whose specialty is remote sensing of winds in the critical 40–200 m height regime. With no sidelobes, WindTracer can scan the space near the ground, even adjacent to obstacles. It provides a 30–60 min warning of changes in the winds approaching a wind farm. This information is important for grid electric power operators and for turbine operators to optimize the operations. The wavelength is the eye-safe 1.6 μm , the maximum operating range is up to 12 km, range resolution is about 50 m, the coverage area

is 100–200 km², and a typical vector velocity accuracy is about 1 m/s. The combination of lidar and radar, called WindTracer Terminal Doppler Solution (WTDS) enables wind hazard detection under wider range of weather conditions.

A general view of WindTracer is demonstrated in [Fig. 28](#). The screenshot from its display ([Fig. 29](#)) shows the radial velocity estimates over a 12-km-diameter circular area.

European companies [Leosphere \(2004\)](#) and [Halo Photonics](#) specialize in building compact Doppler lidars with emphasis on wind farming applications. Leosphere developed several models of Windcube (100S/200S/400S) of the Doppler lidar. Radial

velocity display from 200S model overlaid on the land map is shown in Fig. 30. An example of velocity-height dependency on time acquired with Halo Photonics Doppler velocimeter is demonstrated in Fig. 31. As the wind energy industry continues to grow, the need for more accurate and sophisticated wind data grows as well. Such lidars are used to explore the locations like ridgelines, oceans, lakes, and forested areas. Typically, the lidars provide 100–200 m vertical wind profiles with an accuracy down to 0.1 m/s. Maximum range of the Halo Photonics streamline instrument using 1500 nm laser wavelength is 9.0 km, range resolution 15 m, maximum measured velocity 19 m/s, velocity resolution 0.0384 m/s.

The New European Wind Atlas (NEWA) project has a goal to create a freely accessible wind atlas covering Europe and Turkey. Common to all experiments is the use of Doppler lidar systems. Many European and American companies and universities will participate in the project. Two pilot experiments, one in Portugal and one in Germany, showed the value of using multiple synchronized, scanning lidars (Mann *et al.*, 2017). Example of the scans at three different elevation angles are shown in Fig. 32 received from the WindScanner developed at Technical University of Denmark for the purposes of NEWA, within the

WindScanner.dk project in long- and short-range versions (Mikkelsen, 2014) with the following main parameters (Vasiljevic *et al.*, 2017). Long-range version: pulse mode, range 50–8000 m, 500 range gates, probe length is 25, 35 or 70 m (fixed with range). Short-range version: CW, range 10–50 m, a single range gate, probe length is 0.2–40 m (evolving with range). These instruments confirmed the potentials not only to economically measure the wind field at a single point located within the rotor swept area, but also to map entire wind fields within the volume occupied by modern wind turbine and wind farms.

By combining space and time synchronized measurements along the line of sight from three simultaneously operated wind lidars equipped with synchronized steerable-beam scanners, true 3D wind velocity and turbulence measurements have become attainable for wind energy industry applications (Fig. 33).

WindScanner system consists practically of two or more spatially separated scanning lidars (long- or short-range WindScanners), that are coordinated or controlled by a master computer. The first generation of the long-range WindScanner (LRWS) and short-range WindScanner (SRWS) originate from commercially available vertical profiling lidars Windcube 200 (Werner *et al.*, 2001) and ZephIR, respectively. These profiling lidars were converted into the scanning lidars. The WindScanners have been specifically tailored to perform user-defined and time-controlled scanning trajectories, either independently or in a synchronized mode. A single LRWS can acquire radial velocities simultaneously at a maximum 500 different distances along each line-of-sight at a maximum rate of 10 Hz, whereas a single SRWS can measure radial velocity from one single range at a time but with a maximum rate of 400 Hz.

The lidars in the long-range WindScanner system are usually connected to the master computer using a 3G network. The short-range WindScanner system is formed by connecting the master computer with the lidars via a 300-meter long optic fiber.

The long-range WindScanner system is intended for measurements of mean flow field within a large volume of the atmosphere, while the short-range WindScanner system is typically applied to perform small-scale measurements of turbulent flows around a single wind turbine rotor.

The NEWA project aims to improve wind resource modeling for different site conditions. Areas with steep ridges and forested terrain are of particular interests, since the current engineering (linear) flow models are unable to correctly predict behavior of the flow over the sites with these features. The accompanying projects were focused on optimization of wind generators. To fulfill the project's ambition, it was necessary to investigate how the incoming flow is modified by a wind turbine. Still another objective was to develop numerical tools for wind farm layout optimization in complex terrain.

The site for the tests was chosen in Perdigão, Portugal with the opportunity to measure wind resources along a ridge, occurrences of flow separations on lee sides of hills (i.e., recirculation zone) and valley flows. According to the scientific objectives, the site contains a steep ridge where an isolated wind turbine is operating (Fig. 34, top photo).

A quasi two-dimensional, or a long ridge hill was a logical choice. Also, to assure a two-dimensional flow, dominant winds should be perpendicular to the ridge. Land cover, particularly forests would add to the flow complexity, and is considered desirable, since many wind farms are installed near or within forested regions. The presence of a wind turbine at the site gave the opportunity for wake and inflow measurements.

The two WindScanner systems, comprised a total of six scanning lidars: three LRWSs and three SRWSs. The lidar locations were selected according to the aim to sample the flow field along the South ridge and within the transect perpendicular to the ridges entailing the wind turbine.

The simulation of wind flow was done using steady state formulation for the equations, and the model's wall boundary parameters were calibrated to yield wind speeds of 5–6 m/s and other parameters were taken into account with suggested values. The simulations of the flow from the Northeast and Southwest predict large recirculation zone enclosed in the valley (Fig. 34) and a high complexity of the flow (Fig. 35).

Experimental studies should follow to confirm the simulation with the correctives shown up in the studies. It will be the six-dimensional (6D) maps of wind space, three dimensions of which will be the (x, y, z) coordinates of the space and other three dimensions (V_x, V_y, V_z) will be the velocity components of the wind vectors within that space. If these 6D maps would be supplemented with the temperature in each (x, y, z) point, the information would become seven-dimensional (7D: $x, y, z, V_x, V_y, V_z, T$). The humidity can be the following candidate for the eight-dimensional (8D: $x, y, z, V_x, V_y, V_z, T, h$) space. Reconstructing this 8D space of information as a time sequence, one should get the nine-dimensional (9D: $x, y, z, V_x, V_y, V_z, T, h, t$) space of information. The list of dimension candidates can be changed or extended in correspondence with the tasks of the study.

Non-Doppler, ground-based, scanning aerosol backscatter lidars can measure the wind speed and direction by cross correlation of coherent aerosol structures (Eloranta *et al.*, 1975). The primary assumptions are that the inhomogeneities remain coherent, and that these spatially-coherent turbulent features persist for a time that is long compared to the acquisition time of the lidar system during the advective process.

Non-Doppler incoherent lidars do not require coherent detection, which removes limitations of telescope diameter and relaxes requirements for high-spectral-purity lasers. This lack of restriction becomes more attractive as large lightweight mirrors and small powerful lasers become more affordable and commercially available. In addition to the wind field, these measurements can also be used to compute mean dimensions and lifetimes of turbulence. Unfortunately, the cross-correlation technique does not measure the wind velocity in all conditions. Coherent structures may not be advected with the wind in the scan plane or scan volume. Three-dimensional scan strategies are able to eliminate this possibility but are still susceptible to false velocities from wavelike motions. It is fortunate that irregularities in the aerosol scattering field within turbulent regions are usually oriented in all directions, and, by averaging in space and time, the motion of the coherent structures advecting with the wind dominates the correlation functions.

Based on the aerosol backscatter correlation, a three-beam lidar was developed (Prasad and Mylapore, 2017) to measure wind characteristics for wake vortex and plume tracking applications. This is a direct detection elastic lidar that uses three laser transceivers (Fig. 36), operating at 1030-nm wavelength with ~ 10 -kHz pulse repetition frequency and nanosecond class pulse widths, to directly obtain three components of wind velocities. By tracking the motion of aerosol structures along and between three near-parallel laser beams, three-component wind speed profiles along the field-of-view of laser beams can be obtained. With three 8-in. transceiver modules, placed in a near-parallel configuration on a two-axis pan-tilt scanner (Fig. 37), the lidar measures wind speeds up to 2 km away. Aerosol density fluctuations are cross-correlated between successive scans to obtain the displacements of the aerosol features along the three axes. Using the range resolved elastic backscatter data from each laser beam, which is scanned over the volume of interest, a three-dimensional map of aerosol density can be generated.

Atmosphere Components and Contaminants

3D structure of the water vapor field was observed using a scanning water vapor differential absorption lidar (DIAL) (Behrendt *et al.*, 2009). The instrument is mobile and was applied successfully in two field campaigns. The data products of the DIAL are profiles of absolute humidity with typical range resolutions of 15–300 m and temporal resolution of 1–10 s. Maximum range is several kilometers at both day and night. Spatial and temporal resolution can be traded off against each other.

Fig. 34 Profile of the test site (top). Wind flow in a vertical plane: (a) Northeast winds; (b) Southwest winds. Coordinate system origin corresponds to wind turbine base. Reproduced from Vasiljevic, N., Palma, J., Angelou, N., *et al.*, 2017. Perdigão 2015: methodology for atmospheric multi-Doppler lidar experiments. *Atmos. Meas. Tech. Discuss.* doi:10.5194/amt-2017-18.

Beside humidity, the backscatter field and thus aerosols and clouds can be observed simultaneously. The DIAL transmitter is based on an injection-seeded Ti:Sapphire laser operated at 820 nm which is pumped with a Nd:YAG laser.

A measurement example in vertical pointing mode during the first field deployment of the instrument is shown in Fig. 38. Even with a resolution of only 15 m and 1 s, the noise of the data is low; the high variability of the water vapor field in this case is revealed. Comparisons of the data acquired with the instrument and with the radiosondes launched at the lidar site showed a close agreement.

Range-height-intensity scanning measurement examples are presented in Fig. 39. The complexity of the humidity field is striking. Several horizontal layers can be seen in addition to turbulent structures with high moisture value from close to the ground up to a height of about 300 m.

To measure gaseous and liquid water in the atmosphere, a spectrally resolved Raman lidar based on a tripled Nd:YAG laser (100 mJ per pulse at 354.7 nm with a repetition rate of 20 Hz and a pulse width of 6 ns) was developed at the Wuhan University

Fig. 35 Wind flow in surface 80 m agl: (a) Northeast winds; (b) Southwest winds. Reproduced from Vasiljevic, N., Palma, J., Angelou, N., *et al.*, 2017. Perdigo 2015: Methodology for atmospheric multi-Doppler lidar experiments. Atmos. Meas. Tech. Discuss. doi:10.5194/amt-2017-18.

(Liu and Yi, 2013). At the receiver side, the backscattered photons are collected by a 450 mm Cassegrain telescope. After the bandpass filtering, the light is directed into a double-grating polychromator to separate the wavelengths and to suppress elastic backscatter. A 32-channel linear-array photomultiplier tube is employed to sample atmospheric Raman water spectrum between 401.65 and 408.99 nm. The 354.7 nm elastic Mie/Rayleigh scattering light in each channel is suppressed by more than 13 orders of magnitude (6 orders by the bandpass filter and 7 orders by the polychromator).

The output photons from each channel are counted with a bin width of 200 ns (corresponding to a range bin length of 30 m). The photon counts from 11,000 laser shots are accumulated to produce one photon count profile at each channel. This yields a time resolution of about 10 min for the raw data. The 32-channel photon count data constitute a spectrum- and altitude-resolved atmospheric Raman water signal. Altitude-resolved atmospheric Raman water spectrum signal is demonstrated in Fig. 40. Note that the prominent Raman water vapor signal peak at about 407.57 nm is visible at the altitudes up to 8.0 km.

The lidar-observed Raman water spectrum in the very clear atmosphere is nearly invariable in shape. It is dominated by water vapor, and can serve as a background reference for Raman lidar identification of the phase state of atmospheric water under

various weather conditions. The lidar has measured also the Raman water spectrum of an aerosol/liquid water layer. It was noted that under clear weather conditions the Raman water spectrum intensity in the 401.6–404.7 nm range is permanently at a very low level.

The authors used also a 532-nm polarization/Raman lidar to observe the aerosol/liquid water layers in an apparently cloudless atmosphere (Fig. 41). These layers are characterized by elevated backscattering ratio R and low depolarization ratio δ (generally $\delta < 0.03$) in a narrow altitude range (with a width generally less than 1 km). The layers usually persist for a few to tens of hours.

It was noted by Mukherjee *et al.* (2010) that a Raman-scattering based instrument is expected to be less sensitive than an instrument based on IR absorption. One of the principal reasons for that is a 1012 times weaker Raman scattering cross-section than an IR absorption cross-section. The wavelength dependence of a Raman-scattering cross-section necessitates the use of short

Fig. 41 Time-altitude diagrams of lidar backscatter ratio R and depolarization ratio δ measured by a Raman polarization lidar. Reproduced from Liu, F., Yi, F., 2013. Spectrally resolved Raman lidar measurements of gaseous and liquid water in the atmosphere. *Appl. Opt.* 52, 6884–6895.

wavelengths, often non-eye-safe, that are not appropriate for atmospheric propagation over long distances. On the other hand, strong optical absorption features of many explosives occur in the long wavelength atmospheric window in 8–12 μm .

For a target sample with absorption characteristics at about 10.6 μm , a wavelength of 10.653 μm (10P26 line from the CO_2 laser) was chosen, which is at the peak of the absorption feature. A spatial x-y scan of the local temperature was undertaken. A temperature rise was recorded only where the sample is located. Thus, the spatial dependence of the temperature rise shows the location of the target residue and its wavelength dependence allows identification of the target substance, even in the presence of other absorbers. Detection and identification of trace amounts of TNT at distances of 150 m were demonstrated. The technique should eventually permit real-time detection of explosives at standoff distances approaching a kilometer with high degrees of specificity and confidence.

To enhance the detection sensitivity, Kamerman (2012) proposed to measure the spectral correlation, i.e., the correlation between the sets of spectral lines, not a single one thus defining the degree of similarity between the received spectrum of unknown contaminants and the spectrum of known components which are to be detected. This technique implemented on the pre-detection stage of optical processing overcomes the problem of small cross-section of target chemicals and makes Raman lidar practical for

many important applications. In particular, the short-range stand-off detection of explosive residue or drugs on the exterior of packages, luggage or vehicles now appear to be possible.

Temperature

Temperature remote sensing using the laser radar techniques is based on measurement either of the Raman scattering or of the differential absorption called differential absorption lidar (DIAL). Murray *et al.* (1980) applied a 10 μm DIAL system that utilizes absorption by naturally occurring CO_2 to make path-averaged measurements of atmospheric temperature. Two widely spaced vibrational-rotational lines, the P(38) and P(20) transitions of the 10 μm band, were chosen for their relative high sensitivity and relative freedom from spectral interference. The transmission of one wavelength relative to the other was shown to be an effective measure of the average temperature over a 5 km path. Using CO_2 lidar and scattering from the foothills, relative transmission over that path was measured. A good correlation was obtained between the lidar-measured temperatures and thermometer-measured values.

The first instruments for rotational Raman temperature measurements were proposed by Cooney (1972). Philbrick (1994) measured the temperature structure of the atmosphere based on the rotational Raman scattering in the region between 526 and 532 nm. Arshinov *et al.* (1983) exploited the double-grating spectrometers to clean the signals from the elastic backscatter. Behrendt and Reichardt (2000) presented a filter polychromator in which the interference filters are mounted sequentially under small angles of incidence. High suppression of the elastic backscatter signal in the rotational Raman detection channels allowed temperature measurements independent of the presence of thin clouds or aerosol layers. Behrendt and Reichardt measured the atmospheric temperature in the northern Sweden up to 40 km heights.

Based on a similar double-grating polychromator approach, Jia and Yi (2014) designed a pure rotational Raman lidar in which the wanted pure Raman rotational signals were extracted, and elastically backscattered light was suppressed. A second-harmonic generation Nd:YAG laser was built with the optical head presented in Fig. 42 (D – dichroic mirror; RM – reflecting mirror; BP – bandpass filter; L – lens; FMH – fiber mode homogenizer; F – fiber; FA – fiber bundle array; G – grating; PMT – photo-multiplier tube). The instrument allowed to measure the atmospheric temperature at altitudes of 5–30 km. Fig. 43 compares the results of Behrendt and Reichardt (2000) above acquired in January 1998 in Northern Sweden (Kiruna) with the results of Jia and Yi (2014), acquired in August 2000 in Southern China (Wuhan). Pay attention that at the heights of about 16–17 km the temperatures are equal for both cases.

Fluctuation as a Dimension (Fluctuation Vision)

Atmospheric turbulence provokes much trouble in many applications. Nonetheless, the specificity of fluctuations of the signals propagating in the fluctuating atmosphere and reflected back from specular targets (like optical devices) and from diffuse targets originated the idea of selection of specular targets in the diffuse background, since specular and diffuse targets fluctuate differently when illuminated by the coherent laser light (Molebny, 1993).

It was shown, that these spectra are functions of spatial coherence of laser illumination and relative amplitude of random scanning due to atmosphere turbulence (Molebny *et al.*, 1989). For the diffuse background, the spectra depend also on relative

Fig. 42 Optical layout of the rotational Raman lidar (Wuhan University) for atmospheric temperature measurement. Reproduced from Jia, J., Yi, F., 2014. Atmospheric temperature measurements at altitudes of 5–30 km with a double-grating-based pure rotational Raman lidar. *Appl. Opt.* 53, 5330–5343.

Fig. 43 Comparison of temperature structure for different sites and different seasons. Reproduced from Behrendt, A., Reichardt, J., 2000. Atmospheric temperature profiling in the presence of clouds with a pure rotational Raman lidar by use of an interference-filter-based polychromator. *Appl. Opt.* 39, 1372–1378 and Jia, J., Yi, F., 2014. Atmospheric temperature measurements at altitudes of 5–30 km with a double-grating-based pure rotational Raman lidar. *Appl. Opt.* 53, 5330–5343.

scale of background non-homogeneity. Recursive filtration is one of the ways to implement the fluctuation vision using the atmospheric turbulence. The digitized image of the scene is accumulated at the output of the processing unit in such a way that earlier pixels have less weight. For each pixel in the current frame, the difference is calculated between the current value and the value accumulated from the previous frame. Varying the value of the weight factor, the weight of the preceding history can be adjusted to optimize the signal to noise ratio.

The dependence of spectra on random scanning due to atmosphere turbulence can be avoided due to angular micro-scanning of the beam, or by a scanning of the speckle structure inside the beam. This angular scanning or any other kind of sweeping of the internal speckle structure can be implemented at high frequencies thus simplifying the processing of lidar signals.

Dimension Combinations

Velocity and Temperature

Simultaneous measurements of velocity and scalar fields like temperature involve the combination of different techniques, such as particle image velocimetry (PIV) and planar laser induced fluorescence (PLIF). Tsurikov *et al.* (1999) reported measurements of velocity and conserved scalar fields combining PIV and acetone PLIF imaging in a gaseous turbulent flow. In liquids, there are reports of simultaneous velocity and temperature measurements using PIV and PLIF in a water impinging jet (Sakakibara *et al.*, 1997). Laser induced fluorescence of specially involved (seeded) molecules-tracers (tagged velocimetry) allows for simultaneous velocity and temperature measurements in gaseous flow fields (Hsu *et al.*, 2009; Sánchez-González *et al.*, 2012). A transient NO grid in the flow is “written” using the 355 nm photolysis of NO₂, which is subsequently probed by planar laser induced fluorescence imaging to reconstruct velocity maps.

Experimental setup is shown schematically in Fig. 44. It contains a photodissociation 355 nm Nd:YAG laser operated at 10 Hz producing a total power of 150 mJ/pulse. The 9 mm diameter laser beam is expanded with a $2.5 \times$ beam expander and directed into the chamber perpendicular to the flow axis through sheeting optics. A 50:50 beam splitter is used to optionally split the beam to direct a second “write” laser sheet parallel to the flow axis to obtain the two-component velocity measurements of the flow field. The photo dissociation laser beams are directed through an aluminum mesh or (in another experiment) a micro-cylindrical lens array to produce a periodic modulated pattern of NO photoproducts in the flow.

Each of the two identical fluorescence (probe) laser systems consists of an injection (seeding) Nd:YAG laser operated at 10 Hz. The 532 nm output is used to pump a pulsed dye laser to produce a tunable output beam in a range from 600 to 630 nm using a

Fig. 44 Schematic of the experiments in the repetitively pulsed hypersonic flow (a). Instantaneous images probing the transition of the vibrationally excited NO in the free stream (b) and in the flow over a sphere (c). Components of velocity u/u_0 and v/v_0 , (d, e) and temperature T/T_0 (f) fluctuations normalized to the free stream values (in percentage). Reconstructed from Sánchez-González, R., Bowersox, R.D.W., North, S.W., 2012. Simultaneous velocity and temperature measurements in gaseous flow fields using the vibrationally excited nitric oxide monitoring technique: A comprehensive study. *Appl. Opt.* 51, 1216–1228.

solution of Rhodamine 610 and Rhodamine 640 in methanol. The dye laser output is mixed with the residual 355 nm beam in a frequency mixing unit to produce approximately 10 mJ/pulse in a range from 223 to 227 nm. This output wavelength range permits the probing of fluorescence transitions. For the experiments, the probe beams are directed into the chamber at an angle of 70° from the streamwise flow direction to avoid the aluminum mesh or the microlens array used for the “write” beam. The fluorescence images were acquired with two ICCD cameras mounted on either side of the chamber perpendicular to the laser sheets.

The measurements are performed during the steady flow phase of the pulsed flow. The basic timing sequence consists of an initial laser pulse, the “write” pulse, that photodissociates NO_2 using 355 nm. After a time delay, a first “read” dye laser excites a specific rotational state of the NO photoproduct, and an associated ICCD camera captures a fluorescence image of the flow. After a second time delay, the second “read” system excites a different NO rotational state to capture a second fluorescence image to get a 2D distribution.

A true simultaneous velocity/temperature measurement is possible when the velocity is determined using the instantaneous images generated by sequential “read” pulses. In Fig. 44, diagrams to the right demonstrate measurements in both the Mach 4.6 free stream (b) and in the wake of the Mach 4.6 flow over a cylinder (c). The images (b) and (c) are instantaneous fluorescence shots. The flow movement is from left to right. The cylinder position is shown as a white circle.

Conclusion

Every new dimension of the acquired information can be compared to a new window in the house. The more windows, the brighter the room is. We outlined the main stages of information extension: from a simple single-dimension range measurement to determining the three-coordinate object location in the space, adding velocity and vibrations as dimensions, determining the parameters of the media in which the laser radiation propagates, combining several dimensions from the same laser radar or from several laser radar systems. Velocity and vibrations can be described as single-dimensional (radial component), two-dimensional (lateral x-y directions), or full three-dimensional. Vibrations can have a fourth (spectral) dimension. Fluctuations of the signal reflected from the target can provide still another dimension of the information describing the target. Polarization is a source of information in laser radars that can be used as a dimension in different applications, e.g., remote measurement of object orientation (Molebny, 1975) or its shape (García-Arellano *et al.*, 2017), clutter suppression (Sassen, 2003), object or its material identification (Raghavan *et al.*, 2008), etc. We sketched a hypothetical multi-dimensional laser radar system which is the combination of 3D space coordinates plus 3D velocity in each point of the space + time dimension. This dimensionality can be even broader if temperature or another medium parameter is added. It is very productive to combine the information from laser radar with information from other sources: acoustic (Donzier and Cadavid, 2005; Lindgren *et al.*, 2011), microwave (Duckworth *et al.*, 1995; Yang and Qianqian, 2009), infrared (Tong *et al.*, 1987; Bartlett *et al.*, 2017), etc.

A Review of Laser Range Profiling for Target Recognition

Ove Steinvall, Swedish Defense Research Agency (FOI), Linköping, Sweden

© 2018 Elsevier Ltd. All rights reserved.

Introduction

The classification and identification of small target, and/or targets at long range is a prime need for defense and security. Examples involve targets such as aircraft, unmanned aerial vehicles (UAVs) and missiles as well as small boats at sea and in littoral waters which have become common in illegal immigration, piracy, drug trafficking, and asymmetric threats.

Radar is the dominant sensor for long-range target detection and also offers model- and feature-based classification techniques using high resolution range profiles (HRRPs), target micro-Doppler spectra, range-Doppler imaging, and inverse synthetic aperture radar (ISAR) imaging. Techniques based on target tracking and target behavior are also studied for recognition.

Laser radar (or ladar) can also accomplish small target, or long range, target classification. Laser radar can provide narrow beams resolving multiple targets and can also provide recognition capabilities based on vibration, 1D range profiling, as well as 2D or 3D imaging. In this paper, we will concentrate on range profiling. Compared with its radar counterpart (HRRP) laser radars can offer more stable signals where fluctuations of the range-profile amplitude due to speckle often causes problems in classification.

The speckle problem is much less pronounced for a direct detection optical system, and very high range resolution in the centimeter range can be obtained. This makes a profiling laser radar an interesting candidate for long-range target, or small target recognition, where the transverse resolution for imaging sensors is limited to a single or a few pixels. A laser range finder is today a standard sensor in most EO systems and can have a profiling capability, or be modified to be more suitable for this task.

1D laser techniques for target recognition include vibrometry (Lutzmann *et al.*, 2011) and laser range profiling (LRP) including its extension to tomography. LRP is attractive because the maximum range can be substantial, especially for a small beam width while still preserving a high range resolution. LRP will usually work together with an IR and radar sensor which acquires the target. A laser profiler can complement a jammed radar, or a silent radar wanting to limit the effectiveness of anti-radiation missiles. It can also extend the capability of an IR-sensor to include small and long-range target classification. LRP can be used in a scanning mode to detect targets within a certain sector. The same laser can be used for illumination in active imaging when the target comes closer and is angular resolved.

LRP has been investigated for both search and ID of small surface targets (Kunz *et al.*, 2005; van den Heuvel *et al.*, 2009a; Schoemaker and Benoist, 2011) as well as for aircraft ID (van den Heuvel *et al.*, 2008; Dierking *et al.*, 1998). Recently, we showed by simulations and laboratory measurements that LRP is a promising method of identification of small sea surface targets at long ranges (Steinvall *et al.*, 2012b, 2014; Steinvall and Tuldahl, 2016). A series of laser radar range profiles collected at various aspect angles allows for a tomographic reflective reconstruction of the target (Knight *et al.*, 1989b). Many examples of this are found from simulations and laboratory measurements (Knight *et al.*, 1989a,b; Jin and Levine, 2009; Parker *et al.*, 1988; Henriksson *et al.*, 2012a,b) and other demonstrate field results (Murray *et al.*, 2010). Many of the applications seem to be devoted to satellite imaging (Lasche *et al.*, 2009; Matson and Mosley, 2001). Using time correlated single-photon counting, very high range resolution (millimeter–centimeter) profiling and tomography can be demonstrated (Sjöqvist *et al.*, 2014).

This review article starts with reviewing the theoretical basis of LRP, and relating this theoretical basis to the corresponding techniques for microwave radar. Examples of simulations, and related uncertainty in building a realistic library, to compare measured with stored data, will be discussed. Experimental results will be given for different types of targets and compared with simulated data. Furthermore, examples in signal processing techniques will be discussed. Finally, conclusion and future prospects for the technique will be presented.

Background for LRP

LRP is based on sending out a short pulse, or modulating the laser emission, so that high range resolution is obtained. Depending on the target depth structure the resolution may be high enough to profile this structure, typically meaning at least 10 resolution cells over a target, such as an aircraft.

Direct detection systems, such as present military range finders, offer target maximum ranges in the 10–20 km range and a range resolution in the region 0.2–1 m. The number of speckle lobes N_{sp} falling within the receiver aperture D_{ap} from the target plane from a certain range cell is at a first approximation

$$N_{sp} \sim \left[\frac{D_{ap} D_{target}}{\lambda R} \right]^2 \quad (1)$$

where D_{target} is the illuminated target area, λ the laser wavelength, and R the target range. For $D_{ap}=0.1$ and $D_{target}=1$ m the range for which $N_{sp}=1$ is about 100 km and for $D_{target}=0.1$ m, $R=10$ km. Thus, for very small targets, and long ranges, the speckle noise might be present from a diffuse target. On the other hand, for a glint target turbulence fluctuations will dominate. However, pulse

averaging over 1–3 s will average out most of the turbulence and target speckle fluctuations. This has been demonstrated in both measurements and simulation when range profiling of small surface vessels (Steinvall *et al.*, 2012b; Steinvall and Tulldahl, 2016).

In order to estimate the range performance of a laser profiling system indicative of a laser range finder type we will start by expressing the detected laser power (P_{det}) written as

$$P_{\text{det}} = T_{\text{optics}} \cdot P_0 \cdot \frac{\rho_{\text{target}}}{\pi} \cdot \frac{A_{\text{rec}}}{R^2} \cdot \frac{4 \cdot A_{\text{target}}}{\pi(\phi R)^2} \cdot T_{\text{atm.laser}}^2 \quad (2)$$

where P_0 is the transmitted peak power, R the target range, ϕ the laser divergence, ρ_{target} the target reflectance, and $T_{\text{atm.laser}} = \exp(-\sigma R)$ the one-way atmospheric laser transmission. The signal-to-noise ratio (SNR) is given by $\text{SNR} = P_{\text{det}}/\text{NEP}$. The maximum range for the system as a function of atmospheric extinction can easily be obtained with the help of the Lambert-W function (Steinvall, 2009).

We will choose some sensor data indicative of an eye-safe 1550 nm laser range finder. The laser pulse energy is set to 30 mJ and the pulse length 6 ns, giving a peak power of about 10 MW. The receiver area is assumed to be 0.02 m² corresponding to a diameter of 16 cm, and the receiver noise equivalent power (NEP) was 3 nW. The optical background is in general lower than this figure. The relation between the atmospheric extinction coefficient σ at 1550 nm wavelength and the visibility V was assumed to be $\sigma = 0.996(3/V)^{1.2}$ according to Hutt (Hutt *et al.*, 1994).

Fig. 1 shows the maximum range vs. visibility for different combinations of target strength $A_{\text{target}} \times \rho_{\text{target}}$ m² and the case of an unresolved target. As seen the range can be substantial during a wide range of visibilities. The threshold for the SNR was set to 7. Averaging over 10–100 pulses will improve the SNR approximately as the square root of the number of pulses provided that the individual pulses are summed up with the same “start” bin.

Time correlated single photon counting (TCSPC) is a special form of a direct detection laser radar where a single detected photon will cause the detector to saturate. This technique enables millimeter–centimeter range resolution. In TCSPC, this is accomplished by carefully measuring the time between a laser pulse sync signal and registration of a single-photon event of photons reflected from a target. The measurement is performed multiple times and a histogram of arrival times is computed to gain information about surfaces at different distances within the field of view (FOV) and to exclude spurious detections from detector and background noise. Systems using moderate pulse repetition rates and a limited number of acquisitions are usually called Geiger-mode APD (GMAPD) laser radar, whereas systems using laser pulse repetition rates in the megahertz range, that is, more acquisitions and lower detection probabilities, are termed TCSPC laser radar with single-photon avalanche photodiode (SPAD) detectors. We refer to Sjöqvist *et al.* (2014) for more detailed discussion of these techniques for range profiling and reflectance tomographic imaging.

For a range profile using GMAPDs the number of detected photons per pulse must be kept low, typically 0.1 photon. Otherwise the first photon will block pulses from close lying structures due to the dead time in this form of detection (Geiger mode).

To estimate the maximum range performance the SNR expression is not quite useful. Instead, the detection and false alarm probability ($P_{\text{det}}/P_{\text{fa}}$) should be used. An example of such an analysis is made in Steinvall *et al.* (2012a) where $P_{\text{det}}/P_{\text{fa}}$ is plotted versus range for a visibility $V = 10$ km and a 1 m² diffuse 10% reflectivity target. The average power was 1 mW for the 200 kHz laser with 6 ps pulse length and a 10 cm receiver aperture. The dwelltime T_{dwell} was assumed to be 1 ms which is enough to get a good detection probability. On the other hand, 10–100 ms may be more suitable to collect the range waveform details. We can see from Fig. 2 that both 1060 and 1550 nm laser radars have a good range capability using photon counting with only 1 mW of average power and an integration time $T_{\text{dwell}} = 1$ ms.

Fig. 1 Range performance for a typical profiling system corresponding to a laser range finder at 1550 nm.

Fig. 2 Comparison between 1.06 and 1.5 μm lidar performance using the parameters according to the text above and in Steinvall *et al.* (2012) for a diffuse 10% reflectivity 1 m^2 target. Fig. 3 Simulated laser radar waveforms from an aircraft and reconstruction of the tomographic image using these waveforms. Reproduced from Steinvall, O., Tulldahl, M., 2016. Laser range profiling for small target recognition. Optical Engineering Vol. 56 (3), 031206.

An attractive feature of LRP is the possibility to fuse several range profiles taken at different angles of incidence to reconstruct an image of the object (Murray *et al.*, 2010; Parker *et al.*, 1988). A tomographic image can be obtained by using the Radon transform to reconstruct the shape of the target. Satellite imaging by tomography has been demonstrated with a pulsed, mode locked, coherent system (Matson and Mosley, 2001). Frequency chirp techniques for obtaining high range resolution are also a well known method in coherent laser radar. Other techniques like range correlation methods (pulse compression) have been exploited by others using pseudo-random pulse codes. This was demonstrated in Murray *et al.* (2010) for image reconstruction of a meter sized target at 22.4 km range with 15 cm resolution.

Coherent detection also enables the use of the target rotation, and the generated Doppler spectrum, to determine the object size and rotation speed from 1D measurements related to range profiling.

Fig. 3 shows an example from simulations using several laser range rofiles from different aspects to form a tomographic image. However, the tomographic technique has its limitations in practical systems and is probably most useful for a fixed sensor and a rotation target around its own axis (Henriksson *et al.*, 2012a,b).

Simulating Laser Profiling Data

In order to enable target recognition from range profiling the measured range waveform has to be compared with that from a library containing a number of potential targets. The stored waveforms should contain all possible aspect angles of interest. This fact will widen the library content. Coupled to this data storage is also the question if the whole waveform,

Fig. 4 Left: a point cloud model of aircraft SK37 Viggen using the Riegl VZ-400 laser scanner. Right: the polygon model built with the point cloud as a reference. Images FOI.

or only its features, like individual peak positions and the relative amplitude of peaks should be stored. The best is of course if the whole waveform in addition to the characteristic features can be stored because that will enable a more robust signal processing.

As direct measurements of the target profiles over all aspects are unrealistic for many reasons, the modeling of different target waveforms is inevitable. This can be accomplished if a good 3D CAD model of the target is available. The surface angular reflectivity characteristics at the laser wavelength of interest is given from the bi-directional reflection distribution function (BRDF). This function is hard to measure in practice and often has to be modeled based on known or assumed target surface properties. Examples of studies of the BRDF influence on range pulse waveforms are discussed by [Steinvall \(2000\)](#) and the BRDF effects on ladar-based reflection tomography by [Jin and Levine \(2009\)](#). In general, the more glossy the surface is, the more accentuated will those parts be which are normal to the angle of incidence while other surfaces with a slope toward the beam will be reduced in amplitude. Strong glints from a target can mask the following range information if the dynamic range of the receiver is limited. In order to simulate range profiling data a CAD model of the target is desired. 3D CAD models can in many cases be found on the internet to a varying degree of details. These CAD models seldom contain any information about reflectivity and material properties so this has to be assumed. The most straightforward assumption may be to suppose that the surface is diffuse with a 10–20% reflectivity. If the real target is available for measurements this can be scanned using a commercial laser scanner, for example, the Riegl VZ-400 which has the ability to scan a position within an elevation angle of 160 degrees in a full revolution and with a pitch of 0.005 degrees using a 1550 nm laser. Using calibration charts the correct reflectivity in each scan point will automatically be obtained.

Fig. 4 shows a point cloud of an aircraft generated from a scan using the RIEGL scanner and also the model built with the point cloud as a reference. This polygon model including each surface reflectivity will be the base for simulating the laser radar profiling waveforms. Then a sensor model (in our case called the FOI-LadarSim ([Chevalier, 2011](#))) is applied to simulate waveforms from each pixel at the target (pixel density is selectable) and in that way 1D, 2D, and 3D data can be simulated. Beside sensor parameters and their effects, the atmospheric and target speckle are included in the signal generation.

Fig. 5 shows an example of simulated and measured range profiles. The measurements are made against a physical scaled down model of the aircraft JAS Gripen (length about 1.5 m). The measurements were made at short ranges with a 1.5 ns pulsed low power laser mimicking a typical laser range finder with about 10 ns pulse length against a full-sized aircraft ([Pace et al., 2008](#)).

Fig. 6 illustrate range profiling of a small boat complemented with a tube and a box to alter the profile. The dashed line is the simulated pulse return. Deconvolution of the second echo with the transmitter pulse reveals two peaks interpreted as indicated in the figure.

There are many uncertainties that could result in differences between the measured and the simulated data. Examples include incorrect geometry in the CAD models and unknown reflectance of the surface material. Roughly, the outer shape of the models may be correct but because the simulations take into account even small features there might be errors. One example is the inside of an aircraft engine or air inlet which might be a source of error. To solve this, further validation with access to the physical models would be required.

Other error sources include incorrect sensor and environmental effects modeling. For example, the exact beam distribution and beam pointing error at the target are hard to predict in detail. There are also some uncertainties in the system parameters (noise, receiver electronics, laser power, etc.).

Examples of Range Profiles Studies

Naval Targets

TNO Defense, Security, and Safety in the Netherlands have shown results on laser profiling mainly from naval ships ([Schoemaker and Benoist, 2011](#); [van den Heuvel et al., 2009a,b](#)). One example is illustrated in **Fig. 7**.

Fig. 5 An example of simulated and measured data. Left: a model of the JAS 39 Gripen seen from the front. Measurement data from a scaled down physical model of the aircraft is given by the red curve, while the simulated of the blue. The superimposed planes' picture shows the structures that correspond to every part of the signal. Right: shows the same comparison seen straight at 90 degrees from the main direction. Reproduced from Pace, P., Steinvall, O., Chevalier, T., 2008. Automatic target classification using one dimensional laser profiling. Technical Memorandum DRDC, Ottawa, TN 2007-000.

Fig. 6 Upper image shows the small boat complemented with a tube and a box to alter the range profile together with the model for waveform simulation. The first profile (dashed) is the model generated pulse. Deconvolution of the second echo with the transmitter pulse reveals two peaks interpreted as indicated in the figure. Reproduced from Steinvall, O., Tuldahl, M., 2016. Laser range profiling for small target recognition. Optical Engineering 56 (3), 031206.

Fig. 7 shows the measured and simulated range waveforms from a frigate at 10 km range measured in the head on direction. As seen the correspondence is quite good with the exception from two extra peaks present in the measured waveform. These can be associated with the two extra antenna spheres. In the 3D model these structures above the bridge are absent. The system used in these experiments had a transmitter output at 1570 nm around 30 mJ. The receiver used a 750 mm telescope, with an optical aperture of 125 mm diameter. The receiver bandwidth was 200 MHz (van den Heuvel *et al.*, 2009a,b).

A NATO trial in San Diego under the name "NATO Maritime Target ID" was carried out outside San Diego. Several laser and IR systems were used to investigate small surface classification/identification using both 1D, 2D, and 3D laser radars

Fig. 7 Left: the point cloud of a ship is used to generate simulated range waveforms. Middle: the simulated (blue) and measured range waveforms from 10 km range. Reproduced from van den Heuvel, J.C., Schoemaker, R.M., Schleijpen, R.M.A., 2009a. Identification of air and sea-surface targets with a laser range profiler. Proceedings of SPIE 7323, 73230Y.

(Schoemaker and Benoist, 2011; Steinvall *et al.*, 2010; Armbruster and Hammer, 2012). The authors in Schoemaker and Benoist (2011) examine the discrimination between three different small boats all between 5–6 m in length. A simple and rather crude model of the boats was used to generate the simulated waveforms to compare with the measured. The result shows that the desired accuracy (95% or better) which was achieved in investigating different simulated waveforms for different noise conditions was not achieved for the experimental data.

In a later experiment in Sweden, FOI demonstrated rather good results with a profiling system which had almost the same characteristics as the TNO system (laser pulse width 6 ns, 10 cm optical aperture, 15 mJ /pulse, and 1570 nm laser wavelength at 40 Hz pulse repetition frequency – PRF). The paper Steinvall *et al.* (2015) shows both experimental and simulated results for LRP of small boats out to 6–7 km. Fig. 8 shows the small boats used in the test. These are more different from each other than the boats studied in the San Diego trial mentioned above. In the figure the CAD models of the boats are also shown based on laser scanning.

Fig. 9 shows the structure and the corresponding distances as well as an example of a range waveform. Some interpretation is formulated in the figure text. Fig. 10 shows the echo amplitude variation for the three observed peak during a 10 s data collection at a PRF of 40 Hz. Manual tracking was used to follow the small target at 6 km range which was a demanding task. Also note the high resolution sensors in the SWIR and mid-IR gave hardly any possibility for target classification without a support from the range profile. The SWIR camera had a FOV = 0.7 degree $\times$ 0.6 degree fully zoomed. The illuminator laser had a maximum power of 1.6 W and the beam divergence could be varied between 10 and 50 mrad. The camera had a spectral response between 0.4 and 1.7 μ m and the detector array had 640 $\times$ 512 pixels. The mid-IR camera had a 1280 $\times$ 720 array of 12 μ m pixels responding in the spectral range between 3.7 and 4.95 μ m with a typical sensitivity of 17 mK and a minimum narrow FOV of 0.9 degree $\times$ 0.5 degree.

Airborne Targets

Long-range laser profiling measurements of airborne targets are hard to find in the open literature. Measurements on static targets and results from simulation are reported in open sources. Heuvel *et al.* (van den Heuvel *et al.*, 2009a,b) describes an identification algorithm used to distinguish three aircraft from their simulated range profile with good results. The authors use simulated profiles obtained using 3D computer models for three aircraft: an F15, an F16, and an F117. They assume a lidar with 30 cm range resolution.

Heuvel *et al.* investigate the relation between identification and aspect angle. They assume that all aircraft have the same diffuse reflectivity. The identification range depends both on range and target aspect angle. An analysis as described in van den Heuvel *et al.* (2009a,b) will yield a (Bayes) identification probability for the various aspect angles. The SNR for a given identification probability can be associated with a range for a given system and target. Fig. 11 shows the radial plots of the required range (in arbitrary units) against the aspect angle for an identification probability of 90%. According to the authors it is clear from these plots that the required range is shorter for front view (aspect angle of zero degrees). This may be understood if we consider the aerodynamic shape of the aircraft that is responsible for a low laser return. We see a similar effect at 180-degree aspect angle.

It is also informative to compare the radial plots of the three aircraft. The F16 has a smaller maximum identification range than the F15 which has again a smaller range than the F117. Thus, the F117 can be identified at considerably longer ranges than the F16 on average. This is most likely due to the characteristic shape of the F117 (van den Heuvel *et al.*, 2009a,b).

Example of full scale laser profiling measurements on a real aircraft (SK-60 veteran aircraft) is shown in Fig. 12. Note that the range profiles change shape for rather small changes in azimuth. The measurements were made at 1 km range using a 1570 nm laser.

Fig. 13 shows a profile map from a horizontal scan for two different aircraft. The signature is quite different as can be seen. In Fig. 14 the measured profile covering the whole, aircraft mimicking a long-range profiling is compared using a simple 3D cad

Fig. 8 Test vehicles for the trial in Sweden. The upper boats were slightly modified by placing a stove pipe and a box to change the signature. Boat A (upper): length 4.73 m, width 1.92 m. Boat B (middle): length 6.18 m, width 2.15 m (total length incl. the rear flat plate=6.57 m). Boat C (lower): length 8.64 m, width 3.15 m (total length incl. the rear flat plate=9.55 m). The last row shows the 3D models based on laser scanning using the Riegl scanner. Reproduced from Steinvall, O., *et al.*, 2015. Passive and active EO sensing of small surface vessels. Proceedings of SPIE 9649, 964901.

model from the internet and assuming a complete diffuse surface for the whole aircraft. Many main features compare well but there are also some difference due to the incomplete aircraft model.

Small targets of interest for detection and classification include UAVs and missiles. Laser profiling of these targets may be done but need a much higher range resolution probably 10 cm or less. TCSPC offers a range resolution in the sub-centimeter level and we have demonstrated this against a UAV mockup according to Fig. 15 (Steinvall and Tuldahl, 2016).

Fig. 16 shows the UAV at the 1.3 km distance and the scanning the pattern from the single detector device color-coded in reflected laser intensity. The size of the pixels was about 15 cm in square. Since we had a weak laser we integrated the counting during 5 s/pixel. The laser PRF was 4 MHz and with a pulse duration of 25 ± 5 ps. The laser's average power was 20 mW. The laser divergence was $280 \mu\text{rad}$ and the detector FOV= $150 \mu\text{rad}$ (which gave some "spillover"). Fig. 17 shows the sum of the range waveforms over the entire scan area (corresponding to a fictitious beam divergence of about 1.7 mrad). We can clearly see echoes of the various structures including that from the cone-like front (provide a linear amplitude change with time). The distances derived from the pulse response are consistent with the actual distances within 1 cm.

Fig. 11 Radial plot corresponding to an identification probability of 90% for an F16, F15, and F117, left to right respectively. After van den Heuvel, J.C., Schoemaker, R.M., and Schleijsen, R.M.A., 2009a. Identification of air and sea-surface targets with a laser range profiler. Proceedings of SPIE 7323, 73230Y.

Fig. 12 Range profiles for the different azimuth positions of the SK-60 aircraft. The range profiles are summed over all measurement points on the aircraft for a specific azimuth ($=0$ for head on) and this mimicking a long-range profile when the laser lobe is covering the whole aircraft. Image FOI.

completely disappears, shadowed by the UAV body, and the first wing echo is spread out over time and combined with reflections from the UAV body.

Land Targets and Mapping

Results on LRP of land targets are limited concerning horizontal paths. On the other hand, vertical laser scanning from an airborne platform is well established especially for terrain and underwater sensing.

The civilian market has been leading this field for the last 20 years. Both space and airborne laser radar systems, as well as terrestrial laser radars, have been developed by several different vendors. The large number of publications and applications, as well as the rapid development of hardware, shows the large interest in this technology. A book giving a good overview of topographic laser scanning techniques was published by [Shan and Toth \(2009\)](#). [Fig. 19](#) illustrate some developments of airborne laser scanning system for both terrain and depth sounding applications.

Fig. 13 Laser scan using a beam with 1 mrad beam divergence with the aircraft at 1 km range. Two veteran aircraft SK-60 (left) and Viggen (right) from the Swedish Air Force. Images FOI.

Laser scanners are used on UGVs for navigation and obstacle avoidance. Systems from Teledyne Optech and Velodyne Lidar are the examples of commercial road mapping laser radars with many potential military applications (e.g., generation of synthetic environments, detection of improvised explosive devices, and so on). The accuracy is said to be on the order of centimeters at a maximum range of 100–250 m. Measurement rates are found between 1 and 2 million points per second. This allows a 6-cm point spacing at 10-m range for a vehicle velocity of 43 km/h.

Vehicle borne laser radar is becoming a very important sensor for self-driving cars. This may be the first widespread commercial application of laser radar technology. It will force the technology to be small and compact at a cost of a few hundred dollars per system.

Scanning laser radars have been intensely studied in the United States for missile applications (Gustavson and Davis, 1992). A civilian counterpart is traffic monitoring classifying different vehicles (SICK-Sensor Intelligence, 2017). Target detection and homing were also studied for air to air seekers, and in space for the SDI program. The largest investments in laser radar seeker technology have been made for air to ground seekers. The Low Cost Autonomous Attack System (LOCAAS) was a demonstrator program (Ladar Seeker/ATA Algorithm Captive Flight Test Results, 2017) driven by the Air Force (Eglin Florida). The AFRL's LOCAAS program terminated in mid-2006 without going to production. The seeker was based on scanning laser radar generating 3D imagery of the targets with ATR and aim point selection built into the system. Loitering Attack Missile (Signal, 2017) was a project relying on the laser radar technology developed for LOCAAS. The paper from Andressen *et al.* (2005) gives some insight to this technology.

Laser scanning systems with a profiling capability can also be used for both target search and classification. If the return has a specific signature this could be indicative of a target that differs from the surrounding terrain. In principle, this could include the profiles from land vehicles which probably differs a lot from those from the terrain background. One example of a specific strong and deviating signature is the glint return from optics which can be detected from a scanning system placed on a combat vehicle looking for optical threats (Sjöqvist *et al.*, 2016). One of the problems in these types of systems is to discriminate between real targets like optical sights from other strong reflectors like traffic signs, etc. One technique to overcome this might be to use high resolution range (HRR) profiling based on photon counting (Sjöqvist *et al.*, 2013). See Figs. 20 and 21.

Atmospheric Profiling

One property for a profiling laser may also be to probe the atmospheric transmission, for example, along slant paths. Probing of the density of aerosols and thus the attenuation can be done using the backscatter signal from the atmosphere. Cloud mapping including their height distribution and density (up to a certain level) are also relevant for this type of operation. As an example it is interesting to probe the atmosphere in the dark (e.g., from a ship) when visual references disappear. Atmospheric laser radar or lidar is well investigated in the research community (Molebny *et al.* 2016; Fujii and Fukuchi, 2005; Steinvall *et al.*, 2015b).

Fig. 16 Measurement with the photon-counting system on the UAV mock-up at 1.3 km distance. In the middle a waveform contains the target and terrain background. Right shows the resulting intensity of each pixel (approximately 15 cm square) in the photon-counting system when it was scanned over the target. Reproduced from Steinvall, O., Tuldahl, M. 2016. Laser range profiling for small target recognition. Optical Engineering 56 (3), 031206.

Fig. 17 Summed range waveforms from all 3×15 pixels above the target (UAV). The rear pulses belong to the terrain while the first part is enlarged and shows the range structure of the UAV with very high precision. The wings provide two close echoes because the UAV was not exactly perpendicular to the beam. Reproduced from Steinvall, O., Tuldahl, M. 2016. Laser range profiling for small target recognition. Optical Engineering 56 (3), 031206.

Examples of Tomography Based on Laser Profiling

The aim of reflective tomography is to estimate object surface features based on a set of reflective projections that are measured in angular increments around the object either by rotating the sensor or the object. The basics of laser based reflective tomography are well described by [Knight et al. \(1989b\)](#).

Fig. 18 Illustration of simulated waveforms over the target. The number of detected photons are shown in color scale, and the simulated target aspect angles are presented for the interval from 0 to 35 degrees in azimuth (in steps of 5 degrees). Reproduced from Steinvall, O., Tulldahl, M. 2016. Laser range profiling for small target recognition. *Optical Engineering* 56 (3), 031206.

Fig. 19 (A) The original Hawk Eye – a system which developed further can combine topographic mapping on land and water depth sounding (now made by AHAB Leica Geosystems). The figure (B) shows one example of real data. Below (C and D): a ship before and right after it sunk at 26 m depth. Images AHAB, FOI and the Swedish Maritime Administration. Laser tomography using high range resolution profiling based on TCSPC enables small models mimicking real targets to be studied in detail. Examples are given in Steinvall *et al.* (2014), Henriksson *et al.* (2012a,b), Sjöqvist *et al.* (2014), and Steinvall *et al.* (2012b). The principle is depicted in Fig. 21.

Based on the scheme for filtered backprojection (FBP) using the inverse Radon transform, the tomographic image can be reconstructed. Mathematically, the 2D object can be expressed as (Henriksson *et al.*, 2012a,b):

$$g(x, y) = \sum_{i=1}^m q(z \cos \theta_i + x \sin \theta_i) \Delta \theta \quad (3)$$

where

$$q(r, \theta) = \mathcal{F}^{-1}(f \mathcal{F}(p(r, \theta))) \quad (4)$$

Advanced Optical Technologies 3, 187–197.

Fig. 22 Example of tomography of a small model boat, 43 cm in length. Our laboratory TCSPC lidar system had a time response of 54 ps corresponding to a range resolution of 0.8 cm. Reproduced from Steinvall, O., Chevalier, T., Grönwall, C., 2014. Simulation and modeling of laser range profiling and imaging of small surface vessels. Optical Engineering 53 (2), 029801.

and $\mathcal{F}$, $\mathcal{F}^{-1}$ denote the forward and inverse Fourier transform, respectively, r is the distance along the measurement direction with zero at the rotation center of the studied object (not a polar coordinate), $p(r, \theta_i)$ is the range profile for each rotation angle θ_i , and f is a filter function. Here it was assumed that the rotation axis is parallel to the y -axis. The filter function, f , was chosen to be a generalized ramp function according to:

$$f(\omega) = |\omega| \cdot e^{-\xi|\omega|^a} \quad 0 \leq |\omega| \leq \pi \quad (5)$$

and $\xi = |1/\omega_c|^a$ with ω_c defining the cut-off frequency and a is an adjustable parameter. Typical values used in our work with a photon counting systems (Sjöqvist *et al.*, 2014) to reduce the high-frequency components were $a=3.4$ and $\omega_c=\pi/4$. The values need to be optimized based on the IRF of the measurement system.

FOI laboratory TCSPC ladar system had a time response of 54 ps corresponding to a range resolution of 0.8 cm. Realistic range resolution from conventional high resolution direct detection range finders of laser radars is in the region 0.2–1 m, which correspond to scale factors between 25 and 125. The extreme range resolution of TCSPC ladar makes it possible to perform experiments using laboratory scale models relevant for scaling to data expected with linear-mode laser radar systems for the identification of large-scale objects, allowing testing of possible system performance in a simple and inexpensive way (Steinvall *et al.*, 2014).

Fig. 22 shows examples from the measurements using the 43-cm long fishing boat as a target. Left is an example of the observed waveform looking straight at the fore of the boat, middle, and range profile for 341 degree in steps of 1 degree. Right is a tomographic image obtained by using the Radon transform to reconstruct the shape of the boat. The measurement range in the laboratory was about 40 m and the beam covered the whole FOV of the receiver, which was 10.2 mrad ($1/e^2$) corresponding to 40 cm at the target.

There are many factors affecting the quality of the tomographic image, for example, strong reflections which cause linear features stretching through the reconstructed image. Jin *et al.* has investigated the BRDF effects in ladar-based reflection tomography (Jin and Levine, 2009). The influence from these artefacts can be partly removed by using the “convex hull” method where the first response (opaque surface) at each angle from the object is used to create an image mask outside which the response is known to be zero (Sjöqvist *et al.*, 2014). Critical issues regarding the quality of the reconstructed tomogram beside SNR include defining the center of rotation, applied angular resolution, and the used angular projection sector. The way of presenting the tomogram also has a large influence on the image quality. Often the log intensity including a threshold give a good quality (see Fig. 23) paired with a type of filtering like the “convex hull” mentioned above.

So far only laboratory measurements examples have been presented. There are, however, also several long-range demonstrations reported in the literature. The use of 1D Doppler-resolved projections to form a 2D tomographic image of a rotating object was demonstrated using the MIT Lincoln Labs 10.6 μm Firepond laser radar. With a model of a Thor-Delta rocket target at 5.4 km ground range, Doppler-time-intensity was demonstrated (Knight *et al.*, 1989b). Images of satellites at ranges up to 1500 km were also collected by the Firepond (Gschwendtner and Keicher, 2000) (Fig. 24).

Matson and Mosley (2001) report on the first satellite feature reconstruction, by use of range-resolved reflective tomography techniques collected on an orbiting satellite. The reconstructed features were two retroreflectors mounted on a satellite. The data were collected with a coherent laser radar system located at the Maui Space Surveillance Site in Maui, Hawaii. The laser system called HI-CLASS was a pulse coherent laser radar emitting 30 J/pulse at 30 Hz repetition rate. The acquisition waveform was a gain-switched pulse with a duration of the order of 10 ms, whereas the imaging waveform is a mode-locked version of the acquisition waveform. The mode-locked waveform was a series of micropulses modulated by the gain-switched pulse waveform in which the micropulses are less than 1.5 ns in width and are separated from each other by 40 ns. Fig. 25 shows some results. A key step in the projection creation process was to align the projections to the center of rotation of the satellite.

Fig. 23 Photograph and reconstructions of a model of a DSP satellite. Note the better image quality using log intensity and thresholding. Reproduced from Knight, F.K., Kulkarni, S.R. Marino, R.M., Parker, J.K., 1989. Tomographic techniques applied to laser radar reflective measurements. Lincoln Laboratory Journal 2 (2), 143–158.

Fig. 24 (a) The Laser Geodynamics Satellite (LAGEOS), a 60-cm aluminum sphere with a brass core. The satellite has a total mass of 406 kg and is in a near circular orbit at an altitude of approximately 5900 km. LAGEOS has 426 silica retroreflectors and 4 germanium retroreflectors to serve as a laser-radar target. (b) Range-Doppler image of the LAGEOS satellite collected by the wideband CO_2 laser radar at Firepond. The coarse image was made with a signal bandwidth of 150 MHz, while the fine image was made with a bandwidth of 1 GHz. Doppler velocity resolution is approximately 30 cm/s. Color in the image represents relative signal amplitude. The range and Doppler sidelobes are better than 20 dB below the main lobe. The range-Doppler images are the point-target responses of the imaging laser radar produced by different bandwidths. Figure text and figure from Gschwendtner, A.B., Keicher, W.E., 2000. Development of coherent laser radar at Lincoln Laboratory. *Lincoln Laboratory Journal* 12 (2), 383–396.

Fig. 25 Left: representation of the LACE satellite. Middle: tomographic reconstruction of the two retroreflectors at the satellites arms. Right: thresholded image to remove limited-view artifacts. Reproduced from Matson, C.L., Mosley, D.E., 2001. Reflective tomography reconstruction of satellite features – field results. *Applied Optics* 40 (14), 2290–2296.

Another long-range example is given by Murray *et al.* (2010). They use pulse coded lidar waveforms that have desirable side-lobe-free autocorrelation properties. In opposite to short high pulse energy techniques this will enable high bandwidth ($> \text{GHz}$), low-peak power, compact and efficient fiber laser transmitters and photonic receivers to be used in compact systems. See Fig. 26 for an example of the result.

A theoretical analysis of including turbulence effects for lidar reflective tomography imaging for space objects is presented by Qu *et al.* (2011). The development of laser range profile, Doppler spectra, and range-resolved Doppler imaging technologies are reviewed in the paper (Wu *et al.*, 2014).

Reflective tomography can also include making 3D images from a series of 2D images. Different techniques have been published (Xinwei *et al.*, 2016; Andersson, 2006; Laurenzis and Woiselle, 2014) for this reconstruction but they all rely on evaluating the range from the pixel intensity increase or decrease with time. The convolution of the camera gate function and the laser pulse shape form this time dependence to be used in the 3D reconstruction. The 3D quality depends on the single frame SNR and the number of frames used for the reconstruction. In Fig. 27 we illustrated how thermal and laser imaging can be combined for target detection and classification using a 2D to 3D tomographic technique.

Fig. 26 Left: long-range field test configuration. An unresolved rotating 1 m diameter target consisting of both retro-reflective and diffuse scattering structures is placed on a tower 22 km from the laser platform. The ladar field of view (FOV) is 2 m and the transmitter FOV is 4 m at range. Right: first tomographic image reconstruction of an unresolved target located 22 km from the ladar sensor. Both the retro-reflective (glint) and diffuse cylindrical targets appear in the image. Reproduced from Murray, J., Triscari, J., Fetzer, G., *et al.*, 2010. Tomographic lidar. Signal Processing Techniques for Range Profiling and Tomography

In the microwave radar field signal processing techniques for target classification have been studied more extensively than for laser radar. This should motivate a closer look at the radar signal processing methods to see if they are applicable to laser radar while noting that there are difference in the type of signals they generate.

In the radar field techniques based on sequential classification tracking as well as model and feature-based methods have been developed. The sequential technique is based on successive target measurements performed over long time intervals, typically several seconds or minutes. During this period target maneuvering will be indicative of the type of target. This information from radar (or an optical sensor) will limit the search target search space and allow for other model or feature-based methods to be added for a more robust recognition.

Model-based methods employ physical and/or empirical target models to predict the measured target signals. The measured and predicted (model) signals are compared and the model which gives the smallest difference to the measured signal is chosen.

Feature-based methods do not use a model of the measured signals but rely on extracting a limited number of target features from the measurements. Subsequently, the extracted feature vectors are compared with feature vectors in a training set extracted from measurements.

It seems that model-based methods are most applicable to LRP because real measurements may be hard to achieve at least for military targets. On the other hand, real measured profiles may be collected over time using targets of opportunity.

HRR profiling for microwave radar has been investigated rather extensively (see e.g., Shaw *et al.* (2013), Li and Yang (1993) and references therein). One of the most critical issues about the range profile signature in the microwave domain is its extreme variability as a function of aspect angle. As little as a 0.1-degree aspect angle change can cause such a severe change that the signature is no longer recognizable. This is understood as the radar signal is composed of a number of strong scatter center contribution and a small change of the scattering center positions to a quarter of a wavelength will completely change the phase of the return. This fact motivated that radar signal processing of HRR often contains statistical modeling to capture these variations.

The most direct processing technique for range profiling may be correlation. In this method, the profile is convolved with a reference profile from the model library. It is convenient to normalize the waveforms to the highest peak for example. The method has been applied to real radar HRR data from 24 aircraft with (Hudson and Psaltis, 1993) success provided aspect information is

Fig. 28 Example of measured (full line) and simulated (dotted) waveforms together with the correlation coefficients obtained after matching the largest peak. One can observe how the waveforms both match and mismatch probably due to different angular boat positions and beam jitter. Reproduced from Steinvall, O., *et al.*, 2015. Passive and active EO sensing of small surface vessels. Proceedings of SPIE 9649, 964901.

Fig. 29 Correlation coefficient between measured and simulated waveforms from boat B at 0- and 180-degree aspect. Different target ranges are indicated. Reproduced from Steinvall, O., Tuldahl, M., 2016. Laser range profiling for small target recognition. Optical Engineering 56 (3), 031206.

used, and provided identifications are based on sufficient number of profiles so as to decrease errors due to speckle fluctuations. Li and Yang (1993) used correlation to investigate target classification using experimental data from physical aircraft model with sizes in the 50–80 cm range measured in the frequency range 6–16 GHz.

Fig. 30 The measured distances vs. the nominal together with the standard deviations of the measurements and the difference between measurements and simulations. The aspect angle was 0 degree (boats approaching toward the sensor). Reproduced from Steinvall, O., Tuldahl, M., 2016. Laser range profiling for small target recognition. *Optical Engineering* 56 (3), 031206.

Fig. 31 The ratio of peaks in the waveform for the unmodified boats. Boat 1=A, boat 2=B and boat 3=C. Reproduced from Steinvall, O., Tuldahl, M., 2016. Laser range profiling for small target recognition. *Optical Engineering* 56 (3), 031206.

Fig. 32 Confusion matrix for classification using distance and ratio of the three peaks in each range waveform. Right: results for true positive and false negative. The classification accuracy for a decision tree classifier was 89%. Reproduced from Steinvall, O., Tuldahl, M., 2016. Laser range profiling for small target recognition. *Optical Engineering* 56 (3), 031206.

For radar it has been argued that the magnitude of the HRR profiles is too uncertain to use for target recognition, and one should instead use the positions of peaks in the HRR profile. In Zwart (2004), Zwart applies this approach using the same in-flight measured radar data of five aircraft with promising results. Furthermore, Eigen template based recognition have been investigated in a number of publications, see Xinwei *et al.* (2016) and references therein.

The laser range waveforms are less variable with respect to small aspect changes as the reflection is more or less diffuse in character. Thus, a more parameter-based processing technique seems appropriate to investigate beside correlation.

The correlation for LRP methods has also been tested on small boats (Steinvall *et al.*, 2015a). When the main peak matches a correlation coefficient as exemplified in Fig. 28 was achieved. Note that the correlation value can be rather high even if other the peaks mismatches. In Fig. 29 we exemplify the correlation coefficient for all measurements against the boat B of Fig. 8 and at 0-degree aspect (approaching course) and a few at 180-degree aspect. Most of the 0-degree aspect correlation data show high values, above 0.9 for both maximum and mean values. Lower values can most probably be explained by poor pointing and beam jitter.

As seen from the correlation examples (also see Steinvall *et al.* (2015a)) the discrimination capability only based on correlation analysis may not be sufficient for a robust recognition. It is therefore of interest to add other parameters into the decision process. These can be related to the distance between peaks and the ratio of peak amplitudes.

The absolute distances as shown in Fig. 30 are derived from the peak separation for both simulated and collected range profiles for 0-degree aspect. In general, we can see that the correspondence between the observed and simulated distances is rather good.

The mean peak amplitude ratios for the first and second pair of peaks for every waveforms are shown in Fig. 31, estimated from all measurements at 0 degree and all target types without modifications with the extra box and the pipe. From this we can see that the difference between measured and simulated ratios is rather good irrespective of the lack of detailed reflectivity information and information on how the beam was actually pointed.

Using all available measures that is two distances between peaks and the corresponding ratios of peaks both from measurements and simulations we arrive at a classification accuracy of 89% (Fig. 32). The true positive classification probabilities are now even better, namely 89% for boat A, 100 for boat B, and 67% for boat C with false rates as 11, 0 and 33%, respectively, for A, B, and C. The corresponding values for the positive prediction and false discovery rates are 89, 88, 83% and 11, 12, and 7% respectively.

Heuvel *et al.* (van den Heuvel *et al.*, 2009a) describes a full scenario processing LRP for target classification using a likelihood test. Two aircraft, of which the one to classify is assumed to be a F16, are approaching each other with a speed of about 0.9 Mach at high altitude. The simulated aircraft profiles belong to F117, F15, and F16 obtained from 3D models. An LRP sensor with 30 cm range resolution is mounted on the observation aircraft. Noise has been added so that the signal at distances above 10 km is dominated by noise. The two aircraft are approaching at an angle of about 90 degrees. Atmospheric effects are neglected which is motivated that the scenario is at high altitude. Detection and tracking of the aircraft is based on radar or IRST. Fig. 33 shows the scenario and the result of the Bayesian identification. The F16 is identified at shorter ranges with a maximum probability of 95%. In Fig. 34 the time axis corresponds to absolute ranges between the aircraft and the relative range within the profile. In this figure 250 s correspond to 30 km range and at 320 s the range between the two aircraft is at its minimum, about 5.6 km. This

Fig. 33 Left: the scenario with two aircraft, of which the one to classify is assumed to be a F16, are approaching each other with a speed of about 0.9 Mach at high altitude. Right: the Bayes probabilities for an approaching F16 in the scenario. Reproduced from van den Heuvel, J.C., Schoemaker, R.M., Schleijpen, R.M.A., 2009a. Identification of air and sea-surface targets with a laser range profiler. Proceedings of SPIE 7323, 73230Y.

Fig. 34 Simulated laser range profiles for an approaching F16 according to the scenario. Every image column represents a single profile on a linear intensity scale. The blue line indicates the distance corresponding to the right axis. Reproduced from van den Heuvel, J.C., Schoemaker, R.M., Schleijpen, R.M.A., 2009a. Identification of air and sea-surface targets with a laser range profiler. *Proceedings of SPIE* 7323, 73230Y.

scenario is of high interest as it contains a dynamic change of aspect angle as well as range (and thereby a changing SNR of the waveforms).

Finally, there are a lot of other signal processing techniques which are suitable for target recognition using range profiles. These include machine learning and deep learning involving neural networks, support vector machines and others.

Conclusions

Although not by far as investigated as its microwave counterpart, LRP has some clear advantages to act as a complement or substitute to radar or IR imaging for target classification.

Compared to traditional angle-angle optical sensors LRP can offer range information along the target down to the sub-centimeter level, if needed. While traditional optical imaging needs large apertures, and often turbulence compensation, for long-range target classification, LRP is relatively insensitive to deblurring turbulence and scattering. It is also relative insensitive to first-order pointing error as long some of laser lobe covers the target. LRP can be a natural extension of present laser range finders. The maximum range at which laser range finder type of systems can produce target classification can extend tens of kilometers.

A laser profiling system can complement a microwave radar where it offers additional target classification properties, for example, for small targets using high resolution techniques. It may also back up a radar that is being jammed. The laser in a profiling system may serve as an illuminator for an imaging gated sensor and thus provide a robust recognition containing both angle-angle imaging and range profiling. Lasers can also provide accurate tracking using both imaging and quadrant detector receivers.

Tomography has been shown to be useful to image rotating objects. In general, however, the application of tomography to defense applications is probably limited due to a number of reasons. Among these we note alignment of the profiles may be difficult as well as obtaining many profiles over a sufficiently large angular sector to give a good image quality (Henriksson *et al.*, 2012a,b).

Micro-Lidars for Short Range Detection and Measurement

Vasyl V Molebny, Academy of Technological Sciences of Ukraine, Kiev, Ukraine

© 2018 Elsevier Ltd. All rights reserved.

Introduction

The term micro-lidar has its origin from the Greek word *μικρό* (small) and the abbreviation of “light detection and ranging” meaning “detection and ranging with light.” Often, a similar abbreviation “ladar” is in use where the word “light” is substituted by “laser” (light amplification by stimulated emission of radiation). Another form is “laser micro-radar” (“radar” here is for “detection and ranging with radio waves”). We shall define the laser radar, or lidar, with a prefix “micro” when the distance between the instrument and the object is of the order of a meter or less. Of course, the subdivisions can be involved, creating a series of prefixes from “mini” to “femto” and smaller. The physical principles of detection and ranging can be the same not depending on distance (range) to the object, but can be modified and fitted only for small distances.

Scope of the Chapter

Actually, the “detection and ranging” in the term “lidar” should be understood wider than only “detection” and “measuring the range.” It means acquiring the information about the objects or media due to receiving the optical radiation reflected or scattered in backward direction. Usually, the source of radiation is a laser generating visible or invisible light. There is no severe restriction on the direction of the radiation scattering strongly backward.

The most often used principle of ranging with lidars is based on time-of-flight measurement. This principle is well known when determining the distance from a lightning by taking the count of the time-of-flight of the sound from the moment of light outburst. The idea to use short pulses of light to measure distance was brought out in 1930s by [Lebedev \(2014\)](#). His prototype measured the range up to 3.5 km with the accuracy about 2 m. The principle is applicable for a wide range of distances, from thousands of kilometers to micrometers – for measuring the distance to the Moon, tracking the player position by a play station, or checking the topography of the surface of microchips. It can be a single-dimension measurement (the distance between the lidar and the object), two-dimensional (2D) measurement (e.g., the profile of the surface), and three-dimensional (3D) measurement (e.g., a tomogram of the object).

The light propagates about 0.3 m for 1 ns. If to use bursts of light for measuring a small distance, their duration should be at least an order shorter. There would not be a problem to generate short laser pulses, but when designing a lidar for short distances, the problem is shifted to the detectors and processing. That is why, the time-of-flight technique at small distances uses a phase shift between the sent and the received signals. The micro-lidar can be designed to measure the phase difference between the light carrier frequencies, or between the modulation frequencies.

Continuous-wave (CW) light radiation is used for surface profile measurement, length measurement of small objects, like intraocular distances, small thickness layers or films. To get higher sensitivity, synthetic aperture is added by moving the instrument relatively to the investigated object. Specific field structure can be created by an array of light emitting diodes, enabling to acquire 3D image.

Interferometric methods initiated a new technology of the optical low-coherent tomography (OCT) with multiple modifications and wide practical use, the most exciting of which is a 3D imaging of the structure of the eye. Impressive are also results of the OCT in cerebrovascular and cardiovascular studies and diagnosing. Low-cost nomenclature of OCT using a smartphone is represented by multi-reference technique with its implementation in dermatology.

With micro-lidar, a series of media parameters can be measured. Analysis of Raman spectra allows differentiation between malignant and benign tissues. Analysis of fluorescence delivers information on blood circulation and can help in diagnosing the diseases of the eye. Differences in absorption of light in the anterior chamber of the eye can serve for measurement of the glucose level. Spectral differences in light scattering and absorption for different wavelengths are the basis for the method of measurement of blood oxygenation, including the oxygenation of the vessels of the retina.

In long-range laser radars, it is very important to keep the direction on the target. Similar, but not less sophisticated is the micro-lidar of the CD/DVD pickup head that should keep the head respectively to the fast running track not only along its run, but also at a certain distance in focus of the photodetector. Computer mouse is another example of micro-lidar. Massive production of computers and their periphery made their components so perfect, that they become the basics for other devices, like, for example, the pickup head in the role of the driver of the reference mirror in the smartphone-based OCT instrument.

With the advent of new technologies of vision correction, a problem arose of measurement of the refraction non-homogeneity of the optical system of the eye. Several solutions were found, some of them being typical laser radars. Ray tracing consisted in sounding the eye with narrow laser beam in different points of the eye aperture and measuring the coordinates of the light spot of the laser projection on the eye bottom. The inversion of this method was projecting a single laser beam on the retina, that created there a secondary source of light, and measuring the distortion of the image of this spot of light by the optical system of the eye at the exit from the eye.

The potential of the micro-lidar to measure the velocity of small particles in gas or liquid flow was one of the earliest implementations. Laser velocimeter was called sometimes the anemometer. Among its applications was measurement of missile plume flow, turbulence statistics of the submarine wake, velocity of blood flow in retinal vessels, etc. Several methods were developed using noncoherent and coherent radiation. Translational and axial components of the flow were measured. Doppler principle was incorporated into the OCT instruments enabling the measuring and visualization of the 3D distribution of the velocity in the flows.

Distance Measurement Techniques

Pulse Mode

Since the middle of the 19th century, short light pulses assisted in many discoveries in nature studies (Shapiro, 1984). It was natural that the development of picosecond lasers initiated new experiments in designing the micro-lidars. Park *et al.* (1981) demonstrated an optical ranging system which can see through opaque material. It uses picosecond pulses and a very fast gate with a variable delay at the detector. The system could detect a reflection from a mirror inside an opaque mixture with 1.7 mm range resolution and 0.1 mm transverse resolution. The depth of penetration corresponded to 0.67 cm in human tissue.

A possibility of gated viewing at a small-pathlength difference between object beam and reference beam was demonstrated on recording a hologram with the use of laser light of short pulse duration or short coherence length (Abramson, 1978). Only those parts of the object surface were holographically recorded that corresponded to a small-duration gate.

Fujimoto *et al.* (1986) described the application of femtosecond laser pulses to perform optical ranging using nonlinear cross-correlation gating. The laser pulses are focused onto the sample under study, and the remitted reflections and echoes are measured by nonlinear-optical cross correlation with the incident pulse. The experimental setup (Fig. 1) uses pulses of 65 fs duration at a repetition rate of 125 MHz, laser wavelength 625 nm, and an average power of up to 20 mW. The laser pulses are focused onto the sample under study, and the remitted reflections and echoes are measured by nonlinear-optical cross correlation with the incident pulse. The reference pulse travels through an optical delay line controlled by a stepping motor. The signal and reference are correlated by focusing with a crossed-beam geometry into a 0.5-mm length of angle-phase-matched potassium dihydrogen phosphate (KDP) second-harmonic crystal. Measurement of the integrated second-harmonic energy as a function of the temporal delay between the signal and the reference yields the cross correlation. Spatial resolutions of less than 15 μm was achieved. An example of signals is shown in Fig. 2.

CW Phase Difference Mode

CW modulated signals

In a phase-shift rangefinder, the optical power is modulated with a constant frequency. After reflection from the target, a photodetector collects a part of the laser beam. Measurement of the distance D is deduced from the phase shift $\Delta(\varphi)$ between the

received and modulated emitted signal: $D = (cF/2)((\varphi)/2\pi)$. The unambiguous distance measurement is limited to $(\varphi) = 2\pi$. This principle is often used with conversion of the modulation frequency to a lower intermediate frequency (Amann *et al.*, 2001; Hu *et al.*, 2011).

In the example of Fig. 3, the laser beam is modulated by a sine voltage E_r . After the detection and filtering, the voltage E_m is selected. Both voltages E_r and E_m are mixed with the signals E_{lo} from the local oscillator. The phase difference (φ) is measured between the signals E_{ifm} and E_{ifr} from the outputs of the mixers. This phase difference is then recalculated into the distance D . To get the measurement resolution 2 mm, at the measurement range $D = 15$ m and with the modulation frequency 10 MHz, the phase-shift should be measured with the resolution 0.05 degree.

Journet and Poujouly (1998), measured the phase shift at an intermediate frequency of 125 kHz. The emitter was a laser diode with 12 mW average output power, the receiver used an avalanche photodiode. The phase shift was measured by direct counting with more than 10 bits resolution, that provided about 0.4 mm for a 60 cm range without phase ambiguity. A computer controls the range-finder through a specially developed interface.

In a later version, Poujouly and Journet (2000) used a digital phase-locked loop to reduce the phase noise (Staszewski and Balsara, 2005). They also described the technique based on under-sampling, applied to digital synchronous detection. Its main advantage is a global simplification of the electronic system, leading to a quite simple development of a twofold

modulation system. This new technique is also very interesting to move toward a kind of smart rangefinder able to adapt different parameters to the different steps of the measurement.

Journet and Lourme (2000) proposed to measure the correlation between the transmitted and the received modulation signals this type of modification is not restricted by the sine modulation, because the distance is determined by the delay of the reference signal, at which the correlation has maximum.

Sugimoto *et al.* (2013) proposed to use two sine modulation signals of different frequencies forming a sinc-similar beating signal (Fig. 4), specific points of which are used as references to measure the delay of the received signal relatively to the transmitted signal.

In a wide use in the long-range laser radars (Agishev, 2009), the continuous-wave frequency modulation (CWFM) with a linearly varying frequency is used (Fig. 5), often called chirp modulation due to its similarity to bird's chirping. For this technique,

the frequency difference between the transmitted and received signals is proportional to the time delay and correspondingly, to the measured distance.

Frequency difference techniques

Axial eye length measurement

Sekine *et al.* (1993) described a noncontact technique for axial eye length measurement. According to this method, the wavelength shift of a single-mode laser-diode beam that is irradiated onto the eyeball causes a phase shift in the interference fringes of reflections from the retina and the cornea. Then the optical distance between the cornea and the retina is obtained from the phase-shift measurement.

The schematic arrangement of the optical system is shown in Fig. 6 with the following notations: BS – beam splitter; C – cornea; CL – collimator lens; OA – optical path compensator; OI – optical isolator; R – retina; SF – spatial filter. The light source is a single-mode laser diode (LD). Illumination light coming from the LD is first split to a measuring interferometer and a reference light path. Light that enters the interferometer is again split by a beam splitter and converged separately at the cornea and retina. Reflections from the cornea and retina return to each optical system and interfere with each other. They are then received by a photodetector PD₁. On the other hand, light that enters the reference light path is reflected by mirrors M₁ and M₂, and these reflections cause interference before they are received by photodetector PD₂.

Smoothly varying the light frequency in a given range, the number of phase zeros is calculated in the measuring and in the reference arms (N_m and N_r). It is shown that the eye length L_{eye} can be calculated as $L_{eye} = L_{ref} (N_m/N_r)$, where L_{eye} is the eye axial optical length, $L_{ref} = L_1 - L_2$. $L_{opt} = L_{opt1} - L_{opt2}$ is adjusted to be zero.

Compared to the technique that uses partially coherent light, this technique is inferior in terms of measurement accuracy but superior in its wide, measurable range of 16–32 mm. The results of measurements showed that double standard deviation of measurement was $2\sigma = \pm 0.11$ mm.

Wavelength tuning interferometry

The idea of measuring the distance using the interferometer with changing frequency was implemented by Lexer *et al.* (1997) as the laser wavelength-tuning interferometry of intraocular distances (Fig. 7). The notations are as follows: OS – object signal; RS – reference signal; SP – scattering potential; MI – reference Michelson interferometer; FT – Fourier transform; NC – numerical correction; PD₁, PD₂ – photodetectors; TL – tunable laser. Shifting the wavelength of a tunable laser diode causes intensity oscillations in the interference pattern of light beams remitted from the intraocular structure. A Fourier transform of the photodetector signal yields the distribution of the scattering level along the light beam illuminating the eye (Fig. 8). The authors demonstrated simultaneous measurement of the anterior segment length, the vitreous chamber depth, and the axial eye length in human eyes in vivo with data-acquisition times in the millisecond range.

Dual-beam double frequency configuration

See *et al.* (1985) applied the differential phase-contrast scanning microscope for the surface studies. Molebny *et al.* (1996a,b) described similar configuration to measure the ablation profiles after the Lasik surgeries for the correction of the human vision (Fig. 9). The laser beam having its carrier frequency f_0 is split by the acousto-optical modulator in two components ($f_0 + f_1$) and ($f_0 + f_2$). The frequencies f_1 and f_2 are generated by the driving generator. After being reflected from the specimen, these components are fed to the photodetector whose output is connected to the phase detector. The phase difference $\Delta(\varphi)$ at the frequency $\Delta f = (f_2 - f_1)$ is the measure of the height difference Δh of the surface along the line connecting the beam projections on the surface. To reconstruct the profile, the surface is scanned along the line in the direction of the line connecting

the beam projections (e.g., along the x direction). The next line of scanning is one-step shifted in y -direction. With laser wavelength 630 nm, $f_0 = 80$ MHz and $\Delta f = 1$ MHz, the sensitivity to profile measurement was achieved better than 10 nm. To make the data for the next line of scan more defined, a triple beam configuration was used with beams split in x and y directions (Molebny *et al.*, 1998).

Instead of splitting the frequencies with high-cost acousto-optic modulators (AOMs), a gas laser (Bourdet and Orszag, 1979) or modern two-wavelength laser diodes can be used (Ishii and Onodera, 1991). High relative wavelength stability for large variations in optical path length can be achieved with two or more single-mode lasers locked to a Fabry–Pérot etalon

(de Groot and Kishner, 1991; Gerstner and Tschudi, 1994). A simpler configuration for short path differences can be designed using multimode laser diodes (Rovati *et al.*, 1998; de Groot, 1991).

3D laser microvision

The 3D laser microvision developed by Shimotahira *et al.* (2001) is based on the principle of a step frequency radar. Optically, it is an interferometer that derives the distance having the information of the phase delay of the scattered signal (Fig. 10 with the notations: NBS – non-polarizing beam splitter; AOM – acousto-optic modulator; PZT – piezoelectric transducer). The carrier frequency from the superstructure grating (SSG) laser source is swept stepwise: $f_n = (f_0 + n\Delta f)$. The wavelength of the SSG laser diode is centered at $1.545 \mu\text{m}$. In each frequency step, the following procedure is repeated. The output laser light is split into the probe and reference beams by means of an AOM. The non-refracted beam (the zero-order beam) from the AOM is used as a probe beam, and the refracted beam (the first-order beam) from the AOM whose carrier frequency is shifted from that of the probe beam by the frequency of excitation of the AOM is used as a local oscillator beam. The probe beam reflected from the target is mixed with the reference beam from the AOM in a coherent detector. The heterodyne-detected signal, both amplitude and phase, is stored. After all frequency stepping is completed, the stored data are processed and a 3D image of the target is displayed.

The lateral resolution (x - y plane resolution) depends on the focusing parameters of the objective lens, and it is best only at one focused depth. To remove this difficulty, the synthetic aperture approach is used coming from that of the microwave side-looking airborne radar (SAR) which makes high-resolution maps from scanned microwave echoes. A linear flight path of an airplane is used as a linear scan path of the probing antenna. With the 3D laser microvision, the light scattered from the target is measured while the probe is moving away from the target along a path perpendicular to the surface of the target. Thus the scanned probe collects information about the scatterer and significantly improves the lateral resolution as well as the depth resolution of the 3D laser microvision.

In this instrument, the laser wavelengths cover a range as wide as 30 nm centered at $1.545 \mu\text{m}$ with an output power of 1 mW. A specially developed digital phase meter can measure the phase with an accuracy of 0.03 degree as the time delay between the rising edge of both, returned and reference signals. To obtain 3D information, the probe beam has to be scanned over a 2D surface, 128×128 pix large, and at each location of it, the depth information is probed to construct a 3D image.

Fig. 11 demonstrates the effectiveness of the synthetic aperture method using a target of a micro-strip line array on a Gallium arsenide (GaAs) wafer (a – without the synthetic aperture scanning, b – with the synthetic aperture scanning). The micro-strip lines are shown at the bottom of the figure. The width of each micro-strip line is $15 \mu\text{m}$, the thickness is less than $1 \mu\text{m}$, and the spacing between the adjacent edges of the micro-strip line is $8 \mu\text{m}$. The vertical synthetic aperture was made in the stepwise z direction. Curve *b* in Fig. 11 shows the result of the synthetic aperture scanning. The image clearly separates the edge spacing of the micro-strip lines. Fig. 12 shows a microscope photograph of a tunneling photodiode that is deposited on the GaAs substrate. The overall deposit area is $500 \mu\text{m} \times 500 \mu\text{m}$.

Interferometric Methods

Optical Interferometric Micro-Lidar

Time-of-flight measurement can be combined with interferometry using a Michelson interferometer, where one of the mirrors is replaced by a sample under test (Dresel *et al.*, 1992; Fig. 13 left). A light source with short coherence length is used. The reference

mirror plane and the sample plane are imaged onto a detector. The image of the sample is superimposed with a reference wave. Interference takes place when the light paths from the reference and the sample are equal and only within those speckles that correspond to the surface elements close to the sample plane. These regions are detected and stored, while the reference mirror is scanned along the z axis.

The profile of the sample can be reconstructed by scanning in (x, y) directions. An example of a reconstructed profile is presented in [Fig. 13](#) right.

The first biological application of low-coherence interferometry for the measurement of axial eye length was reported by [Fercher *et al.* \(1988\)](#). Different versions of low-coherence interferometry were developed for noninvasive measurement in

biological tissues. Taking an eye as an object, there will be several positions of the reference mirror along the z axis, where the interference gives maximal signal (Fig. 14 left). They correspond to the cornea, lens, and retina. Scanning in (x, y) directions yields the profiles of these surfaces. Fig. 14, right, shows an example of the structure of the human retina reconstructed from the data of measured intensity of light scattered from the eye bottom, the beam being shifted laterally scan-by-scan.

Optical Low-Coherence Tomography

Time-domain optical low-coherence tomography

This interferometric lidar technique was soon baptized by Huang *et al.* (1991) as the optical coherence tomography (OCT). To be more accurate, it should be named the optical low-coherence tomography. OCT imaging system based on a fiber-optic Michelson interferometer is shown in Fig. 15. The advantage of the fiber optics technology is that the setup is robust and easier in alignment. In the schematic, a Michelson interferometer contains a circulator for dual balanced detection. Dual balanced detection adds the signal from the interference of the sample and reference arms and subtracts excess noise from the light source. The sample/probe arm may be interfaced to a variety of imaging devices.

Early OCT instruments used a low-coherence light source and interferometer with a scanning reference delay arm. This method is known as a traditional or time-domain OCT (TD-OCT). OCT found its first application in ophthalmology for diagnosing ocular diseases such as glaucoma, age-related macular degeneration, and diabetic retinopathy.

Spectral-domain optical low-coherence tomography

Later on, the spectral/Fourier domain OCT (spectral-domain optical low-coherence tomography (SD-OCT)) and the swept source/Fourier domain OCT (SS-OCT) were developed, also termed optical frequency domain imaging (OFDI). The SD-OCT has a powerful sensitivity advantage over the time domain detection, since it measures all of the echoes of light simultaneously. This discovery drove a boom in OCT research and development. The sensitivity is enhanced by 50–100 times, enabling a corresponding increase in imaging speeds. The second type of Fourier domain detection, SS-OCT, uses an interferometer with a narrow-bandwidth, frequency swept light source and detectors which measure the interference output as a function of time. It has the advantage that it does not require a spectrometer and line scan camera. Therefore, it can operate at longer wavelengths where

camera technology is less developed and it can achieve imaging speeds which are much faster than spectral/Fourier domain OCT which is limited by the camera speed. The primary challenge in swept source/Fourier domain OCT is that it requires a high-speed, swept narrow line width light source.

Schematic of a typical spectral domain OCT instrument is presented in Fig. 16. The reference arm has a fixed delay and is not scanned. Interference is detected with a spectrometer and a high-speed, line scan camera. A computer reads the spectrum, rescales it from wavelength to frequency, and Fourier transforms to generate axial scans.

Swept-source optical low-coherence tomography

Schematic of a typical swept source OCT instrument is shown in Fig. 17. It contains a frequency swept light source. The reference arm has a fixed delay and is not scanned. The example shows a sample arm with catheter/endoscope interface and the system is assumed to operate at $1.3\ \mu\text{m}$ wavelengths. This geometry enables dual balanced detection, canceling excess noise in the laser. A portion of the frequency swept light is directed into a Mach-Zehnder interferometer which acts as a periodic frequency filter. This interferometer configuration is more efficient than the classic Michelson interferometer because all of the light is detected. It avoids the spectral resolution and pixel limitations which are inherent in spectrometers and line scan cameras.

Commercial OCT Instruments for Ophthalmology

Fig. 18 shows (from left to right): (1) an early retinal imaging prototype instrument. The OCT system is interfaced with a slit lamp biomicroscope. The OCT beam is scanned using a pair of galvanometer-actuated mirrors. This system was used at the New England Eye Center during the mid-1990s; (2) Zeiss Cirrus spectral OCT – one of the latest, cutting-edge ophthalmic instruments available today; (3) Copernicus REVO spectral OCT.

Color encoding of the OCT data

Display techniques were developed to display OCT data in the form of thickness maps. An early example of a time-domain OCT topographic color-encoded map of retinal thickness is shown in **Fig. 19** left (Hee *et al.*, 1998). An example display of the spectral-domain Zeiss Cirrus instrument is shown in **Fig. 19** right (Mazzarella and Cole, 2015).

Fig. 20 High-speed intravascular C7XR optical coherence tomography (OCT) system (left); vessel visualization (right). *Source:* internet

OCT in Cerebrovascular and Cardiovascular Research

Fig. 20 left demonstrates the C7XR OCT system (Guiagliumi *et al.*, 2016), that was introduced as the first commercially available FD-OCT system for coronary imaging in 2009. **Fig. 20** right shows an example of intravascular OCT imaging (Adler, 2012). The mechanical actuation necessary to sweep the source wavelength is on the nanometer scale and therefore is accomplished in a compact MEMS-based packaging.

The C7XR system has a spatial resolution of 15 μm and acquires 500 axial lines per frame at a rate of 100 frames/s. At the tip of the catheter, there is a 125- μm -diameter optical fiber assembly that consists of an integral side-looking lens. The optical assembly is encapsulated in a hollow torque wire that translates motion from a drive motor located outside the patient's body. The C7XR system can volumetrically image a 5-cm vessel segment in approximately 3 s.

The latest generation of this type OCT system, the Ilumien Optis, has a higher image acquisition rate (180 frames/s) and can acquire a 75-mm pullback image in only 2.1 s (see Section Relevant Websites). This system has instant 3D reconstruction capability and is used for optimizing stent planning.

Another OCT system developed at the Massachusetts General Hospital (MGH, Boston, MA) has a high-speed wavelength swept laser that uses a polygon-mirror/grating filter to tune over a broad (120-nm-wide) bandwidth centered at 1320 nm. Its axial resolution is 7 μm , and the ranging depth is 4.6 mm in tissue.

The same MGH academic group constructed an OCT system that uses a very broad bandwidth light source and common-path SD-OCT technology, termed microoptical coherence tomography (μOCT), whose resolution is improved by an order (axial resolution $\leq 1 \mu\text{m}$ and a lateral resolution $\leq 2 \mu\text{m}$ in tissue). It provides clear pictures of cellular and subcellular features (Liu *et al.*, 2012).

The Terumo (Tokyo, Japan) OFDI system uses a 1.3- μm scanning laser as a light source. The imaging range is 5 mm with an axial resolution of less than 20 μm in water.

Multiple Reference OCT for Dermoscopy

Development of the newest modalities of OCT is oriented not only on super-fast techniques or having super-high resolution, but also on making the instrument as cheap as possible. One of the examples is a multiple reference OCT (MR-OCT) system (Hogan and Wilson, 2009; Dsouza *et al.*, 2014). The idea is to use a simple along- z scanner made, for example, of a voice coil actuator (VCA). Similar actuator can be taken from a typical CD/DVD pickup head (Subhash *et al.*, 2015) whose role in the pickup head was to keep the CD/DVD track in focus at the photodetector (**Fig. 21** left).

In a prototype, the depth scanning was achieved by using a miniature recirculating optical delay based on a voice coil motor actuator and a partial mirror. The actuator was extracted from a CD optical pickup head and can provide an A-scan rate of 50–600 Hz with an axial displacement of about 60 μm . The prototype MR-OCT sensor setup (Subhash, 2014) was based on a smartphone platform using the Android operating system (**Fig. 21** right). The notations in **Fig. 21** are as follows: PUH – pickup head, SLD – superluminescent diode, L_1 – L_3 – lenses 1–3, BS – beam splitter, PM – partial mirror, VCA – voice coil actuator, RM – reference mirror, D – distance between PM and RM, S – scan range, TD – total depth scan range. Recirculation is provided by adding the PM in front of the RM at a distance D , recirculating in this way the scan range S several times and extending the TD.

Devices With Photonic Arrays

Focus Tracking Micro-Lidars

For some purposes, critical is not the absolute value of the distance but the deviation from a given value. Typical example is a CD/DVD pickup head whose application in the MR-OCT system was described in the previous paragraph.

Fig. 21 Pickup head with a voice coil actuator (VCA) and the lens (at the left); experimental setup of a multiple reference-optical coherence tomography (MR-OCT) system using the same VCA with the reference mirror instead of the lens. Reproduced from Subhash, H.M., Hogan, J.N., Leahy, M.J., 2015. Multiple reference optical coherence tomography for smartphone applications. SPIE Newsroom. doi:10.1117/2.1201503.005807.

Fig. 22 Pickup head and the principle of focus tracking. Reproduced from Pohlmann, K.C., 2011. Principles of Digital Audio, sixth ed. New York, NY: McGraw-Hill.

A pickup head consists of a transmitting and of a receiving channels (Pohlmann, 2011). The transmitting channel contains a laser diode irradiating the polarized light at an infrared wavelength, a diffraction grating, a polarization beam splitter with a quarter-wave plate, a collimator lens, and an objective lens (Fig. 22). Laser radiation reflected from the CD passes through the objective lens, the collimating lens, the polarization beam splitter, and then is focused by a cylinder lens on the four-quadrant photodetector with four photodetectors A, B, C, and D. The quarter-wave polarization plate converts the linear polarization of the light into the circular one. On the way back, the circular polarization changes the direction of vector rotation, and after the quarter-wave plate, the linear polarization becomes orthogonal to the initial polarization. This conversion enables transporting the light to and from the disk without losses in the beam splitter.

After the cylinder lens, the beam shape at the detector array is either elliptic or circular. The circular shape occurs only if the reflective surface of the specimen is placed exactly at the focal plane of the optical path. The laser beam in this case has a diameter of less than 1 μm . The elliptic shape occurs when the beam reflection takes place out of focus. The orientation and size of the elliptic beam pattern respectively depend on the location and distance from the focal plane. The detector array has four areas,

denoted as A , B , C , and D . They deliver photocurrents, depending on the illuminance integrated over their area, which are subsequently linearly converted into voltages. From these voltages (denoted also as A , B , C , and D) the focus error V_0 can be derived as $V_0 = (A + C) - (B + D)$. When $V_0 = 0$, the laser beam is focused on the disk, if $V_0 > 0$, the disk is too far, and when $V_0 < 0$, the disk is too close. This voltage is applied to the VCA (motor) that adjusts the distance to the position until V_0 equals 0. The mentioned diffraction grating, installed at the exit from the laser, produces a pair of diffracted beams in $+1$ and -1 orders symmetrically situated relatively to the main beam. Projected on the track in the way that the side beams are clinging to the track, one at the left side, another at the right side as shown in Fig. 23.

Besides the four areas A , B , C , and D in the form of quadrants, the photodetector array contains also two additional photodiodes E and F . The filtered difference TR of the signals F and E creates the tracking signal keeping the central laser spot on the track.

Range Imaging With Matricial Light-Emitting Diode Array

Reconstruction of the shape of the surface from the interferometric data has a long history, it was summarized by Creath (1988) with many examples. When a fringe pattern is recorded by a detector array, there is an output of voltages representing the average intensity incident upon the detector element over the integration time. As the relative phase between the object and reference beams is shifted, the intensities measured by point detectors will change.

Some techniques change the phase stepwise by a known amount between intensity measurements (Surrel, 1993), whereas others integrate the intensity while the phase is being shifted (Sasaki and Okazaki, 1986). The first is usually referred to as a phase-stepping technique, and the second as an integrating-bucket technique.

An example implementing the four-bucket algorithm was described by Wang *et al.* (2010). The instrument measures 3D surface profiles and is based on an light-emitting diode (LED) array phase-shift rangefinder (Fig. 24). It employs the fast electronic scanning of a 2D array of LED light sources instead of mechanical scanning, which means no moving or rotating parts are needed in the system. By using high-sensitivity photodiodes (PD) and high-accuracy analog-to-digital converter (ADC) to sample and demodulate the incoming light signal, a high range resolution can be obtained. Fig. 25 illustrates four-bucket principle. A sine wave signal is sampled four times (A_0 , A_1 , A_2 , and A_3) within a modulation period, and each sample point is delayed by a quarter

period of the modulation frequency. From this sampling, based on Nyquist theorem, the phase delay of the signal can be determined and recalculated into the measured distance.

Fig. 26 shows the block diagram of the phase-shift rangefinder using a heterodyne technique. Since the modulated LEDs have temperature drift, two receiving channels are used in the system, of which one serves as a reference channel. The signals from the outputs of two mixers are filtered by band-pass circuits tuned on f_1 with a bandwidth Δf_1 . Then, the two signals are sent to the phasemeter, where the phase measurement is implemented.

The instrument is insensitive to ambient light, since the dc-offset of the received signal is removed. It is no problem to use a large pixel array size and high spatial resolution by utilizing a low-cost close packaged LEDs. The system can be very robust and can be used to perform inexpensive and real-time range scanning for many robotic and industrial automation applications, including those in hazardous environmental conditions. By combining with the mature and low-cost 2D charge-coupled device/complementary metal-oxide semiconductor (CCD/CMOS) imaging technique, it also can achieve real-time, high-quality 3D imaging, which is another important application prospect for this range imaging system. The authors found that the range images can be acquired at a rate of 10 frames/s with a depth resolution better than ± 5 mm in the range of 50–1000 mm.

Time-of-Flight Principle With Matricial Detectors

To get the information in the 3D space, not only the matrices of emitters can be used, but also the matrices of photodetectors as well (Mutto *et al.*, 2012). Such micro-lidar (sensor) may be conceptually interpreted as a set of a multitude of single devices. It does not mean that the matrix of emitters should be manufactured in a single chip with the matrix of receivers. It only means that a single emitter may provide an irradiation that is reflected back by the scene and collected by a multitude of receivers close to each other.

Once the receivers are separated from the emitters, the former can be implemented as CCD/CMOS pixels integrated in a matrix. The lock-in pixels matrix is commonly called time-of-flight (ToF) camera sensor, and, for example, in the case of the MESA

Imaging SR4000 it is made by 176×144 lock-in pixels (see Section Relevant Websites). Such matricial ToF sensor IR emitters are common LEDs and they can be positioned in a configuration mimicking a single emitter co-positioned with the center of the receivers matrix, as shown in Fig. 27. Indeed the sum of all the IR signals emitted by this configuration can be considered as a spherical wave emitted by a single emitter. Fig. 28 shows the actual emitters distribution of the MESA Imaging SR4000.

The operation of a ToF camera as imaging system can be summarized as follows. Each ToF camera sensor pixel, at each period of the modulation sinusoid, collects four samples of the IR signal reflected by the scene. This information is enough to reconstruct the depth values for each pixel and to build the map of distances in the scene. Accurate description of this kind of ToF camera is given by Lange (2000) in his PhD work. Hansard *et al.* (2012) and DAGM Workshop Proceedings (Kolb and Koch, 2009) can be recommended for further reading.

Pattern-Projecting Matricial Sensors

In 2012, the Microsoft Kinect version of the play station was released which included the depth mapping with a light-coded range camera capable to estimate the 3D geometry of the acquired scene at 30 fps with VGA (640×480) spatial resolution (Fig. 29). From the functional point of view, the Kinect range camera is similar to the ToF camera described previously, since they both estimate the 3D geometry of dynamic scenes, are similar also in that they use matricial detectors, but they differ in the principles: the Kinect technology is based on pattern-projection analysis, several patents were issued to PrimeSense (now Apple) (Freedman *et al.*, 2012; Sali and Avraham, 2014; Cohen *et al.*, 2016). Some commenting authors (Mutto *et al.*, 2012) call this technique “matricial active triangulation.” Light patterns can be generated by a light modulator as random distributions of light and dark spots. It can be also a diffraction or speckle pattern. García *et al.* (2008) projected coherent light through ground glass generating

random speckle patterns. The spatially random patterns are seen by the sensor. Low correlation between different patterns is used for both 3D mapping of objects and range finding.

Asus X-tion Pro and X-tion Pro Live (see Section Relevant Websites) are other products with a range camera based on the same chip initially manufactured by PrimeSense. All these range cameras, support an IR video-camera and projecting the IR light coded patterns. In this technology, each pixel needs to be associated to a code-word, i.e., a specific local configuration of the projected pattern. A correspondence estimation algorithm analyzes the received code-words in the acquired images in order to compute the conjugate of each pixel of the projected pattern.

Further modifications of the pattern-projection technology are proposed involving combinations of cameras (Sali and Avraham, 2016), or adding a laser illuminator for TOF range measurement (Devaux *et al.*, 2013; Nehmadi and Guterman, 2016).

Micro-Lidars Measuring the Media Parameters

Nephelometers

The typical lidar configuration is shown in Fig. 30 which is the same for hundred-kilometers space lidars and centimeter- and even micrometer-scale micro-lidars (Lonnqvist, 1999). The angle θ between the direction of the laser beam and the optical axis of the receiver can vary from 0 (or near zero) to 180 degrees. The transmitter and the receiver can use a common optics (monostatic configuration) or, they can use separate optical systems (bistatic configuration). The second one is often preferable to exclude the scatter of the transmitted laser light in the optical system. The volume, from where the information is got, is limited in the first approximation by the section of the laser beam encircled by the receiver's field of view.

Jerlov (1976) considers scattering in the concepts of large-particle optics as the result of three physical phenomena: (1) through the action of the particle, light is deviated from rectilinear propagation (diffraction); (2) light penetrates the particle and emerges with or without one or more internal reflections (refraction); (3) light is reflected externally. The amount of scatter (scatterance β) depends on the angle θ . The function $\beta(\theta)$ is called indicatrix. The indicatrix describes the amount of light that is scattered at every possible combination of angles of incoming and outgoing light (influx and efflux angles). The character of scatter depends on how polydispersed system is. Monodispense sytem has oscillatory β curve. The most striking and distinctive feature of a polydispersed system is the pronounced forward scattering. Fig. 31 represents the function $\beta(\theta)$ of the oceanic water at different depths. It is clearly seen that at small depths the indicatrix has more oblong shape in the forward direction. Deeper oceanic waters are clearer and their indicatrix is nearer to that of the pure water.

Fig. 31 Indicatrices of the oceanic water at different depths (normalized to β at 90 degree). Reproduced from Jerlov, N.G., 1976. *Marine Optics*. Amsterdam: Elsevier.

Fig. 32 TSI 3563 nephelometer with additional temperature, humidity, and pressure sensors. Reproduced from Mizrahi, A., Russell, L., Three wavelength integrating nephelometer. Available at: https://www.esrl.noaa.gov/gmd/aero/instrumentation/neph_desc.html.

The instrument for measurement of scatterance (scatterance meter) is called nephelometer. Jerlov (1976) described the nephelometer for measurement of the function $\beta(\theta)$. Angular dependence of scatterance is not always required. In some case, it is enough to have only value of scatter at a certain angle, for example, for turbidity measurement (Mitchell, 2010). For pollution measurement, or for determination of the complex refractive indices of aerosol, use only an integrated value of scatter (Han et al., 2009). At the same time, additional information can be derived when measuring the scatter at different wavelength (Anderson et al., 1996). The three-wavelength model TSI 3563 (Fig. 32) splits the scattered light into red (700 nm), green (550 nm), and blue (450 nm) wavelengths. The TSI nephelometer measures back-scattered light at these wavelengths as well. The one wavelength Radiance Research nephelometer measures forward scattering at 550 nm only.

The main body of the TSI 3563 nephelometer is a 10-cm-diameter aluminum tube, 90 cm long (Mizrahi and Russell). Along the axis is an 8-cm-diameter tube set with aperture plates. The plates range from 7 to 170 degrees on the horizontal range of the lamp. The backscatter shutter allows blocking of the angles from 7 to 90 degrees so that only backscattering is measured. The light trap provides a dark reference against which to measure the scattered light.

The receiving optics is located on the other side of the tube from the trap. The light that passes through the lens is separated by dichroic filters into three wavelengths. The first is a color splitter that passes 500–800 nm light and reflects 400–500 nm light. The reflected light passes through a filter centered at 450 nm (blue) into a photomultiplier tube (PMT). The light that passes through the first splitter goes to a second splitter which passes 500–600 nm light and reflects 600–800 nm light. The reflected light passes through a filter centered at 700 nm (red) into a second PMT. The light that passes through both splitters passes through a filter centered at 550 nm (green) into a third PMT. For further reading we recommend the review of integrating nephelometers of Heintzenberg and Charlson (1996).

Smoke Detectors

Lidar principles are widely used in office and home appliances. A smoke detector is an example. Dohl (2015) patented the smoke detector with a plurality of light emitting devices of different wavelengths and with another plurality of scattered light receiving sections. Fig. 33 demonstrates the design of the smoke detector with one such section in which the optical axes of light emitting diode and of photodetector meet in the scattering volume outside the detector. There can be several LEDs in one transmitting position (Fig. 34), for example, blue and infrared. Such coupling of the light wavelengths enables the differentiation of the type of the smoke: if the signal is higher in the longer wavelength channel, the device decides that the larger particles are contained in the smoke, and vice versa: if the signal is higher in the shorter wavelength channel, the instrument decides on the prevailing number of smaller particles. Positioning the receivers at different angles relatively to the optical axis of the light emitting channel can give the information on the complexity of the scattering particles: in the suggestion that the smoke particles have more complicated shape than the particles of the vapor, the device can suggest whether the scattering particles are of the smoke origin or, they are the water vaporization particles.

Flow Cytometry

When analyzing the smoke detector, we noted that the complexity of particle shape results in higher scatter in the lateral direction relatively to the laser beam. This feature of particle scatter is used in flow cytometry that is performed on particles in suspension (e.g., cells or nuclei). The cell suspension is injected into a flow chamber of the fluidic system, where cells are forced into single file and directed into the path of a laser beam (Craig, 2014). Laser light is focused on these single particles/cells and can be measured

Fig. 33 One channel of the smoke detector. Reproduced from Dohl, M., 2015. Smoke Detector. US Patent 8,941,505. January 27, 2015.

Fig. 34 Two-channel positioning in the multichannel smoke detector. Reproduced from Dohl, M., 2015. Smoke Detector. US Patent 8,941,505. January 27, 2015.

by photodetectors as it is scattered off particles/cells when they pass in front of the beam. Fig. 35 demonstrates the principle of the Sysmex XT-2000i and XT-1800i Automated Hematology Analyzers.

When the laser beam interacts with a single particle/cell, light is scattered but its wavelength is not altered (elastic scattering). The amount of scattered light can be used to identify the particle/cell because it is related to the physical properties of the particle (size, granularity, and nuclear complexity). Light scattered at a 90 degree angle (side light scatter) is related to the internal complexity and granularity of the particle/cell. Neutrophils produce much side scatter because of their numerous cytoplasmic granules. Light that proceeds in a forward direction (forward light scatter) is related to the particle size. Large cells produce more forward scatter than small cells. As illustrated in Fig. 36, differences in light scattering are used to distinguish the particles: the

Fig. 35 Configuration of the Sysmex XT-2000i and XT-1800i automated hematology analyzers. Reproduced from Craig, F.E., 2014. Flow cytometry. In: McKenzie, S.B. (Ed.), *Clinical Laboratory Hematology*, second ed. Essex: Pearson, pp. 956–974.

Fig. 36 Distinguishing the particles. Reproduced from Craig, F.E., 2014. Flow cytometry. In: McKenzie, S.B. (Ed.), *Clinical Laboratory Hematology*, second ed. Essex: Pearson, pp. 956–974.

lymphocytes as the smallest ones are in the low side-signal domain, and the neutrophils, being the biggest ones having the most complicated shape are in the high side-signal domain.

In addition to elastic light scattering, flow cytometers are used to detect bound fluorescent markers (fluorochromes), which are molecules that are excited by light of one wavelength and emit light of a different wavelength (fluorescent light). Fluorochromes can label the antibodies or specific changes in DNA or RNA (**Figs. 37** and **38**). Flow cytometers use light of a single wavelength generated by a laser to excite fluorochromes bound to the particle of interest. Light emitted from the fluorochrome is separated from the incident laser light using a combination of filters and mirrors. A PMT then detects and quantifies the emitted light.

Clinical flow cytometers usually contain an argon laser that generates light at 488 nm. This single wavelength is often used to excite three different fluorochromes, each emitting light at different wavelengths. Using three different fluorochromes allows detection of three different antigens on the cell. Excitation of additional fluorochromes to detect further antigens usually requires a second laser light source (e.g., helium neon, emission 633 nm). Two laser light sources allow to identify up to six antigens on each cell analyzed.

Raman Micro-Lidars

In an inelastic scattering of a photon, some of its energy is lost or increased. Correspondingly, the frequency of the photon is shifted to red or blue. A red shift means that part of the photon energy is transferred to the interacting matter (Stokes Raman scattering). In the blue shift, internal energy of the matter is transferred to the photon (anti-Stokes Raman scattering). Detecting the Stokes or anti-Stokes lines in the scattered spectrum is related to the spectroscopy. Still, in practice, when applied to the techniques of studying the properties of atmosphere, the terms “lidar,” “Raman lidar” are used. When coming to the microworld, we may use the term “Raman micro-lidar.” Detecting the inelastic scattering and its usage for measuring the parameters of the medium has a wide field of applications. We recommend for further reading the book edited by [Baudalet \(2013\)](#).

The role of the Raman micro-lidar is to make an “optical biopsy,” i.e., to diagnose disease such as cancer and atherosclerosis without removing tissue from the body in the way by revealing the differences between cancerous and normal tissues of various organs due to morphological and molecular changes in the tissue. We shall refer here to key optical methods of Raman inelastic

backscattering reflectance and time-resolved spectroscopy. Various human tissue types (prostate, breast, lung, colon, and gastrointestinal) have been studied using optical biopsy (Jelínková, 2013).

The first work on using the Raman scattering to detect cancer was published by Alfano *et al.* (1991). Alfano and Pu (2013) summarized the achievements in the mentioned book of Jelínková. The peak height ratios for Raman data analysis were able to differentiate normal tissue and malignant tumor in breast, gynecological, and cervical tissue. These basis spectra represent the epithelial cell cytoplasm, cell nucleus, fat, β -carotene, collagen, calcium hydroxyapatite, calcium oxalate dihydrate, cholesterol-like lipid deposits, and water.

Motz *et al.* (2004) and Haka *et al.* (2006), both from MIT, developed an optical fiber Raman probe and collected Raman spectra of breast tissue. Their portable Raman system with optical fiber probe is schematically shown in Figs. 39 and 40. An 830-nm-diode laser is focused into the excitation fiber of the Raman probe through a bandpass filter. Consisting of a single central excitation fiber

Fig. 40 Schematic of the Raman spectroscopy system used for experimental testing of the Raman probe tip. Reproduced from Haka, A.S., Volynskaya, Z., Gardecki, J.A., *et al.*, 2006. In vivo margin assessment during partial mastectomy breast surgery using Raman spectroscopy. *Cancer Research* 66 (6), 3317–3322.

surrounded by 15 collection fibers of 200 μm core diameter, the diameter of the probe is less than 2 mm. The linear array of collection fibers at the proximal end is coupled to a spectrograph.

Light delivery and collection can be accomplished by using optical fibers that can be incorporated into a biopsy needle (Haka *et al.*, 2005). As opposed to biopsy, a spectroscopic needle measurement has the advantage of providing immediate diagnosis. With the development of minimally invasive breast cancer therapies, such as radiofrequency ablation (Fornage *et al.*, 2004), there is the potential for diagnosis and treatment to be performed in a single procedure.

Working on even less invasive instrument, Komachi *et al.* (2005, 2009) designed a micro-Raman probe with a 600 μm diameter, that can be inserted into coronary arteries. Custom-made filters attached to the front end of a probe eliminate the background Raman signals of the optical fiber itself. Measurement of the Raman spectra of an atherosclerotic lesion of a rabbit artery in vitro demonstrated its excellent performance.

Further studies resulted in a Raman spectroscopy technique to simultaneously identify micro-calcification status and to diagnose the underlying breast lesion, in real time, during stereotactic core needle biopsy procedures (Barman *et al.*, 2013). An approach was introduced based on diffuse reflectance spectroscopy for detection of micro-calcifications that focuses on variations in optical absorption stemming from the calcified clusters and the associated cross-linking molecules. A new powerful decision algorithm was derived from correlating the diffuse reflectance spectra with the corresponding radiographic and histologic assessment.

Time-Resolved Fluorescence Spectroscopy

Fluorescence spectroscopy is one of the optical techniques used to investigate biomolecules whose photoexcited emission is characterized by spectral distribution, photon yield, lifetime of the excited state, as well as polarization. The first measurements were all performed by methods that involved the human eye. Significant advances in instrumentation, particularly in regard to time-resolved measurements, were achieved with the advent of lasers. Time-resolved fluorescence spectroscopy derived short-pulse lidar principles and can provide information on not only the location and intensity of the key biomolecules but also their local biophysical microenvironments (Alfano and Pu, 2013). It also provides temporal information on the underlying dynamics of molecular processes concerning the chromophores and the environment responsible for the fluorescence in tissues. Picosecond techniques enable the study of dynamics of relaxation in macromolecules.

The experimental arrangement for the time-resolved fluorescence measurements of the human breast tissues is schematically shown in Fig. 41. Ultrafast laser pulses of 100 fs duration, 0.1 nJ per pulse, at 620 ± 7 nm from a colliding pulse mode-locked dye laser system at a repetition rate of 82 MHz is used to pump the samples. These laser pulses are amplified and their frequency is doubled in KDP crystal resulting in 310 nm wavelength. The resulting fluorescence emission is collected and directed onto the slit of a synchro-scan streak camera with a temporal resolution of 16 ps. A narrow band filter of 340 ± 5 nm is used to collect the tissue fluorescence and a 310 nm notch filter – to cut off the excitation wavelength. The recorded temporal profiles are analyzed to obtain temporal and polarization information.

Typical time-resolved fluorescence profiles excited by 310 nm from malignant tumor and from normal tissue at 340 nm emission band are shown in the inset of Fig. 41. There is a marked difference between the curve profiles of malignant and

Fig. 41 Time-resolved fluorescence experimental setup and fluorescence profiles with 310 nm excitation and 340 nm emission: malignant tumor (red), normal breast tissue (blue). Fig. 42 Absorptivity of oxygenated and deoxygenated hemoglobin. Reproduced from Delori, F.C., 1988. Noninvasive techniques for oximetry of blood in retinal vessels. *Applied Optics* 27, 1113–1125.

nonmalignant sample. All temporal curves are analyzed to compare the slow and fast components of fluorescence decay. Also, the amplitude ratios of fast to slow components are analyzed to find the differences.

Oxymetry Lidars

The degree of blood oxygen saturation is one of the diagnostic parameters. Different absorptivity of light propagating in the blood with oxygenated and deoxygenated hemoglobin depending on the light wavelength (Fig. 42) is the basis for pulse oximetry. The technique of pulse oximetry using the cost-effective and patient-friendly sources of light is described in the book of Moyle (2002).

The oxygen supply of the retina is no less important for the human vision. The supply is provided by both the choroidal and retinal circulation. The choroid serves as the oxygen source for the photoreceptors in the avascular outer retina, whereas the retinal circulation plays a critical role, mediated by its autoregulatory capacity, in maintaining the oxygen supply to the neural elements and nerve fibers in the inner retina. Because of the high oxygen needs of the retina (cerebral tissue), any alteration in circulation such as seen in diabetic retinopathy or vascular occlusive diseases results in functional impairment and extensive retinal tissue damage.

Measuring oxygenation of blood could help to assess the circulatory and respiratory condition of patients. The retina is highly metabolically active tissue and information on retinal and choroidal oxygenation would give vital clinical information on the metabolic state of the retina, which may improve the understanding of retinal metabolism in health and disease. Malfunction of the retinal vasculature can result in serious eye diseases, which can affect vision considerably, for example, central retinal arterial occlusion or central retinal vein occlusion.

But how to get information on oxygenation of blood vessels from the bottom of the eye? The principle of pulse oximetry cannot be applied directly since it operates in the transmissive mode. Hickham *et al.* (1963) proposed to measure blood oxygenation in retinal vessels crossing the optic disk by using a two-wavelength (510 nm and 640 nm) photographic technique. This was the first time the oxygenation of the human retina was measured noninvasively, and following these studies many techniques have been developed. Laing *et al.* (1975) modified the instrument having used two other wavelengths (470 nm and 515 nm).

These methods involved laborious microdensitometric analysis of photographic negatives obtained under controlled conditions. To take into account the light scattered by the red blood cells (RBCs) in whole blood, the introduction of a calibration procedure was needed. To overcome the problem, Pittman and Duling (1975) introduced three closely spaced wavelengths. The contribution of scattering to the optical density at each wavelength was determined from optical density values at two isosbestic wavelengths (546 and 520 nm) and the optical density at the third wavelength (555 nm).

Delori *et al.* (1983) implemented this idea using a fundus camera adding there a photoelectric system with control and processing electronics (Fig. 43). Actually, it was the transformation of the fundus camera into a micro-lidar (Delori, 1988).

Most of the knowledge on retinal oxygenation comes from animal studies. Hardarson (2012) describes in his PhD thesis the retinal oximeter Oxymap designed at the University of Iceland which is based on a fundus camera to which an image splitter is attached to simultaneously capture four images of the same area of the fundus (Fig. 44). The images are captured at 542 nm, 558 nm, 586 nm, and 605 nm. All analyses were performed with the 586 nm (isosbestic) and the 605 nm (non-isosbestic) images. The 542 nm and 558 nm images were not used. Discarding of 542 nm and 558 nm was based on earlier testing, which revealed that optical density ratios, using these wavelengths gave less reliable results.

Fig. 44 Retinal oximeter on the platform of Canon CR 6-45NM. Reproduced from Hardarson, S.H., 2012. Retinal oximetry. PhD Thesis, University of Iceland, Reykjavik.

Kristjansdottir (2014) described the Oxymap T1 instrument developed at the University of Iceland (Fig. 45 left) based on the Topcon TRC-50DX mydriatic retinal camera. Two highly sensitive digital cameras, image splitter, optical adapter, and light filters are added. A fundus image captured by camera is split into two by the image splitter. One camera captures the image at 570 nm while the other captures the same area of the fundus simultaneously, at 600 nm (Fig. 46). This is done by inserting two narrow 5 nm band pass filters into the light path to each camera of the oximeter. Another light filter (80 nm band pass filter, 585 nm

Fig. 45 Two variants of redesigning the Topcon TRC-50DX mydriatic retinal camera: left – (Kristjansdottir, 2014); right – white light was emitted by the standard 100W bulb (B), which was filtered to select a single wavelength of light by an optical filter. center wavelength) is also inserted into the fundus camera itself to exclude unnecessary light exposure to subjects' eyes, only allowing light between 545 and 625 nm to exit the camera lens.

A specialized software, Oxymap Analyzer, was developed for calculation of blood vessel oxygen saturation. It analyses two spectral images (570 and 600 nm, the isosbestic is 570 nm wavelength), automatically detects blood vessels, selects measurement points and measures the brightness on vessels at each wavelength. From their ratio, the optical density is calculated. Examples of oxygenation maps of healthy eye and the eye with central retinal vein occlusion are given in Fig. 47. A clear difference is seen in venular oxygen saturation (red color indicates 100% and violet indicates 0% oxygen saturation).

Another approach was introduced by Holm (2014). He also used the Topcon TRC-50DX mydriatic retinal camera (Fig. 45 right) but modified the processing just subtracting one image from another. He developed the intensity-based algorithm using the approach of Saleh and Eswaran (2012) aimed at reducing background variations within the images to improve the contrast between the retinal vasculature and the background tissue, and to reduce the amount of segmentation noise. In the intensity-based algorithm only the green channel is used since it has the maximal contrast of the vasculature. The weighted sum of all three color-channels is used for Gabor filtering. A review of recent achievements in the field of oxymetry is given in the publication of Li *et al.* (2015).

Glucose Lidars

A wide range of optical technologies have been designed in attempts to develop robust noninvasive methods for glucose sensing in biological fluids, especially in human blood (Tuchin, 2009). The methods include infrared absorption; near-infrared scattering; Raman, fluorescent, and thermal gradient spectroscopies; as well as polarimetric, polarization heterodyning, photonic crystal, optoacoustic, optothermal, and OCT techniques. None of them is in a wide clinical use. We shall restrict our interest with two of them that could be easier qualified as lidar techniques.

Differential absorption glucose content measurement

Zhou *et al.* (2011) presented a method of glucose concentration detection in the anterior chamber with a differential absorption optical low-coherence interferometry technique. The anterior chamber is located between the cornea and the lens, with the thickness of 3.13 ± 0.50 mm. It is filled with transparent liquid-aqueous humor, with a total volume about 250 μ L. In the experiments, the cornea and aqueous humor can be treated as nearly non-scattering substance. The difference in the absorption coefficient is much larger than the difference in the scattering coefficient, thus the influence of scattering can be neglected. The light directed on the iris being back-reflected passes the anterior chamber twice (Fig. 48).

Two light sources, one centered within (1625 nm) and the other centered outside (1310 nm) the glucose absorption band, are used for differential absorption measurement. Schematic diagram of the differential absorption system is shown in Fig. 49. The notations are as follows: FC – fiber coupler; OF – optical filter; WDM₁ – wavelength division multiplexer; WDM₂ – wavelength demultiplexer; M – vibrating mirror; L – lens. The light emerging from the eye carries the information of glucose concentration.

In the eye model and pig eye experiments, the authors obtained a resolution glucose level of 26.8 mg/dL and 69.6 mg/dL, respectively. This method has a potential application for noninvasive detection of glucose concentration in aqueous humor, which is related to the glucose concentration in blood.

Polarization-based glucose content measurement

Malik and Cote (2010) described their experiments with the idea to use the polarization parameters of anterior chamber aqueous humor to measure the glucose content. Glucose sensing using optical polarimetry is based on the phenomenon of optical activity,

which is the rotation of the orientation of plane polarized light passing through a solution of optically active molecules. The idea of the experiment was to measure the polarization parameters of the light that has passed through the cornea across the anterior chamber of the eye (inset of Fig. 50). The light has to be incident at a relatively glancing angle with respect to the posterior corneal surface in order for the beam to exit the anterior chamber through the cornea.

The problem, the authors met, is the birefringence of the cornea. In polarimetric glucose sensing through the anterior chamber of the eye, this corneal birefringence masks the optical rotation due to glucose in the aqueous humor, and therefore acts as a noise source. When the cornea moves due to eye motion, its birefringence changes the polarization of the light and this is a significant source of polarization noise. In addition, the index mismatch between the cornea and air causes the light beam to bend as it propagates and this complicates the ability to couple the light across the anterior chamber of the eye. It was demonstrated that change in the polarization vector due to corneal birefringence is at least an order of magnitude larger than that due to the change in optical path length and glucose concentration.

In his PhD work Malik (2011) made an effort to understand whether corneal birefringence is wavelength independent. This is important to know since the assumption is that by using multiple wavelengths this noise source may be canceled out. He designed a prototype and used two wavelengths: 635 nm and 532 nm. Experimental setup of the dual-wavelength optical polarimeter is presented in Fig. 50. The notations are as follows: P – polarizer; FC – Faraday compensator; BS – beam splitter; FM – Faraday modulator; PD – photodetector; LIA – lock-in amplifiers. The conclusion of this study was that using a dual-wavelength polarimetric approach has a potential to minimize the corneal birefringence noise and thus quantify blood glucose concentration.

Micro-Lidars for Velocity Measurement

Laser Velocimetry

Velocity measurement was another option that was tried as one of the first applications for lasers as transmitters in laser radars. The earliest publication was made by Yeh and Cummins (1964) from Columbia University who used a microscale lidar to study flow patterns in fluids by injecting dyes into the flow stream, illuminating the stream with monochromatic laser light, and measuring

the Doppler shifts in the Rayleigh scattered light. Twelve years later, the so-called “laser dual beam method” was patented (Schodl, 1976), according to which, two adjacent remote focal points are formed, where the light beams are focused. The particles in the gas stream passing through the focal points reflect light, generating start and stop pulses in the detectors, their time difference being used to calculate the velocity of the stream. Rotating the plane of the pair of the beams, the velocity can be determined in two dimensions. The first of these methods that measured the radial component of the velocity required monochromatic light, whereas the second one measuring the transversal components of the velocity is not limited by the degree of the coherence of light.

Analyzing different approaches to modeling and classification of the methods of velocity measurement, Molebny (1981) paid attention that the model of any of the known methods can be designed to include a field of readout points or readout strips, which would serve as references to measure the velocity. The readout points can be created by focusing the beams of light in adjacent points of space, or creating interference strips in the volume under study. These readout points can be immovable, fixed in space, like in the second of the above mentioned methods, or they can move (run), like in the field of interference of two beams of light with differing wavelengths. The interference can take place in the volume under study, or in the detector plane. Following this classification, we can get the information on the velocity from the field of fixed points, or from the field of moving points.

Fig. 51 left (a) and (c) illustrates the principle of measuring the velocity when the scattering particle crosses two zones. In the case (a) they are the zones (strips) illuminated by light, and the receiver sees both of them. In the case (b) the zones are created by

the fields of view of the receivers. For a single scattering particle, the interval Δt is measured. For multiple particles, the correlation interval Δt is measured.

Fig. 51 right (c) and (d) illustrates multiple zones created by a spatial grating at the transmitter side (a) or at the receiver side (b). In both cases the frequency is measured that is created by bursts of scattered light when the moving particle crosses the illuminated zone.

The book summarizing the first decade of intensive studies of the new instrument – laser Doppler Anemometer (LDA) was published by Durst *et al.* in 1976, its second edition appeared in 1981 (Durst *et al.*, 1981). For further reading we recommend later publications of Albrecht *et al.* (2003), Zhang (2010), and specifically for ocular blood flow – the book of Schmetterer and Kiel (2012).

Blood flow measurement in retinal vessels

Successful application of laser velocimetry for flow measurements was described with application to blood vessels. The feasibility of using laser Doppler velocimetry (LDV) to measure blood flow in individual retinal vessels was first demonstrated by Riva *et al.* (1972), patented later (Riva, 1979). In accordance to the patent, the laser beam was directed into the eye (Fig. 52), the light scattered from the retina was received by the detector. After the detector, the signal was amplified, a loudspeaker was used as a measuring device. The type recorder and other devices was also foreseen for analysis. The laser light scattered from the retina contained the components scattered by RBCs flowing in the retinal vessels and the light scattered from the walls of the vessels and other structures that did not move (Fig. 53). At the output of the detector, the difference frequency was filtered and amplified. It was the Doppler-shift frequency spectrum that was further analyzed. In the experiments, the blood flow in a retinal artery of an anesthetized rabbit was studied. The maximum Doppler frequency shift arising from the light scattered by the RBCs flowing at the maximum speed was estimated from the spectrum and from the intraocular scattering geometry.

Fig. 52 Schematic of laser Doppler velocimeter patented by Riva in 1979. Reproduced from Riva, C.E., 1979. Blood Flow Measurement. US Patent 4,142,796. March 6, 1979.

Fig. 53 Light scattered from moving (violet) and nonmoving (green) structures creating the Doppler-shift frequency spectrum. Source: Internet

Two-directional velocity measurement

Several years later, a new approach for determining blood velocity was proposed (Riva *et al.*, 1979, 1983). The procedure involves collecting the light scattered by the RBCs in two distinct directions separated by a known angle. Subsequent analysis yields an absolute measure of the velocity that is independent of the exact orientation of the vessel and of the relative angular orientation of the incident and scattered light beams with respect to the flow direction.

Velocity Measurement With Optical Doppler Tomography

Conventional LDV found its application to measure mean blood perfusion in the peripheral microcirculation. However, strong optical scattering in biological tissue limits the spatial resolution of flow measurements by LDV. Chen *et al.* (1997) described the OCT technique that provides not only in vivo blood flow measurement at discrete locations but also the tissue structure surrounding the vessel. Blood flow in a vein is imaged in Fig. 54, displaying a color-coded velocity image, and a velocity profile along the vein cross-section. The magnitude of blood flow velocity is maximal at the vessel center and decreases monotonically toward the peripheral wall. In a horizontal cross-section of the velocity image near the vessel center, an excellent fit of the velocity profile to a parabolic function indicates that blood flow in the vein is laminar.

Time dimension in velocity measurement

Ma *et al.* (2010) introduced a novel method to measure absolute blood flow velocity in vivo. It measures the velocities of blood plasma across the heart outflow tract. In experiments involving a chicken, the authors acquired four-dimensional (4D) $[(x, y, z) + t]$ images of absolute velocity distributions of the blood plasma with high spatial and temporal resolution in vivo. They reconstructed 4D microstructural images and obtained the orientation of the heart outflow tract at its maximum expansion. Assuming flow is parallel to the vessel orientation, the obtained centerline indicated the flow direction. Using this method, the flow velocity profiles were compared at various positions along the heart outflow tract of the chicken embryo.

OCT capillary velocimetry

OCT found its applications also in cardiovascular diagnostics and studies of cranial vascularization, etc. To demonstrate applications of OCT capillary velocimetry in cerebrovascular research, a 1310 nm spectral/Fourier domain OCT microscope was used for in vivo imaging of the rat cortex (Srinivasan *et al.*, 2012). The light source consisted of two SLDs yielding a spectral bandwidth of 170 nm. The axial (depth) and transverse resolution was 3.6 μm in tissue, full-width-at-half-maximum, and the imaging speed was 47,000 axial scans per second (17.3 μs exposure time), achieved by an In GaAs line scan camera. Capillary velocimetry and its imaging was performed during a hypercapnic challenge in a rat. An example of such imaging is given in Fig. 55.

Speckle contrast tomography

A novel tomographic method based on laser speckle contrast was introduced by Varma *et al.* (2014) that allows the reconstruction of a 3D distribution of blood flow in deep tissues. The experimental setup uses a temperature controlled continuous laser diode (785 nm, 90 mW) to probe the sample. A pair of galvo controlled mirrors are used to scan the laser point source. The light source is focused on the bottom of the sample and the produced speckle patterns are imaged from the top with a monochrome scientific CMOS camera, with exposure time 1 ms. The horizontal field of view is about 4 cm, a pixel diameter is 3×10^{-4} cm. The laser was set in every position during 0.5 s to acquire 35 intensity images. An example of a 3D slice plot of the reconstructed flow velocity for original velocity of 3.18 cm/s is shown in Fig. 56.

Triple-beam spectral-domain OCT

The three beam spectral-domain SD-OCT system (Fig. 57) consists of three independent subsystems. The SLD sources are operated at a central wavelength of 840 nm with a bandwidth of 50 nm and coupled into three miniature fiber collimators to reconstruct the 3D velocity vector. The three beams are split into reference and sample beam via a beam splitter. The notations in Fig. 57 are as follows: C – miniature fiber collimator, FC – fiber collimator, L – lens, G – grating, BS – beam splitter, M – mirror, PP – dispersion-compensating prism pairs, NF – neutral density filter, FPT – facet prism telescope, T – telescope, MEMS – two-axis gimbal-less scanning mirror, LS – linear stage, SLD – superluminescent light emitting diode, CAM – line scan camera.

In the sample arm the two-axis gimbal-less MEMS mirror is used which is advantageous compared to a 2D galvo scanner, because both scanning axes are already in the same imaging plane. The MEMS mirror is driven with voltages ranging from 0 to 136 V. Any scan patterns can be realized (linear, raster, circular, and resonant patterns). Maximum optical scan angles of ± 11.5 degree can be achieved.

Fig. 58 displays the 3D velocity profile evaluation in the numbered vessels in the points on the circle. Arrows with numbers show the calculated vessel orientation clockwise relatively to the x axis. Reconstructed velocity profiles for the corresponding vessels around the optical nerve hypoplasia range from 0 to 40 mm/s.

Acoustical Studies and Vibrometry

Laser Doppler vibrometry

Doppler effect is used also to measure vibrations where they can exist. Laser Doppler vibrometry can provide advanced measurements in multiple physiological systems relevant to laboratory and field assessment of human stress and emotion (Tabatabai *et al.*, 2013). It can provide advanced recordings of myocardial and vascular performance, of respiratory efforts and sounds, and of tremor activity. It is responsive to laboratory stressors; muscle vibratory activity can be sensed from multiple muscles, including facial muscles, and the comparison is favorable with electromyography. Laser velocimetry can reliably assess facial muscle activity, associated with emotion and stress at low levels – below the threshold for visible facial deformations.

Wang *et al.* (2011) demonstrated a high-sensitivity pulsed laser vibrometer used to remotely determine the detailed, time-phased mechanical workings of various parts of the human heart. Results reported were validated by electrocardiography and accelerometer readings.

Successive pulse illumination in acoustical studies

In acoustical studies, Degroot (2009) used a method of successive pulse illumination of the investigated field with injected scattering particles (**Fig. 59**). She made videoregistration synchronously with pulse illumination, and measured the shifts of particles in successive frames in different phases of the acoustic process. An example of a 2D distribution of particle velocities is given in **Fig. 60**.

Vibration measurement of the vocal folds

An original technique was developed and used for clinical studies by George *et al.* (2008). To measure vibration dynamics of the vocal folds, they used a high-speed TV camera registration of a laser line projected onto the object in the triangulation mode and calculated the amplitude distribution for each frame (**Fig. 61**). The endoscopic laser projection system stretches a laser line beam in one direction and projects it as a thin laser sheet at an angle onto the surface of the vocal folds. The laser projection channel consists of a semiconductor diode laser and a cylindrical optical system.

Fig. 61 Schematic view of the laser triangulation laryngoscope and color coded 3D vibration pattern of the vocal folds. Reproduced from George, N.A., de Mul, F.F.M., Qiu, Q., Rakhurst, G.R., Schutte, H.K., 2008. New laryngoscope for quantitative high-speed imaging of human vocal folds vibration in the horizontal and vertical direction. Journal of Biomedical Optics 13, 064024.

The laser projection channel is firmly attached to a 90 degree rigid endoscope, which acts as the receiving channel. The optical axes of the two channels are separated by a distance of 9 mm at the tip of the system. Within a normal working distance of 60–70 mm from the tip of the endoscope, the laser line is 18–20 mm long and 0.4 mm wide. A semiconductor laser emits at 653 nm, delivering an effective laser power density of 1.8 mW/mm², keeping below the exposure limit of 2 mW/mm². The red laser is used because it gives minimum absorption and satisfactory reflectance by the tissue in the visible spectral region.

A compact high-speed digital color camera is used for recording the images. It can record images continuously for a maximum of 2 s at the rate of 4000 fps with an image resolution of 256 × 256 pixels. Temporarily stored data in the camera memory is downloaded to the computer for further analysis. Vibration profiles in both horizontal and vertical directions were calibrated and measured with a resolution of ± 50 mm.

Wavefront Sensing Micro-Lidars

In laser weapon, to deliver the maximum density of energy to the target, atmospheric turbulence should be compensated by means of irradiating the target with a wavefront conjugated laser beam (He, 2002). The wavefront distortion is measured by a laser radar that receives the back reflected laser radiation with a matrix of photodetectors and provides the data for conjugation.

A similar need to measure the wavefront aberrations flared up in ophthalmology with the advent of vision correction using the ablation procedure after the successful wavefront corrections made on live human eye by Pallikaris *et al.* (1990), Seiler *et al.* (1990), McDonald *et al.* (1990), and others. Taboada and Archibald (1981) were the first engineers who paid attention to the potential of ultraviolet excimer laser to ablate the corneal epithelium. Trockel *et al.* (1983) used this effect for making the incisions correcting the ametropia.

Liang *et al.* (1994) used the matricial sensor, manufactured in Arizona by Platt, to measure the wave front aberrations in the human eye using the laser light reflected in outward direction from retina. The task to measure the inward, physiologically genuine, wavefront aberrations was discussed between Molebny and Pallikaris in 1995 (Molebny, 2013). The first clinical ray tracing aberrometer was tested on the live human eyes in the hospital of Crete University in 1998.

Hartmann–Shack Ocular Wavefront Sensing

The idea of light projection through “a perforated screen” was described by Hartmann (1904), developed further by Shack and Platt (1971) who replaced the perforated screen with “an array of contiguous lenticular elements.” A complete system designed and fabricated for astronomy was delivered to Cloudcroft, NM in the early 1970s but was never installed, and the facility was decommissioned (Platt and Shack, 2001).

Liang *et al.* (1994) with lenslet array from Platt, and Molebny *et al.* (1996a,b) with home-made holographic Fresnel micro-lenses built their wavefront sensors in which the laser light was projected on the retina, and back reflection captured by video cameras through the multielement optics.

A simplified schematic is shown in Fig. 62. A thin laser beam is directed into the eye, and being reflected from the retina, exits the eye. Usually, the microlenses are arranged in the form of matrix. Each microlens of the lenslet array projects its part of the beam cross-section on the CCD (CMOS, or other type) camera. Computer reconstructs the wavefront, and can calculate any of the derivative parameters of the optical system of the eye. The combination of a set (a matrix) of lenses (a lenslet array) and a 2D photosensitive detector are usually called Hartmann–Shack sensor. The image in the plane of the photosensitive detector is called hartmanngram. The synonyms of Hartmann–Shack sensor are Shack–Hartmann or Hartmann–Platt sensor.

Fig. 62 Principle of measuring the wavefront errors in the eye with Hartmann–Shack sensor. Source: Molebny.

Commercial Hartmann–Shack aberrometers

Let us look at some examples of commercial aberrometers based on Hartmann–Shack wavefront sensing. One of the oldest companies on the market was VISX, later integrated with Abbott medical optics (AMO). iDesign is one of the latest instruments (see Section Relevant Websites). The maximal pupil diameter is 7 mm, the range of measured aberrations from -16 D to $+12$ D of sphere and astigmatism up to 8 D, with the dynamic range for higher order aberrations $8\text{ }\mu\text{m}$ root-mean square (RMS). The number of analyzed points is 1250. The previous WaveScan model captured 240 data points, and had the range of higher order aberrations $1.3\text{ }\mu\text{m}$ RMS. Besides wavefront measurement, the instrument combines functions of corneal topography, autorefractometry, pupillometry, and keratometry. The Hartmann–Shack approach is used in this instrument not only for the wavefront sensing but also to collect information on corneal topography.

Topcon having come later to the market, used a lot of experience from the earlier models of other manufacturers, especially for the interface. Like iDesign machine, Topcon's KR-1W has also five functions: wavefront measurement, corneal topography, autorefractometry, pupillometry, and keratometry (see Section Relevant Websites).

iProfiler (Fig. 63 left) from Carl Zeiss Vision GmbH also keeps the tendency of combining several functions in one instrument: ocular wavefront aberrometer, autorefractometer, corneal topographer, and keratometer (see Section Relevant Websites). Ocular wavefront is reconstructed up to seventh-order Zernike decomposition. The instrument is provided with touch screen. The instrument measures both eyes automatically in approximately 30 s. An example of displayed data with a map of an ocular wavefront errors is shown in Fig. 63 right. The map is color-coded (the scale is shown to the left of the wavefront map).

Wavefront Reconstruction

Presentation of measured wavefront data and the procedure of the wavefront error reconstruction for ophthalmologic applications were described by Southwell (1980), applied by Lane and Tallon (1992).

In general, aberrometers measure the gradient of the wavefront error function or, in other words, the deflection of rays from an un-aberrated direction. From each measured ray or location in the wavefront, the data contain four numbers. The first two are the horizontal (x) and vertical (y) coordinates of the location given. The second two numbers are the measured horizontal and vertical component values of the gradient. When reconstructing, the value of wavefront error should be calculated in each (x, y) point. 2D distribution (a map) of this error can be found as an approximation using the values of wavefront error in each point, or as an interpolation.

Analytically, the approximated surface of the wavefront error contains a set of 2D polynomials that is similar to a stack of multiple layer transparencies. This way of presentation is called a global one because each member of the polynomial is a component describing the whole map, not a part of it. Interpolation describing local specificities (in each zone of the map) is called a zonal presentation.

The approximation based on Zernike polynomial presentation is not the only possibility. Other types of polynomials can be used: Bhatia–Zernike, Fourier, Fourier–Mellin, Taylor, Bessel, Legendre, Didon, Karhunen–Loeve, etc. In most cases, preference is given to Zernike polynomials, because their components, describing the lower-order aberrations, coincide with the conventional ophthalmologic description. When the wavefront error is reconstructed in Zernike polynomials, it can be transformed into the presentation as a Fourier series, and vice versa (Dai, 2006). The same transformation can be done from Zernike to Taylor polynomials, and vice versa. The simplest way of interpolation is linear, just connecting two points. More sophisticated is connecting by a curve, satisfying certain requirements.

Ray Tracing Aberrometry

The first ophthalmology-related publications baptizing the technique as ray tracing were made by Molebny *et al.* (1997) and by Navarro and Losada (1997). The ray tracing technique uses measurement of the position of a thin laser beam projected onto the retina. A beam of light is directed into the eye parallel to the visual axis having passed a two-directional (x, y) acousto-optic deflector and a collimating lens (Fig. 64).

The front focal point of the collimating lens is positioned in the center of scanning C of the acousto-optic deflector. Each entrance point, one at a time, provides its own projection on the retina. The position sensing detector measures the transverse displacement δx , δy of the laser spot on retina. An objective lens is used to optically conjugate the retina and the detector plane.

Commercial iTrace visual function analyzer

Fig. 65 shows a version of iTrace visual function analyzer, one of its functions is the wavefront sensing. A set of entrance points overlaid on the image of the eye is encircled by a green outer contour corresponding to the shape of the pupil, which is reconstructed from the eye image. In the process of beam displacement over the eye aperture, data on the transverse aberration for each point of the beam entrance into the eye are collected. They represent a 2D distribution known as a retinal spot diagram (Fig. 65 right bottom). The instrument uses a narrow (0.30 mm) diode laser beam with the wavelength 785 nm being displaced over the entrance pupil of an eye while kept parallel to the visual axis. To measure the positions of laser spots on retina, x and y linear arrays (each of 512 photodetectors) are used.

In the process of measurement, an image of the pupil is captured, its size and position are automatically measured in each TV frame. The permission on firing the probing radiation is given by the software only when the positions of the pupil and visual axis are within a predetermined correspondence. The data, captured with a position-sensing detector, are processed and transferred to

Fig. 64 Ocular ray tracing with a fast x - y acousto-optic deflector. Source: Molebny.

the computer. The total time of scanning for the entire aperture of the eye is within 100 ms. The duration depends on the number of test points at the eye entrance pupil (from 64 to 256). Acousto-optic deflectors are very fast devices: transition time for switching a position is about 10 μ s, i.e., for 256 points, less than 3 ms is necessary. This is a great advantage of acousto-optics as compared to much slower scanners (no more than 20 points/s), used in the laboratory studies of Navarro and Moreno-Barriuso (1999).

Reconstructed maps and functions

Examples of reconstructed wavefront maps are given in Fig. 66, both in 2D and 3D versions. The acquired data are used also to calculate the derivative parameters of the optical system of the eye like point spread function (PSF) and modulation transfer function (MTF). Examples of the PSF and MTF are given in Fig. 67. The instrument allows both 2D and 3D display of both of them, as well as including in calculations any combination of Zernike modes. Any of these functions can be calculated for any size of the pupil.

Locating the visual axis

To optimally correct refractive errors, the eye must be properly positioned for measurements before and during surgery. Manzanera *et al.* (2015) showed that the optimal positioning is in favor of the visual axis. According to Reinstein (2009), corneal refractive ablations centered on the visual axis result in high quality of vision. Based on three-beam scanning micro-lidar, a technique was proposed to objectively locate the visual axis of the eye (Molebny, 2017) which is defined as the line connecting the point of fixation and the center of the foveola. The laser beam consists of three components (f_0 , $f_0 + F_x$ and $f_0 + F_y$), two of them ($f_0 + F_x$ and $f_0 + F_y$) being shifted along x and y axes relatively to the central one (f_0). The triple-beam is scanned along a closed trajectory (Fig. 68), the difference in depth between two pairs of beams Δh_x and Δh_y is determined in the process of scanning. The center of the foveola is defined as the crossing of steepest inclinations (Fig. 69).

Conclusion

When I started working on this chapter, it seemed to be a short walk across a small section of the big and mature field of laser radars, from which this younger sister section borrowed the principal ideas. The reality brought me to a shoreless ocean of new ideas and new opportunities. Technology solutions in this younger sister field appeared even more sophisticated: think about the clever CD/DVD head-up multiplied in millions of computers and other cutting-edge gadgets. Or recollect the flow cytometry taking the responsibility not only to quantitatively evaluate the number of any kind of cells in the human blood, but also to interrogate the signaling from the most dangerous tumor qualifying cells.

The intelligence of military rangefinders look like a children toy in comparison with the interactive play stations analyzing a huge amount of information and evaluating not only the distances to several players but also their positions and movements. Micro-lidars opened new perspectives in studying the human vision and measuring its parameters that enabled achieving the eagle acuity. Micro-lidars make feasible what could not be done with other means, for example, to objectively locate the visual axis of the eye that can't be anatomically even defined.

OCT whose birthday was just several years ago having achieved the highest level of both, information values and financial costs, is attacked today to have replaced the expensive distance-modulation parts with the cheap voice coils from the CD/DVD head-ups.

Sophisticated play stations are only the introduction to what is the dream of the mankind – to robotics, where the micro-lidars will play an important role of the robotic eyes communicating with the robot's brain.

Acknowledgment

The author thanks Dr. Paul McManamon for his idea to inspire the writing of this chapter.

EDITORS IN CHIEF

Bob D. Guenther received his undergraduate degree from Baylor University and his graduate degrees in Physics from University of Missouri. He has had research experience in condensed matter and optical physics. For 9 years he was active in research management as a Senior Executive in the Army, responsible for the physics research sponsored by the Army. After retiring from the government he held the position of Interim Director of the Free Electron Laser Laboratory and helped establish Duke's Fitzpatrick Center for Photonics and Communication Systems and served as Executive Director of the Center until his retirement. In a continuation of the retirement process, he moved to Applied Quantum Technology and has just retired from that company. He is author of the textbook, *Modern Optics*, second edition. He is now composing an elementary book in optics.

Duncan G. Steel is the Robert J. Hiller Professor of Electrical and Computer Engineering, as well as Professor of Physics and Biophysics. Prior to joining the faculty of the University of Michigan in 1985, he was a senior research scientist at Hughes Aircraft Company at the Hughes Research Laboratories. At the University of Michigan, he was Area Chair and Director of the Optical Sciences Laboratory for 20 years until 2007 when he took over the position of Chair of the Biophysics Research Division during its transition to an academic unit. As an educator and teacher, he has chaired or cochaired over 60 doctoral committees. His research includes coherent optical studies of semiconductors and their application to quantum information. His work also included 30 years of studies on age-related modifications in proteins where he exploited numerous optical techniques including single molecule studies in neurons in his studies on Alzheimer's Disease. He was a Guggenheim Scholar and received the 2010 Isakson Prize from the American Physical Society.

INTRODUCTION

This is the second, updated edition of the *Encyclopedia of Modern Optics*. There are 197 entries, many of them new or updated, reflecting the enormous progress in the optical sciences and technology and the ever-expanding impact since the publication of the first edition. Some of the new topics are:

- Nano-photonics and Plasmonics
- Quantum Optics
- Quantum Information
- Optical Interconnects
- Photonic Crystals and Their Applications
- High Efficiency LED's
- Displays
- Transformation Optics
- Fiber Lasers
- Terahertz
- Multidimensional Spectroscopy
- Organic Optoelectronics
- Gravitational Wave Detectors
- Meta Materials and Plasmonics

Selection of article topics and recruiting authors for those topics in this edition has been the work of the topical editors listed in the prologue. They were able to solicit contributions from internationally recognized leaders in their field.

The entries of the encyclopedia are arranged by subject as best as possible, a task made difficult because the field is now highly interdisciplinary and there are many subjects that have an impact in many different areas. We have added references to other articles so that readers can obtain a deeper understanding of the material or understand how a specific discussion on basic science may impact an application or technology.

RF Coherent Detection on Top of Direct Detection Lidar

Barry L Stann, John F Dammann, Mark M Giza, Brian C Redman, and William C Ruff, Army Research Laboratory, Adelphi, MD, United States

© 2018 Elsevier Ltd. All rights reserved.

Introduction

This article presents research focused on technologies that will lead to low cost, small size, low weight, and low power laser radars (lidar) for applications such as surveillance, and autonomous vehicle navigation. The motivation is to exploit the very high angular and range resolution of lidar and the robust and predictable nature of lidar signatures, which provide true 3-D images that are critical for the aforementioned applications.

The lidar architecture treated here combines the merits of low-cost, rugged, reliable continuous wave (CW) semiconductor lasers and detectors with modern frequency modulation (FM) radar signal processing technology (Stann *et al.*, 1996). In contrast to previous FM/CW lidar concepts, in the architecture to be presented here the FM is applied to a radio-frequency (RF) subcarrier, not the optical carrier. Such an architecture is referred to in this article as incoherent FM/CW lidar. This architecture focuses on the low-altitude, relatively short-range (< 1 km) applications where the adverse effects of weather on propagation are minimal.

Presently there are several approaches to semiconductor laser lidar. A classic technique using CW semiconductor lasers or even light-emitting diodes (LEDs) involves measuring the range-dependent phase shift of a constant frequency RF subcarrier; two or more frequencies may be used to eliminate range ambiguities. An innovative embodiment of this technique was recently described by Anthes *et al.* (1993). Another technique investigated by a number of researchers is to modulate the CW source with a pseudorandom code and to cross-correlate the transmitted and returned waveform to determine range. Lee and Ramaswami (1992) recently described an implementation of this architecture with an added resolution-enhancement technique. The incoherent FM/CW lidar architecture discussed here has advantages over these techniques, especially for the low-cost applications. In the following text we discuss the important system aspects and advantages of the incoherent FM/CW lidar architecture and present a short mathematical analysis of the ranging theory. We then show some of the recent experimental results obtained with a breadboard version of the lidar coupled with a two-axis galvanometer-type beam scanner. This includes images of a truck obtained outdoors with a higher-power, improved version of the lidar. This follows previous work we had reported that included images taken in the laboratory with a preliminary version of the lidar. Following this we discuss an adaptation of the incoherent FM/CW ranging technique to a 32×32 pixel focal plane array (FPA) breadboard lidar. Images collected in the laboratory are shown and discussed (Stann *et al.*, 2004).

Incoherent FM/CW Lidar Architecture

Lidar Block Diagram

This section describes the lidar architecture and discusses some of the engineering issues associated with an actual design. Referring to the block diagram of the lidar (Fig. 1), a trigger circuit initiates the generation of a linear frequency-modulated (chirp) signal, that is, a signal whose frequency increases linearly as a function of time over period T . Other modulation waveforms are appropriate for this architecture; this one is chosen because the signal processing required to form range gates is readily understood, and the processor has low bandwidth, which makes it easy to implement. For the architecture discussed here, the start frequency of the chirp signal is typically in the tens to low hundreds of megahertz and the stop frequency in the hundreds of megahertz. The difference between the start and stop frequencies, ΔF , is chosen to establish the lidar resolution ΔR according to the usual equation from FM radar theory, $\Delta R = c/2\Delta F$, where c is the velocity of light (Stann *et al.*, 2004). Various commercial devices are available for generating the chirp signal. For short-range, high-resolution applications, commercial oscillators using monolithic microwave integrated circuits (MMICs) or hybrid technologies can be used. For long-range, high-resolution applications, precision linear tuning characteristics are required, which means that YIG-tuned oscillators or direct digital frequency synthesis devices are necessary. For applications where precision oscillators are not affordable, but tuning precision is still required, additional hardware may be built into the lidar that continuously measures the chirp-tuning characteristics. With this information, appropriate compensation techniques can be applied that effectively back out the tuning nonlinearities.

The chirp signal is fed into a wideband power amplifier that modulates the current driving a semiconductor laser diode. A circuit between the power amplifier and the laser diode matches the driving impedance of the amplifier to the laser diode impedance over ΔF . This causes the light beam intensity to remain highly modulated over the chirp bandwidth. Presently, commercial GaAlAs laser diodes are sold that have 2-GHz modulation bandwidths and output powers to 4 W. These specifications support designs with range resolutions less than 0.3 m and ranges to the low kilometers if the processing bandwidth is narrow.

The laser diode converts the chirp current waveform into a light waveform where the power is proportional to the driving current. This light is collected by a lens, collimated, and directed through a hole in a mirror toward a target. The transmitted light that is reflected by the target and propagated back to the lidar is reflected by the mirror and collected by a second lens that focuses

Fig. 1 Block diagram of the incoherent FM/CW lidar. Source: SPIE.

the light onto the active region of a photodiode. This optics design is used in our present breadboard; other optics designs are suitable with this lidar architecture. (Not shown in Fig. 1 is a two-axis beam scanner placed in the transmit/receive path of the light to facilitate image formation.)

The photodiode effectively converts the received light into a current proportional to the light power; thus it recovers a current waveform identical to the original modulating waveform, except for a reduction in amplitude and a time delay equal to the propagation time from the lidar to the target and return. Commercial photodiodes, readily available for this purpose, have bandwidths to 2 GHz. Current from the photodiode is converted into a voltage with a wideband amplifier. The output of the amplifier is mixed with an undelayed sample of the transmitted chirp waveform, and the output of the mixer is fed into a low-pass filter to recover an intermediate frequency (IF) signal with mean frequency f_{if} given by

$$f_{if} = \Delta F \frac{\tau}{T} \quad (1)$$

where τ is the round-trip time delay for the transmitted signal. For moving targets there is a Doppler shift that is made small relative to f_{if} by proper selection of T . Eq. (1) follows from standard FM radar ranging theory and can be found in any radar textbook. Using $\tau = 2D/c$, where D is the distance from the sensor to the target, and substituting this expression into Eq. (1) yields

$$f_{if} = 2\Delta F \frac{D}{cT} \quad (2)$$

which shows that the frequency of the IF waveform is directly proportional to the range to the target. It follows that the range to the target can be determined by measurement of the frequency of the IF waveform using the Fourier transform or some other technique.

Unfortunately, this straightforward method to obtain target range is not normally effective because the mixer creates a “self-clutter signal” at its IF port that may be larger than the target signal by several orders of magnitude. The self-clutter signal is usually caused by imperfections in the construction of the mixer that allow a detected portion of the local oscillator (LO) to appear at the IF port. Self-clutter signals can also be generated when a small fraction of the LO power leaks over to the receive port, travels toward the first microwave device in the receive path, and is reflected back toward the mixer. The self-clutter signal is an arbitrarily shaped function that is essentially unchanged over many chirp periods. This fact is employed to subtract the clutter signal from the IF signal.

To achieve this, switch S1 is opened to interrupt the transmission of light to the target, therefore leaving only the self-clutter signal present at the low-pass filter output. Switch S2 is closed, thereby directing the clutter signal into a circuit that samples and stores the waveform. For subsequent chirp periods, S1 is closed and S2 is open. The total IF signal is now sampled and stored and then fed into a stage that subtracts the self-clutter signal on a chirp-by-chirp basis. In the last stage, the discrete Fourier transform (DFT) of the subtracted data is performed to map the received time-domain IF signal into the frequency domain, or equivalently, the range domain to indicate distance to the target. The updating rate of the stored self-clutter signal is based on the rate of change of the self-clutter signal and the degree of cancellation required to meet lidar sensitivity requirements.

Advantages

The presented approach to FM/CW lidar contrasts with the traditional approaches where the optical carrier is frequency-modulated and the optical signal is coherently detected. These approaches require highly coherent lasers to detect targets at substantial ranges. The short coherence length of the CW semiconductor lasers used in such designs preclude target detection beyond a few tens of meters or less (Dieckmann, 1994). Even if the coherence length were significantly increased through the use of an external resonator or other techniques, problems resulting from the required precise alignment of return and LO signals, speckle, and large optical Doppler shifts would remain. For these reasons, the incoherent FM/CW lidar can be much less complex and costly, and yet more rugged and reliable.

The incoherent FM/CW ranging approach is a linear system, that is, any number of target and clutter returns will be separated in the range image if they are physically separated by more than ΔR . This is a very important feature if, for instance, the target is partially obscured by foliage or smoke, as one may often expect on battlefields. The phase measurement scheme of Anthes or the superresolution technique of Lee cannot resolve more than one target at a time in the lidar beam. A pulsed system can resolve multiple targets only if its pulse width is less than $2\Delta R/c$ and its receiver bandwidth is sufficient to fully resolve the return pulse, which degrades the Signal-to-noise ratio (SNR). Practical pulsed systems use much longer pulses and corresponding lower bandwidths, and resort to superresolution techniques such as leading-edge detection based on a threshold set at a constant fraction of the peak of the return (Stann *et al.*, 1995). This achieves a high range measurement precision, but requires a high SNR and still cannot resolve closely spaced multiple targets. Thus a target within a smoke cloud may not be discernible even if the lidar power is sufficient to penetrate the smoke. The incoherent FM/CW approach can resolve targets separated by ΔR without requiring a high SNR and with low signal processor bandwidths.

Another advantage of the incoherent FM/CW approach is inherent in its use of CW diode lasers. Diode lasers are limited in peak power by catastrophic damage mechanisms, and, like other semiconductor devices, provide more average power efficiently when operated CW. Most commercial applications of diode lasers, such as for compact disks, barcode scanners, and communications, are for CW devices. Therefore we may expect these devices to improve in performance and especially cost without any Department of Defense (DoD) investment. Finally, the incoherent FM/CW technique can provide Doppler information commensurate with the mean frequency of the AM that gives target velocity and may aid in target detection in a clutter environment.

Mathematical Analysis

This section presents an idealized mathematical analysis to give the reader insights into the formation of range gates by the incoherent FM/CW lidar and the relationship of system parameters to range resolution. This analysis is also instructive in that it shows that the theory is valid when ΔF is as large as or larger than f_0 as in our case, but unlike the case in radar, where ΔF is much smaller than f_0 . The discussion here treats only the core theory of the lidar and does not include any analysis of the many other signal processing techniques used in FM radar that can also be exploited to handle problems unique to any real lidar application. Some of the common techniques include the use of alternative modulation waveforms (triangle waves, pseudorandom codes, etc.) to simplify the formation of range cells or inhibit the detection of jamming signals or other operating sensors, the application of weighting on the Intermediate-frequency (IF) waveform to reduce range sidelobes, IF amplifier limiting to effectively normalize the range response to any target return amplitude, the addition of gates to inhibit the detection of clutter and aerosols, Doppler detection to determine target velocity, and methods to determine whether a target is approaching or receding.

FM ranging theory

An analysis of FM ranging theory begins with an expression for the frequency of the transmitted chirp waveform

$$f(t) = f_0 + \frac{\Delta F t}{T}, \quad -\frac{T}{2} \leq t \leq \frac{T}{2} \quad (3)$$

where f_0 is the center or carrier frequency of the chirp waveform and t is time. The phase of the transmitted chirp waveform is

$$\phi_x(t) = \int_{-\infty}^t 2\pi \left(f_0 + \frac{\Delta F}{T} t' \right) dt' \quad (4)$$

While the phase of the received signal is

$$\phi_r(t) = \int_{-\infty}^{t-\tau} 2\pi \left(f_0 + \frac{\Delta F}{T} t' \right) dt' \quad (5)$$

The phase difference between the transmitted and the received is

$$\Delta\phi(t) = \phi_x(t) - \phi_r(t) \quad (6)$$

or

$$\Delta\phi(t) = \int_{t-\tau}^t 2\pi \left(f_0 + \frac{\Delta F}{T} t' \right) dt' \quad (7)$$

Performing the integration and inserting the limits yields

$$\Delta\phi(t) = 2\pi\left(f_0 t + \frac{\Delta F}{2T} t^2\right) - 2\pi\left(f_0(t - \tau) + \frac{\Delta F}{2T}(t^2 - 2t\tau + \tau^2)\right) \quad (8)$$

Canceling the terms and dropping the τ^2 term because τ is set much less than T leaves

$$\Delta\phi(t) = 2\pi f_0 \tau + 2\pi \frac{\Delta F}{T} \tau t \quad (9)$$

The mixer and following filtering process yields the IF waveform,

$$V_m(t) = a_r \cos(\Delta\phi(t)) \quad (10)$$

or

$$V_m(t) = a_r \cos\left(2\pi\left(f_0 \tau + \frac{\Delta F}{T} \tau t\right)\right) \quad (11)$$

where a_r represents the amplitude of the received signal after considering all propagation, scattering, detection, and mixing losses and amplifier gains.

An examination of Eq. (11) shows that the IF waveform is a cosine function whose argument contains two terms. The first is recognized as a fixed Doppler phase term that is proportional to the carrier frequency and time delay or distance to the target. The second term is a function of time and contains the frequency of $V_m(t)$, $\left(\frac{\Delta F}{T}\right)\tau$, which is proportional to τ or the distance to the target. A plot of this function (Fig. 2) as a function of the normalized range $\tau\Delta F$ and normalized t illustrates this behavior. Here the dark regions represent the minimum of $V_m(t)$, and the bright regions represent the maximums. The important feature to notice is that the number of periods observed over normalized time or one sweep of the modulation increases proportionally with the normalized range.

From this, it follows that the target distance can be determined simply by measurement of the frequency of $V_m(t)$ over T . The usual method for determining the frequency content of a waveform requires computing the Fourier transform of the waveform

$$F(f) = a_r/T \int_{-\frac{T}{2}}^{\frac{T}{2}} \cos\left(2\pi\left(f_0 \tau + \frac{\Delta F}{T} \tau t\right)\right) e^{-2\pi f t} dt \quad (12)$$

Performing the integration yields

$$F(f) = e^{j2\pi f_0 \tau} \left(\frac{\sin\left(\pi\left(\Delta F \frac{\tau}{T} - f\right)T\right)}{\pi\left(\Delta F \frac{\tau}{T} - f\right)T} \right) + e^{-j2\pi f_0 \tau} \left(\frac{\sin\left(\pi\left(\Delta F \frac{\tau}{T} + f\right)T\right)}{\pi\left(\Delta F \frac{\tau}{T} + f\right)T} \right) \quad (13)$$

where the factor a_r which modifies the entire equation, has been dropped to effectively normalize the amplitude of the lidar response to a target. For a lidar architecture employing the *DFT* to establish range cells, each complex output sample of the transform represents the magnitude and phase of the respective harmonic frequency components of the input waveform that occur

Fig. 2 Intermediate frequency (IF) output waveform as a function of time and normalized range. Source: SPIE.

at integer multiples of $1/T$. This allows f to be replaced in Eq. (13) with n/T , yielding

$$F(n/T) = e^{j2\pi f_0 \tau} \left(\frac{\sin(\pi(\Delta F \tau - n))}{\pi(\Delta F \tau - n)} \right) + e^{-j2\pi f_0 \tau} \left(\frac{\sin(\pi(\Delta F \tau + n))}{\pi(\Delta F \tau + n)} \right) \quad (14)$$

The exponential factors in Eq. (14) represent the Doppler component present in each harmonic line, while the $\sin(x)/x$ factors represent the amplitude of the Doppler components. For n greater than three or four, the second term can be ignored because it is much smaller than the first. Examining the first term shows that each harmonic component of $F(\frac{n}{T})$ has a maximum for

$$\Delta F \tau = n \quad (15)$$

which means that the output samples of the discrete Fourier transform have been mapped to normalized range according to Eq. (15). Equivalently, each output sample corresponds to a range gate.

Fig. 3 shows how the amplitude of individual harmonic lines or range gates of Eq. (14) behave as the normalized target range moves from 0 to 18. These plots are called range responses. For instance, the top plot shows the magnitude of the first range gate (harmonic number 0) as a function of target range. As expected, the magnitude of this range gate is maximum at zero range and decreases with increasing range. The rapid modulation in the basic $\sin(x)/x$ shape of the function is caused by the second term in Eq. (14), which is still strong at small n .

The notion of range resolution can now be established from one of the higher-harmonic-number range responses. From these responses, the normalized distance between the 0.64 levels of the mainlobe of the range response is equal to 1, which means that

$$\Delta F \Delta \tau = 1 \quad (16)$$

Using the substitution, $\Delta R = c\Delta \tau/2$, one finds that the range resolution equals

$$\Delta R = \frac{c}{2\Delta F} \quad (17)$$

In the design of an FM radar, ΔF is a small percentage of f_0 . Under these conditions, the previous closed-form theory is known to be valid. For a high-resolution design of this lidar, ΔF is a high percentage of f_0 , raising the question of whether the theory still holds. To investigate this issue, the lidar was simulated with a brute-force computer code that more closely modeled the processes in an actual system. Comparisons of the results obtained from this model and the closed-form theory showed no significant

Fig. 3 Range-gate output as a function of normalized target range. Source: SPIE.

Fig. 4 Discrete Fourier transform (DFT) of intermediate frequency (IF) signal—two targets. Source: SPIE.

differences. Additional verification of the validity of the closed-form theory is evident in the experimental results of the following sections.

Ladar Hardware

A breadboard of the incoherent FM/CW was built to validate the theory and collect high-resolution imagery of targets. The optics and microwave elements of the imaging ladar are organized as shown in the block diagram in [Fig. 1](#), except for the placement of a two-axis galvanometer-type beam scanner in the transmit/receive path. Presently, a 100-mW laser diode at 817 nm is employed as the transmitter, and an avalanche photodiode is used for the receiver. The usable bandwidth of the laser and photodiode combination is about 1.3 GHz, and the AM index is approximately 86%. A personal computer (PC) was configured to set the beam pointing direction, trigger chirps, sample the IF data, cancel the self-clutter, form the range gates, and display the data. This system can collect 80×80 pixel image files and display the collected and processed data in several formats.

Point-target measurements

Point-target measurements recovered from tests with the incoherent FM/CW ladar illustrate the theory and some of its performance characteristics. To accomplish this we recorded the IF signal for targets at an approximately 9-m range for a chirp that starts at 600 MHz and ends at 1200 MHz. The DFT is used to map the IF signal into range gates. [Fig. 4](#) shows when the transform result is used on an IF signal comprised of returns from targets at two different ranges. As discussed earlier, the ladar is a linear system; thus multiple targets can be ranged simultaneously as evidenced by the two impulses present at range-gate 39 and 48. For this test $\Delta F = 600$ MHz thus the distance between range-gate is 0.25 m. This corresponds to 9.75 m for the first target and 12 m for the second target. The first target was deliberately set at 9 m which should correspond to range-gate 36. This error is caused by additional delay in the microwave lines internal to the ladar. When a target is in the middle of a range gate and a Hanning window is used, DFT samples on either side of the maximum should theoretically be 50% of the maximum value, and all others should be substantially suppressed. This is roughly true in the figure. Discrepancies from the theoretical distribution are usually caused by nonlinear FM characteristics in the chirp signal. Other causes may include amplitude modulation of the IF signal due to nonflat amplitude-versus-frequency characteristics of the microwave components, laser diode, and/or detector diode. Nonlinear phase-versus-frequency characteristics of these same devices can also cause spreading of the signal distribution. Additional hardware can be added to the system to measure component errors, and appropriate compensation can be applied to the IF signal to minimize spreading effects. Little effort has been expended so far in reducing these errors in the breadboard ladar.

Imaging measurements

The imaging capabilities of the ladar were tested at an outdoor site on the ARL Adelphi, MD, campus. [Fig. 5](#) shows the site with an Army pickup truck oriented perpendicular to the ladar at about a 52-m range. All specularly reflective surfaces on the truck were masked with black tape for laser safety reasons. A calibrated standard reflectivity target (18%) is positioned in the lower right of the photograph, and a grassy hill is located about 15 m beyond the truck.

An 80×80 pixel image of the truck was collected with the imaging ladar for aspect angles of approximately 0, 45, and 90 degrees. For brevity, [Fig. 6](#) shows only the 0 degree result. The uppermost image is formed pixel by pixel by summing outputs from all of the range cells from the front of the truck to beyond the hill. The bottom image sum outputs from the range cells from the front through the rear bumper of the truck only, thereby eliminating the returns from the hill and enhancing the contrast of the truck from the background. The pixel density is sufficient to allow one to determine that the target is indeed a pickup truck. The calibration target appears in each image in the lower right.

32 × 32 Pixel FPA Ladar Breadboard Using Incoherent Chirped Amplitude Modulation

Introduction

This section presents a FPA ladar architecture that is useful for a variety of applications such as reconnaissance and robotic navigation and is based on the optically incoherent FM/CW ranging architecture reported in the previous section. The incoherent FM/CW ranging architecture is a natural fit to a FPA design because the final system bandwidth is low enough to provide sufficient

signal-to-noise while using low-cost and low power laser diodes. In the following text we describe the FPA architecture, optoelectronic (OE) detector design, read-out based on code division multiple access (CDMA) techniques, and signal processing. We then summarize work to build a brassboard and related hardware modifications to reduce pixel-to-pixel cross-talk, and the addition of a 32-channel data acquisition system (DAS) and new signal processing and display software. Imagery collected in the lab is displayed along with a discussion of the improvements to image quality achieved with the reduction of pixel-to-pixel cross-talk.

Incoherent FM/CW FPA Breadboard Architecture

In the following text, we briefly describe the operating principles of the 32×32 pixel FPA lidar breadboard using the block diagram shown in Fig. 7. A clock circuit controls the generation of a chirp signal that serves as the laser intensity modulation and RF LO signal. As in the previous section the chirp signal is simply a sinusoidal waveform whose frequency linearly increases over a period T and then flies back to the original start frequency (i.e., sawtooth FM). The chirp signal for our breadboard has a start frequency of 200 MHz and a stop frequency of 800 MHz. FM/CW radar ranging theory supports a rich variety of improvisations to the basic sawtooth modulation format. However, to simplify our present work with the lidar breadboard, we use only the pure sawtooth modulation format, which yields high range resolution with the least amount of lidar signal processing.

To modulate the laser illumination, the chirp signal is fed into a wideband RF power amplifier with a low output driving impedance. Output from the amplifier and a dc current are summed in a bias tee to provide a modulated current drive for a

Fig. 7 Laboratory lidar breadboard block diagram. Source: SPIE.

broad-area semiconductor diode laser at 808 nm with a bandwidth at least equal to the bandwidth of the chirp waveform. A high-percentage intensity modulation of the light beam is desirable. The divergent laser beam from the semiconductor laser is collected with a collimator and focused to project a beam sufficiently wide to encompass or floodlight the target scene of interest.

A small portion of the transmitted beam is reflected from the target toward the lidar and collected by the receiver optics. An array of OE-mixing metal-semiconductor-metal (MSM) detectors is located at the focal plane of the receiver optics (Ruff *et al.*, 2000; Shen *et al.*, 2000). When the transmitter RF modulation waveform (LO voltage) is applied across the OE-mixing detectors, a photocurrent response is recovered at each detector that is the product or mixing of the RF LO and the intensity modulated light waveforms. (Note that in contrast to optically coherent detection with an FM-CW waveform, for the chirped AM system the LO is an RF voltage waveform not a laser beam, and the frequency of the intensity modulation of the transmitted laser light is chirped, not the frequency of the laser light's electromagnetic wave.) With sawtooth modulation, the instantaneous transmitted and received chirp waveforms differ in frequency (by the IF) because the round-trip light propagation time delays the received chirp waveform with respect to the LO chirp waveform. Thus, mixing of the LO and return signal in the detectors produces a sinusoidal photocurrent (IF waveform) whose frequency is proportional to range.

To recover the photocurrents from the individual pixels, we employ a unique read-out based on CDMA techniques discussed in more detail in a previous publication (Stann *et al.*, 2003). To implement this technique, we multiply the LO signal for each column of the array by a unique binary code that induces a phase shift on the LO of either 0 or 180 degrees. The net effect is to nearly orthogonalize the photocurrents for all pixels in a row, thus allowing all currents to be combined into a single wire that connects to a transimpedance amplifier (TIA) to the side of the detector array. The TIA converts the photocurrents into a voltage that is then sampled at the code clock rate by an analog-to-digital converter (A/D). The CDMA FPA read-out technique was originally conceived because it allowed us to obtain read-out function with discrete electronic components without having to build a custom read-out integrated circuit (ROIC), which requires substantial development time and is usually expensive. As mentioned, the CDMA technique multiplexes all of the pixel photocurrents in a row onto a single row readout line. This reduces the number of readout lines from 1024 to 32 for the 32×32 pixel FPA. The CDMA readout also requires that different codes modulate the LO drives for each column, so that 32 code modulated LO drive lines are required for the 32×32 pixel array. Thus, the total number of drive and readout lines is 64 for the 32×32 pixel array. In general, an $N \times N$ pixel array will require N readout and N LO lines (a total of $2N$) for the CDMA read-out. Demuxing of the data is done digitally in software on a PC. Here the data from each row's A/D is successively multiplied by the codes associated with each pixel, which are generated in software, to recover the IF signal from the respective pixels. The fast Fourier transform (FFT) is taken for each of the demuxed photocurrents, i.e., each of the IF signals, to map the data space into a three-dimensional image space.

32 × 32 Pixel Laboratory Breadboard Hardware

Fig. 8 shows the front view of our laboratory breadboard. We illuminate with a 3.2-W GaAs multi-stripe diode laser where some of the power is coupled into a fiber cable and directed to allow flood illumination of the receiver field of view (FOV). The receiver lens is 5 cm in diameter, and its position is adjustable to center the FOV on the FPA and to adjust the focus.

A fan-in/fan-out board feeds-in code-modulated LO signals to the FPA columns and feeds-out the photocurrents from each FPA row. Circuitry to apply the codes to the FPA columns are on separate boards that plug-into the rear of the fan-in/fan-out board. Each column driver board supports circuitry to drive two detector array columns. The RF LO signal enters the board from a single input and is immediately fed into a two-way power splitter. Each two-way splitter output is fed into the LO port of a balanced mixer where they are bi-phase modulated by the PN code applied to the IF port. These modulated outputs are then amplified by a pair of MMICs amplifiers that are connected to microstrip lines on the fan-in/fan-out board. CAT5 cables carry the code signals and

Fig. 8 Front (top) view of 32×32 pixel laboratory breadboard. Source: SPIE.

power to the driver board. The RF bandwidth extends from 200 to 800 MHz and each channel can deliver up to 100 mW into a $50\text{-}\Omega$ load. This signal level is more than adequate to drive the GaAs detector array and is likely to be adequate to drive an InGaAs array.

The FPA row output currents are fed through the fan-out board to the TIA boards plugged into the back of the fan-in/fan-out board. Each TIA board supports four amplifier channels. Each channel includes a TIA stage based on a new wideband, FET input, operational amplifier that allows high transimpedance gains with wide bandwidths. This capability is especially important for achieving low noise amplification which in-turn increases the lidar's maximum range. The current operating parameters of each amplifier chain are as follows: a transimpedance gain of $300\text{ M}\Omega$, a low-pass cutoff of 200 kHz, and a highpass cutoff of 50 Hz. CAT5 computer patch cables connect the power, grounds, and output signals to a 32-channel DAS that acquires the TIA amplifier outputs. The 32-channel DAS can sample (with 8 bits) each channel at up to a 400 kHz rate; for the current experiments we sample at a 93 kHz rate to facilitate debugging of the lidar.

The code generator appears in the lower middle of the picture. The code generator is based on a classical linear feedback shift register (LFSR) design where the outputs of the fourteenth and fifteenth stages of the LFSR are fed into an exclusive OR, and the resulting output is then fed into the first stage of the LFSR. This process yields a fifteen-bit maximal length binary PN code that repeats every 32,767 ($2^{15} - 1$) clock cycles. The code sequence is clocked out at 93 kHz into a series of parallel-out shift registers that provide 32 replicas of the code delayed by two clock periods (i.e., 2 chips). Additional circuitry is included on the board to restart the code sequence at the beginning of each FM chirp, and to inject a seed word into the code generator to insure that the sequence is initialized identically for every chirp. To mitigate transient effects in the driver and TIA boards, the code is run continuously except for a $10\text{-}\mu\text{s}$ period at the beginning of each chirp in which the registers are cleared, and the seed word is injected.

The chirp generator is built around a low-cost, commercial, direct digital synthesizer (DDS) chip (not shown in Fig. 8). Output from the DDS is multiplied-up in frequency by phase-locking to a voltage-controlled microwave oscillator. The basic operating parameters for the chirp generator, including FM deviation, center frequency, and chirp rate, are entered on the lidar control and processing PC which then feeds the data to the chirp generator. The nominal parameter settings are 600 MHz for the FM deviation, 500 MHz for the center frequency, and 3 Hz for the chirp rate. Once the operating parameters are loaded, the chirp generator runs continuously, and sends a digital low-to-high transition at the beginning of each chirp to initialize and start the code generator, and to start the data acquisition process.

Lidar control, signal processing, and display is performed on a PC. A Labview code performs the lidar control and data acquisition functions along with providing display of some intermediate signal processing steps to aid in monitoring system performance. The Labview code captures data from the 32-channel DAS at a 3-Hz frame-rate and stores it on a hard disk. A "C"

Fig. 9 Metal-semiconductor-metal (MSM) detector array on PC board mount (left), upper right corner of FPA chip showing bypass capacitors (right). Source: SPIE.

code is running concurrently that reads the data from the hard disk, performs the demuxing operations required for the FPA read-out, computes the Fourier transform of the resulting IF signals to range-gate the data, and displays the data in stereo. This process occurs continuously requiring a period of one to two seconds. The interactive 3-D display (stereo display), written at ARL, thresholds the intensity-versus-range signal for each pixel and draws a rectangle at each range where the threshold is exceeded. The size of the rectangle matches the area subtended by the pixel at that range, so a large flat object would be precisely tiled by the rectangles, but rough or very small objects would appear like a point cloud. The display allows a user to zoom and pan around the data and also allows stereoscopic viewing. The depth perception afforded by the stereoscopic viewing and the capability to change perspective enables the user to interpret the data in much the same way as he or she views complex scenes in real life.

MSM Detector Design and Mounting Scheme

The mounting technique for the FPA is shown in the left of [Fig. 9](#). Here LO signals are input from the fan-in/fan-out board to IC socket pins that are soldered into the FPA mount. Microstrip lines (i.e., conductors routed over a ground plane) then carry the LO signals to pads in close proximity to the FPA mounting position; standard wirebonds connect these pads to bonding pads on the FPA chip. The width of the microstrip conductors and the dielectric thickness were made as small as possible but consistent with commercial printed circuit board fabrication techniques to allow maximum distance between lines and therefore achieve minimum cross-talk. This new board also featured IC socket pins that mated with the pins soldered into the FPA mounting board to facilitate changing of the FPA. S_{12} measurements on the new fan-in/fan-out board and FPA mounting board showed that the cross coupling was usually less than -40 db over the lidar's RF bandwidth.

The FPA is 32×32 -pixel interdigitated-finger MSM photodetector array with integrated capacitors at the row outputs shown on right of [Fig. 9](#). The integrated capacitors will replace the discrete capacitors mounted on the fan-in/fan-out board. These capacitors bypass the LO signal currents to ground thereby suppressing LO signals that may enter the TIAs and create noise. They additionally prevent the row busses from being modulated by the LO voltages which would create pixel-to-pixel cross-talk. The integrated capacitors perform the bypassing function more effectively than the discrete capacitors because the lead inductance between the FPA row output and ground will be much lower.

The 32×32 FPA of $60 \mu\text{m}$ pixels is fabricated on semi-insulating GaAs. The thickness of the second silicon nitride layer is such that the capacitance at the end of each row is approximately 15 pf.

Results of Laboratory Breadboard Tests

In this section we briefly discuss our most recent imaging experiments with the breadboard lidar to give the reader some measure of its performance. For these tests, the bandwidth of the modulation is 600 MHz; this establishes a distance of 0.25 m between range cells. All data for a single lidar frame is collected in approximately 0.33 s; this yields a lidar frame rate of 3 Hz that is also the final signal processing bandwidth. The receiver lens diameter is 5.0 cm. As mentioned, some light power from the 3.2-W laser illumination module is coupled into a fiber optic patch cord and light at the output of the cable is then passed through a lens system to form a circular flood illumination field that overlaps the FOV of the receiver. This technique yields a much more uniform illumination field than can be obtained by using the light that is emitted directly out of the laser. The fiber collects 300 mW of laser light; the portion of this light that is in the FOV of the receiver is about 200 mW thus each pixel is illuminated with approximately 0.2 mW of optical power.

The first imaging test examined the lidar performance for a single pixel at one range. Here the collimator of the 100-mW laser illuminator was adjusted so that a small spot (less than the size of a projected pixel) was projected on the wall approximately 11-m

Fig. 10 Ladar impulse response (range dimension). Source: SPIE.

Fig. 11 Impulse response (cross-range dimension; expanded vertical scale on right). Source: SPIE.

distance from the breadboard. The range performance or impulse response in the range dimension is shown in Fig. 10. The horizontal axis is displayed in units of resolution cells which for the amount of FM deviation used (600 MHz) corresponds to 0.25 m; the vertical axis is simply amplitude in arbitrary units. The response peaks at 43 units (11.75 m), as expected, with an amplitude of 38 units; low responses before and after the peak (2.5 and 4 units of amplitude, respectively) are caused by reflections on the microwave transmission lines feeding various components in the breadboard and can be eliminated by improving impedance matching at those points. Overall, the performance in range is acceptable and can be easily improved by more careful attention to the microwave design.

The impulse response in the cross-range or azimuthal dimension is shown in left of Fig. 11. In this figure, the horizontal axis is expressed as pixel number (0 corresponds to pixel number 1) and the vertical axis is again in arbitrary units; the light is positioned on row 21, column 19. As expected, largest amount of signal energy appears at the correct pixel position, however lower values appear at all the other pixel positions. In actuality this will happen because the code read-out concept as implemented here with maximal length pseudorandom sequences will have some non-zero signal level in the other pixel positions. This level of cross-talk is for the most part established by the length of the sequence; other factors such as bandlimiting of any amplifier or filter in the code application or IF signal chain will also affect the cross-talk level (Stann *et al.*, 2003). Considering the situation where the code length (32,767 bits is used in the breadboard) is the only factor, the cross-talk-to-signal ratio should be about -45 db. To better examine the cross-talk level we expanded the vertical scale and displayed the results in the right half of Fig. 11. Here we found that the cross-talk level in pixels to the left of pixel 19 is about -43 db after correcting for the Johnson noise present when the illumination was shut-off. This result is satisfactory considering that any filtering effects in the breadboard will degrade cross-talk

level over the ideal situation. For pixels to the right of pixel 19, the cross-talk level is approximately 10 db higher; this level is expected to degrade image quality particularly in situations where large portions of a target are at a same range. We believe that the cause for this elevated cross-talk level on the right side of the signal is that the LO signals that are routed on the right hand side of the fan-in/fan-out board are coupling to the IF output lines that are also routed on the right hand side of the board and then feeding back to the FPA pixel output bus. This causes a small amount of LO signal from all of the LO lines on the right hand side of the fan-in/fan-out board to be applied to all the detectors in a row. When this happens, the photocurrent in the illuminated pixel becomes modulated at a low level by the codes for other columns. The demuxing step then reports that some signal energy is present in those codes or pixel positions. As mentioned we believe that the problem can be mitigated by improving the RF bypassing of the FPA row output busses by building-in capacitors at the end of each row of the FPA chip. In summary the azimuthal cross-talk is reduced about 20 db over the results achieved in the prior year with the FPA mounted in the leadless chip carrier.

For the imaging test, we set up a scene about 10 m from the breadboard in the back of our lab bay as shown in Fig. 12. Here a cardboard "A" is supported on a pedestal followed by a poster board to the left side of the "A" and 0.25 m further in range. A brown cardboard box is positioned roughly behind the poster board about 0.75 m further in range. A white cardboard box is alongside the brown cardboard box and 0.25 m further in range.

As mentioned earlier, the lidar breadboard can run continuously where a Labview code performs the lidar control and data acquisition functions while a "C" code performs pixel demuxing, range-gate formation, and stereo display. The 3-D image produced by the "C" code updates about every 1–2 s depending on what intermediate data is displayed in the Labview program. This capability is particularly interesting because successive frames are sequentially shown while the viewer can rotate the image to

Fig. 12 Laboratory scene. Source: SPIE.

Fig. 13 Breadboard lidar image of laboratory scene. Source: SPIE.

other aspects. In Fig. 13 we show the laboratory scene as imaged from one viewpoint, but displayed at two aspects. The “A” is very well-formed and shows a clear staircase function along the legs as one would expect for an image with pixel-limited resolution. It appears even clearer with the stereo display on the lidar’s PC where degradation caused by the screen capture and other processes needed for presentation in a written report are absent. The poster board one resolution cell behind the “A” is clearly separated from the “A” and exhibits the shadow of one leg of the “A.” About six artifacts are present in the space between the poster board and the two cardboard boxes. These are the result of somewhat less than theoretical performance of the code-multiplexed read-out. As alluded in the previous section, diagnostic measurements indicate that the cause of this degraded performance is LO signals coupling into the IF output lines and then backing-up into the FPA photocurrent busses. We are reasonably confident that the new FPA design with built-in bypass capacitors at the end of each photocurrent buss is expected to attenuate the LO signals and therefore eliminate the image artifacts. The last two boxes are clearly imaged and show the shadow of the “A” and their respective range displacements. The farthest box has a bright region on its left side; this is caused by a glint return from scotch tape on the box.

Conclusions

We have demonstrated the range measurement capability of an incoherent FM/CW lidar where the FM is applied to an RF subcarrier that AMs the light output, instead of to the optical carrier. We outlined the theory of this approach and proved that it is applicable even when the FM bandwidth is greater than the center frequency of the AM. To mitigate the problems of self-clutter created by mixer imbalances or other processes, we proposed and demonstrated in software a simple subtraction technique that can effectively remove false targets caused by such self-clutter. Measurements made with the breadboard imaging lidar have shown that the range resolution is commensurate with the FM bandwidth. An implementation of the self-clutter cancellation technique in the lidar indeed shows that near-range false targets can be eliminated. Measurements have also shown that the lidar can simultaneously resolve and display multiple targets in the same image pixel that are displaced in range by more than the intrinsic lidar resolution. Finally, images collected of a truck demonstrate the potential of this lidar to enhance the contrast of a target in a clutter background.

Overall, this lidar approach should be advantageous for a number of low-cost short to mid-range commercial and military applications, for a variety of reasons. The use of incoherent light detection should inherently produce a lidar that is less costly and complex, and more rugged and reliable, than lidars that use coherent detection. FM ranging techniques have very low post-mixing signal-processing bandwidths, thus substantially simplifying and reducing the cost of the signal processor. Additionally, the ability to detect multiple targets in one pixel may facilitate signal processing for lidars that may have to function in environments where clutter and aerosols are present. Finally, semiconductor laser diodes provide more average power when they are operated CW; thus acceptable lidar SNRs may be easier to achieve using low-power inexpensive lasers.

We built and successfully tested a 32×32 pixel lidar breadboard using the incoherent FM/CW ranging principles. Also demonstrated was the use of a unique code multiplexing scheme to read-out the FPA post-mixing signals that was built using discrete components. The 32×32 pixel lidar breadboard image quality is substantially improved over image quality obtained with prior work when the FPA was mounted in a standard leadless chip carrier. Now, the images contain clear shadows and completely filled-in backdrops. Currently the system is amplifier noise limited where the noise performance is a factor of roughly 10 worse (in a voltage sense) than the level theoretically achievable. For the future we will need to investigate techniques to improve the signal-to-noise of the receiver. The most desirable method is to develop an OE-mixing detector with a modest amount of gain ($10 \times$). We also believe that the OE mixing detector should be designed using InGaAs that will allow the breadboard to operate at eye-safe wavelengths.

Introduction

For the sake of developing unambiguous specifications for an optical imaging system, it becomes imperative to define a unique image of an object, and so a one-to-one correspondence between points on the object and image is often assumed. This is an approximate model, and except for a few trivial cases, image formation by real optics can never render a point image corresponding to a point object. This is so, primarily for two reasons. First, the presence of residual aberrations in real optical systems, inhibits transformation of the homocentric bundle of rays, originating from a point object and admitted by the imaging system in the object space, into a homocentric bundle of rays converging to the desired point in the image space. Next, even a completely aberration free system does not form a point image corresponding to a point object on account of the inevitable effects of diffraction arising out of finite size of aperture of any real imaging system.

Fig. 1 shows the schematic of an axially symmetric imaging system forming image of the point object O at the image plane located at O' . The entrance pupil and the exit pupil are located at the points E and E' , respectively.

Let (X, Y) and (ξ, η) be the rectangular Cartesian coordinates of a point on the exit pupil plane and the image plane, respectively. The corresponding origins are taken at E' and O' . α is the image space semi-angular aperture, and $(n \sin \alpha)$ is the image space numerical aperture, where n is the refractive index of the image space. Normalized coordinates for points on the exit pupil plane are (x, y) . They are related to the geometrical coordinates by

$$x = \left(\frac{X}{h}\right) \quad y = \left(\frac{Y}{h}\right) \quad (1)$$

where h is the radius of the exit pupil. The normalized coordinates (u, v) for points on the image plane are given by

$$u = \left(\frac{n \sin \alpha}{\lambda}\right) \xi \quad v = \left(\frac{n \sin \alpha}{\lambda}\right) \eta \quad (2)$$

On account of axial symmetry, the normalized distance from the axis of any point with coordinates (X, Y) on the exit pupil plane can be expressed as

$$r = \sqrt{x^2 + y^2} = \frac{\sqrt{X^2 + Y^2}}{h} \quad (3)$$

Similarly the normalized distance p of any point on the image plane with geometrical distance χ from O' is given by

$$q = \left(\frac{n \sin \alpha}{\lambda}\right) \chi = \left(\frac{n \sin \alpha}{\lambda}\right) \sqrt{\xi^2 + \eta^2} \quad (4)$$

Fig. 1 Object/image planes and entrance/exit pupils of an axially symmetric imaging system.

The complex amplitude $F(u, v)$ on the transverse image plane located at O' is given by the finite Fourier transform of the complex amplitude $f(x, y)$ on the exit pupil at E' , and is given by

$$F(u, v) = \iint f(x, y) e^{i2\pi(ux+vy)} dx dy \quad (5)$$

The limits of integration are set by the finite contour of the pupil. The intensity pattern $I(u, v)$ is equal to the squared modulus of the complex amplitude

$$I(u, v) = |F(u, v)|^2 \quad (6)$$

For axially symmetric systems, the intensity distribution on the blur patch is same along any azimuth on the transverse plane at O' , and the two dimensional Fourier transform of Eq. (5) reduces to a Hankel transform of the circularly symmetric pupil function $f(r)$.

$$F(p) = m \int f(r) J_0(pr) r dr \quad (7)$$

where

$$p = 2\pi q = \frac{2\pi}{\lambda} (n \sin \alpha) \chi \quad (8)$$

and m is a multiplicative constant.

The intensity distribution $I(p)$ is given by

$$I(p) = |F(p)|^2 \quad (9)$$

For aberration free uniform amplitude imaging systems with axially symmetric circular aperture the pupil function $f(r)$ is given by

$$f(r) = \begin{cases} 1, & 0 \leq r \leq 1 \\ 0, & r > 1 \end{cases} \quad (10)$$

The amplitude distribution $\hat{F}(p)$ in the blur patch on the transverse image plane along any azimuth from the optical axis is given by

$$\hat{F}(p) = m \int_0^1 J_0(pr) r dr \quad (11)$$

Defining the normalized amplitude $\hat{F}_N(p)$ as $\hat{F}_N(p) = \hat{F}(p)/\hat{F}(0)$, we get

$$\hat{F}_N(p) = 2 \frac{J_1(p)}{p} \quad (12)$$

The normalized intensity is given by

$$\hat{I}_N(p) = |\hat{F}_N(p)|^2 = \left[\frac{2J_1(p)}{p} \right]^2 \quad (13)$$

where $J_1(p)$ indicates value of the Bessel function (of the first kind) of order 1 for argument p .

This blur patch consists of a bright central lobe surrounded by bright and dark rings with decreasing intensity, and is known as the Airy pattern. The intensity on the transverse plane along any azimuth from O' is shown in Fig. 2. This pattern is known as the Airy pattern. The uniform amplitude pupil of the imaging system is often called the Airy pupil.

Abbe/Rayleigh limit of two-point resolution on the transverse image plane is based on the intensity distribution in the Airy pattern, and the least resolvable distance $\delta\chi$ on the transverse image plane is proportional to $\{\lambda/n(\sin \alpha)\}$, where $n(\sin \alpha)$ is the numerical aperture of the imaging system and λ is the working wavelength. For three dimensional objects, in the two-dimensional image of an axial section of the object the least resolvable distance becomes larger than $\delta\chi$ on account of overlap of defocussed images of neighboring axial sections of the object. The axial distance beyond which this effect becomes insignificant is related with

Fig. 2 Airy pattern: the point spread function (PSF) for an aberration-free diffraction limited imaging system.

the location of first zero in the axial distribution of intensity, and this axial resolution $\delta\zeta$ is proportional to $\{\lambda/[n \sin \alpha]^2\}$. It should be noted that both these results refer to aberration-free diffraction limited systems. In presence of aberrations, usually the least resolvable distance obtained in practice is much larger than $\delta\chi$ obtained for aberration free systems.

In order to cater to the needs of diverse applications, it becomes necessary to develop different types of imaging systems with prespecified requirements for $\delta\chi$ and/or $\delta\zeta$; in general, for real time whole field imaging systems, this calls for tailoring of the point spread function (PSF) on the transverse image plane and/or of the distribution of intensity along the axis in the neighborhood of the image plane. In some related applications, sometimes it becomes necessary to tailor the three-dimensional PSF.

Optical Masks

A straightforward approach to tailor the PSF is to use masks over the pupil of the imaging system. From the early days of development of the theories of image formation different types of mask, for example, amplitude, phase and mixed masks are being explored to accomplish the desired goals. Since these three types of mask are lossy, lossless and leaky, respectively, the lossless phase masks are often preferred in practical applications.

Some of the well-known applications of optical masks are:

- apodization
- high frequency enhancement in images
- superresolution
- tailoring the depth of focus
- optical traps.

Apodization is a technique widely used in astronomy for imaging of a faint star in the vicinity of another star that is brighter by several degrees of magnitude, and in spectroscopy for imaging a faint line neighboring a line that is brighter by several degrees of magnitude. This is accomplished with the help of an optical mask on the pupil of the imaging system for lowering down the intensity of the sidelobes in the PSF. It is interesting to note that the name “apodization” is derived from Greek “ α ” implying “to take away,” and “ $\pi\omicron\delta\omicron\sigma$ ” meaning “feet.” In terms of Fourier optics, apodization leads to increase in modulation transfer function (MTF) of the lower spatial frequencies in the image and a concomitant decrease in MTF of the higher spatial frequencies in the image. Optical masks can also be synthesized to accomplish the opposite effect, and this phenomenon is called “High frequency enhancement in images.” However, in both cases, the cut-off frequency in the image is not affected by the use of optical masks. As mentioned earlier, the cut-off frequency in an imaging setup is determined by diffraction effects corresponding to the image space numerical aperture and the working wavelength.

Superresolution refers to imaging techniques that can lead to resolution in the image beyond the diffraction limit. Obviously it calls for narrowing down the central lobe of the diffraction limited PSF; but, any attempt to achieve the same is accompanied with increase in intensity of the sidelobes, so much so that the advantages accruing from narrowing of the central lobe cannot be effectively harnessed for increase in resolution. Attempts for superresolution have, therefore, been directed to post-processing of data obtained from scanning techniques for imaging. The narrow central lobe obtained by optical masks can be used for narrow scanning spot, if the noisy sidelobes are eliminated with the help of a suitable spatial filter. On the other hand, if the PSF is tailored by an optical mask in a manner so that at least several sidelobes surrounding the narrow central lobe have low intensity, the imaging set up can be used to obtain resolution beyond the diffraction limit, albeit over a restricted field of view.

Applications of optical imaging can be classified on the basis of requirements for large depth of focus, or small depth of focus. Note that the depth of focus for diffraction limited aberration free systems is determined by the image space numerical aperture, and the working wavelength; also residual aberrations affect the depth of focus considerably. Optical masks can be conveniently used for tailoring the depth of focus.

Single and multiple optical traps have opened up new frontiers in the field of micro and nanotechnology for manipulation of minute particles. Suitable optical masks for tailoring the number, shape and location of optical traps constitute a major challenge.

For the sake of systematic analysis and synthesis of optical masks to be used on the pupil, the pupil function $f(r)$ describing transmission of the mask is expressed in terms of a set of base functions $b_n(r)$ as

$$f(r) = \sum_{n=0}^{N-1} a_n b_n(r) \quad (14)$$

Typically, Straubel functions, trigonometric functions, Bessel functions, Chebyshev functions, Zernike polynomials, prolate spheroidal wave functions, etc. have been experimented within search for suitable base functions. Often the convenient amenability of obtaining the finite Fourier or Hankel transforms has weighed in favor of choice of base functions. If the members of the set of base functions are mutually orthogonal, the number of terms to be used in specific applications need not be determined heuristically, for the addition or removal of any term of the series does not affect other terms. With this backdrop in view we explore the use of Walsh functions in analysis and synthesis of optical masks.

Walsh Functions

Walsh functions were introduced by Walsh in 1923 as “a closed set of normal orthogonal functions” defined over the interval $(0, 1)$ and having values $+1$ or -1 within the interval. They are a complete set of normal orthogonal functions over a given finite interval and take on values $+1$ or -1 , except at a finite number of points of discontinuity, where they take the value 0. The order of the Walsh function is equal to the number of zero crossings within the specified domain over which the set is defined. The complete set of Walsh functions not only provides a viable alternative but also introduces a significant simplification in the approach of using suitable base functions. They have the interesting property that an approximation of a continuous function over a finite interval by a finite number of base functions of this set leads to a piecewise-constant approximation to the function. Also, the system of Walsh functions possesses some unique properties among all the systems orthonormal in Hilbert space $L_2(0, 1)$. In fact, the system of Walsh functions may be derived from the character group of the dyadic group which is a topologic group derived from the set of binary representations of the real numbers. This topology of the dyadic group makes properties of the system of Walsh functions strikingly different from those of other systems. Walsh functions have been utilized to a great advantage in the field of signal coding and transmission, in allied problems of information processing and in digital signal processing. Two dimensional Walsh functions in the usual rectangular coordinates have been extensively used in digital image processing applications. For the treatment of problems of image formation where one usually deals with some form of axial symmetry, it is useful to develop Walsh functions in polar coordinates. For systems with rotational symmetry about the axis, it is sufficient to deal only with radial Walsh functions. The latter have been developed as a special case of Walsh functions in polar coordinates and have been found to be quite useful in the treatment of problems of pupil plane filtering and the studies on aberrated optical imagery.

One Dimensional Walsh Functions

A Walsh function of a single variable x is represented as $W_k(x)$ where the subscript k refers to the order of the function. The function takes on values either $+1$ or -1 over a specified domain and the set of Walsh functions is orthogonal and complete in the interval. The same implies the following relation for members of the set of Walsh functions defined over the interval $(0, 1)$

$$\int_0^1 W_k(x)W_{\ell}(x)dx = \delta_{k\ell} \quad (15)$$

where $\delta_{k\ell}$ is the Kronecker delta defined as

$$\delta_{k\ell} = \begin{cases} 0, & k \neq \ell \\ 1, & k = \ell \end{cases} \quad (16)$$

The set has a further specification through the unique definition of the zeroth element of the set as

$$W_0(x) = 1, \quad 0 \leq x \leq 1 \quad (17)$$

Fig. 3 shows the first four one-dimensional Walsh functions $W_k(x)$, $k=0, 1, 2$, and 3.

Fig. 3 One dimensional Walsh functions, $W_k(x)$, $k=0,1,\dots,3$.

In order to obtain an analytical representation for the unidimensional Walsh functions $W_k(x)$, let the integer k be expressed as

$$k = \sum_{i=0}^{(v)-1} k_i 2^i \quad (18)$$

where k_i are the bits, 0 or 1 of the binary numeral for k , and 2^v is the integral power of 2, whose value just exceeds k . Thus for $k=0$, 1 , $v=1$; for $k=0, 1, 2, 3$, $v=2$; for $k=0, 1, 2, 3, 4, 5, 6, 7$, $v=3$, and so on.

For all x in the interval $(0, 1)$ we define

$$W_k(x) = \prod_{i=0}^{(v)-1} \text{sgn}[\cos(2^i \pi x k_i)] \quad (19)$$

where

$$\begin{aligned} \text{sgn}(x) &= +1, & x > 0 \\ &= 0, & x = 0 \\ &= -1, & x < 0 \end{aligned} \quad (20)$$

It may be noted from Fig. 3 that the order of the Walsh function is given by the number of zero crossings, i.e., the sign changes of the function in the interval $(0, 1)$.

Two Dimensional Walsh Functions in Rectangular Coordinates

In two dimensions, the orthogonality condition takes the form

$$\int_0^1 \int_0^1 W_k(x) W_\epsilon(y) W_\epsilon(x) W_\epsilon(y) dx dy = \delta_{k\epsilon} \delta_{\epsilon\epsilon} \quad (21)$$

Fig. 4 depicts a few two dimensional rectangular Walsh functions $W_k(x)W_\epsilon(y)$, $k=0,1,2,3$, $\epsilon=0,1,2,3$.

Fig. 4 Two dimensional rectangular Walsh functions $W_k(x)W_\epsilon(y)$, $k=0,1,2,3$, $\epsilon=0,1,2,3$.

Two Dimensional Walsh Functions in Polar Coordinates

In polar coordinates the orthogonality condition reduces to

$$\frac{1}{\pi} \int_0^1 \int_0^{2\pi} \varphi_k(r) \mathcal{A}_\epsilon(\theta) \varphi_\epsilon(r) \mathcal{A}_\epsilon(\theta) r dr d\theta = \delta_{k\epsilon} \delta_{\epsilon\epsilon} \quad (22)$$

where $\varphi_k(r)$ and $\mathcal{A}_\epsilon(\theta)$ are the radial Walsh function and azimuthal Walsh function, respectively.

Fig. 5 depicts a few two-dimensional polar Walsh functions $\varphi_k(r) \mathcal{A}_\epsilon(\theta)$, $k=0,1,2,3$, $\epsilon=0,1,2,3$.

Azimuth Invariant Case: Radial Walsh Functions

Alike the case of unidimensional Walsh functions, $W_k(x)$, radial Walsh functions $\varphi_k(r)$ of index $k \geq 0$ and argument r over the interval $(0,1)$ require integer k to be expressed in the form

$$k = \sum_{i=0}^{\gamma-1} k_i 2^i \quad (23)$$

where k_i are the bits, 0 or 1 of the binary numeral for k and 2^γ is the integral power of 2 that just exceeds k . Thus for all r in $(0,1)$ we define

$$\varphi_k(r) = \prod_{i=0}^{\gamma-1} \text{sgn}[\cos(2^i \pi r^2 k_i)] = \prod_{i=0}^{\gamma-1} \text{sgn}[\cos(2^i \pi t k_i)] = \varphi_k(t) \quad (24)$$

where $t=r^2$.

The first four radial Walsh functions $\varphi_k(r)$, $k=0,1,2,3$ are shown in (r, θ) space in Fig. 6(a). The corresponding radial variation of $\varphi_k(r)$ along any azimuth is shown in Fig. 6(b).

For azimuth invariant case the orthogonality condition takes the form

$$\int_0^1 \varphi_k(r) \varphi_\epsilon(r) r dr = \frac{1}{2} \delta_{k\epsilon} \quad (25)$$

Note that in $t(=r^2)$ space, the variation of $\varphi_k(t)$ with t is identical as the variation of one dimensional Walsh functions $W_k(x)$ with x .

Walsh Filters as Optical Masks on Pupil

Walsh filters of various orders may be obtained from the corresponding Walsh functions by realizing values of $+1$ or -1 with 0 or π phase, respectively. Note: $e^{i0} = +1$, and $e^{i\pi} = -1$. Radial Walsh filters, derived from radial Walsh functions, form a set of orthogonal phase filters that take on values either 0 or π phase, corresponding to $+1$ or -1 values of the radial Walsh functions over prespecified annular regions of the circular filter. Order of these filters is given by the number of zero-crossings, or equivalently phase transitions within the domain over which the set is defined.

Radial Walsh filters may be used as optical masks on the pupil plane of a rotationally symmetric imaging system for tailoring of the distribution of intensity on and around the focal/image plane of optical imaging systems.

Fig. 5 Two dimensional polar Walsh functions $\varphi_k(r) \mathcal{A}_\epsilon(\theta)$, $k=0,1,2,3$, $\epsilon=0,1,2,3$.

Fig. 6 (a) Radial Walsh functions $\varphi_k(r)$, $k=0,1,\dots,3$ in (r,θ) space. (b) Radial Walsh functions $\varphi_k(r)$ vs. r along any azimuth θ , $k=0,1,\dots,3$.

Intensity Distribution on the Transverse Image/Focal Plane With Walsh filters as Optical Masks

For the k th order radial Walsh filter on the pupil, the pupil function may be expressed as

$$f(r) = \varphi_k(r) = \sum_{m=1}^M e^{ik\psi_m} B_m(r) \quad (26)$$

where $B_m(r)$ are zero-one functions defined as

$$\begin{aligned} B_m(r) &= 1; \quad r_{m-1} \leq r \leq r_m \\ &= 0; \quad \text{otherwise} \end{aligned} \quad (27)$$

where

$$r_m = \left[\frac{m}{M} \right]^{\frac{1}{2}} \text{ and } r_{m-1} = \left[\frac{m-1}{M} \right]^{\frac{1}{2}} \quad (28)$$

and $M=2^J$ is the largest power of 2 that just exceeds k . Over the m th zone of $\varphi_k(r)$, value of $k\psi_m$ is 0 or π , if $\varphi_k(r) = +1$ or -1 , respectively, as per the governing relation Eq. (24).

For better accuracy of results each of the M zones of the pupil is divided into J number of equal area subzones such that the whole exit pupil has $T=MJ$ number of equal area concentric zones (Fig. 7). The outer and inner radii of the j th subzone of the m th zone are given by

$$r_m^j = \left[\frac{(m-1)J + j}{T} \right]^{\frac{1}{2}} \text{ and } r_m^{j-1} = \left[\frac{(m-1)J + (j-1)}{T} \right]^{\frac{1}{2}} \quad (29)$$

respectively.

The normalized complex amplitude distributions on transverse plane in the farfield for Walsh filters $\varphi_k(r)$ is given by

$$F_N(p) = 2 \sum_{m=1}^M \exp[ik\psi_m] \sum_{j=1}^J \int_{r_m^{j-1}}^{r_m^j} J_0(pr) r dr = 2 \sum_{m=1}^M \exp[ik\psi_m] \sum_{j=1}^J \mathcal{J}_m^j(p) \quad (30)$$

Fig. 7 (a) m th zone in a radial Walsh filter $\varphi_k(r)$ consisting of M concentric equal area zones. (b) j th subzone in the m th zone of the phase filter consisting of J equal area subzones in the m th zone.

where

$$\mathcal{J}_m^j(p) = \left[\frac{r_m^j J_1(pr_m^j) - r_m^{j-1} J_1(pr_m^{j-1})}{p} \right] \quad (31)$$

The normalized intensity distribution on the transverse image plane with radial Walsh filters on $\varphi_k(r)$ the exit pupil is given by

$$I_N(p) = |F_N(p)|^2 = 4 \sum_{m=1}^M \sum_{u=1}^M \cos[k\psi_m - k\psi_u] \sum_{j=1}^J \sum_{v=1}^J \mathcal{J}_m^j(p) \mathcal{J}_u^v(p) \quad (32)$$

For a Walsh filter of zero order on the exit pupil, the transverse intensity distribution on the image/focal plane is the Airy pattern where the normalized central intensity at the origin has magnitude one as in Fig. 4. For any Walsh filter of nonzero order on the exit pupil, the central intensity is zero. There is no central lobe in the transverse intensity distribution on the focal plane in presence of a radial Walsh filter of any order, except for the order zero. A central dip is surrounded by bright and dark rings for all nonzero orders of radial Walsh filters. Fig. 8 presents the intensity distribution on the transverse image/focal plane in presence of selected radial Walsh filters $\varphi_k(r)$, $k=1, \dots, 7$ on the pupil. For the sake of comparison, a part of the Airy pattern is also shown superimposed on the intensity distribution for the filter $\varphi_k(r)$.

Distinct characteristics of the PSF corresponding to individual Walsh filters deserve attention, and may be harnessed in emerging applications like optical encryption. On the other hand, a finite set of orthogonal Walsh filters has already been utilized in the design of optimum amplitude filters for Luneburg's third apodization problem. This problem involves determination of the optimum amplitude filter maximizing the fraction of encircled energy within a circle of prespecified radius w with respect to the total energy in the diffraction pattern. The circle is taken as concentric with the center of the PSF. The amplitude transmission of the optimum filter was taken as consisting of a weighted combination of the first weight radial Walsh functions, so that the pupil function is expressed by

$$f(r) = \sum_{k=0}^7 a_k \varphi_k(r) \quad (33)$$

Fig. 8 Normalized intensity distribution on the transverse image/focal plane with radial Walsh filters $\varphi_k(r)$, $k=1, \dots, 7$.

and the apodizing amplitude filter consists of eight concentric equal area annular zones, amplitude over the whole region of each zone being same. Fig. 9 shows five such filters corresponding to five prespecified values for the radius w . w is expressed in the same dimensionless unit as p . Corresponding PSFs on the image plane are shown in Fig. 10. Note the discerning effects of apodization by the five different filters.

Intensity Distribution Along the Axis Around the Image/Focal Plane

The complex amplitude distribution $F(\chi, \Delta\zeta)$ on the transverse plane located at O'' on the axis needs to be calculated by using Fresnel diffraction formula. With reference to Fig. 11 and Fig. 12, let $E'O' = R'_0$, $E'O'' = R'$ and $O'O'' = R' - R'_0 = \Delta\zeta$, where $\Delta\zeta$ refers to the location of the transverse plane with reference to the focal/image plane, and χ refers to the perpendicular distance of a point on the transverse plane from the axis. Detailed derivation of the Fresnel diffraction formula shows that the complex amplitude

Fig. 9 Optimum eight step apodizing filters corresponding to different values of w . —, $w=0$; — —, $w=2.0$; - · - ·, $w=3.0$; · · · ·, $w=4.0$; xxxx, $w=5.0$. Reprinted with permission from Hazra, L.N., 1977. A new class of optimum amplitude filters. Optics Communications 21, 232–236.

distribution on the transverse plane at O'' is given by a two dimensional Fourier transform of the defocused pupil function of the imaging system. For an axially symmetric pupil function, the 3D distribution of the complex amplitude near the region of the image/focal plane is given by, to a multiplicative factor C ,

$$F(\chi, \Delta\zeta) = C \int_0^1 f(r) \exp[ik W_{20} r^2] J_0(pr) r dr \quad (34)$$

In Eq. (36) below, the axial shift $\Delta\zeta$ of the transverse plane is expressed in terms of “defocus” aberration W_{20} , where the wave aberration function $W(r)$ is given by

$$W(r) = W_{20} r^2 \quad (35)$$

W_{20} is related to $\Delta\zeta$ by

$$W_{20} = \frac{1}{2} n h^2 \left(\frac{1}{R'_0} - \frac{1}{R'} \right) = \frac{1}{2n} (n \sin \alpha)^2 \Delta\zeta \quad (36)$$

where h is the maximum semidiameter of the exit pupil.

Instead of actual distances χ and $\Delta\zeta$, expressions for complex amplitude $F(p, a)$ are derived for normalized dimensionless parameters p and a , respectively. p has been already defined in Eq. (8), and the reduced axial coordinate a is related to $\Delta\zeta$ by

$$a = \frac{1}{n\lambda} (n \sin \alpha)^2 \Delta\zeta \quad (37)$$

where $\Delta\zeta$ is the actual longitudinal shift representing the axial distance of the transverse plane from the paraxial focal plane, as shown in Fig. 11. n represents the refractive index of the image space, and $(n \sin \alpha)$ is the image space numerical aperture.

W_{20} is related to a by

$$kW_{20} = a\pi \quad (38)$$

Notwithstanding the use of Hankel transform in evaluation of the complex amplitude on a defocused plane, it should be noted that the numerical results for intensity remain valid even for larger values of a if the oscillatory integral in Eq. (34) is evaluated correctly. Special measures were undertaken in our numerical quadrature algorithm as noted below.

In presence of phase filter $Q(r)$, the defocused pupil function $f(r)$ is given by

$$f(r) = \exp[ik\{Q(r) + W_{20}r^2\}] \quad (39)$$

For better accuracy of results each of the M zones of the pupil is divided into J number of equal area subzones as in Fig. 7 such that the whole exit pupil has $T=MJ$ number of equal area concentric zones. For each of these subzones the outer and inner radii r_m^j

Fig. 10 Point spread functions (PSFs) corresponding to the optimum filters of Fig. 9. The intensity scale is linear up to $p=6.0$; a logarithmic scale is used for $p \geq 4.0$ for better display of the sidelobes. —, $w=0$; — —, $w=2.0$; - - - , $w=3.0$; , $w=4.0$; xxx, $w=5.0$. Reprinted with permission from Hazra, L.N., 1977. A new class of optimum amplitude filters. *Optics Communications* 21, 232–236.

and r_m^{j-1} are given by

$$r_m^j = \left[\frac{(m-1)J + j}{T} \right]^{\frac{1}{2}}$$

$$r_m^{j-1} = \left[\frac{(m-1)J + (j-1)}{T} \right]^{\frac{1}{2}} \quad (40)$$

The normalized complex amplitude at a point O'' on the axis is

$$F_N(a) = F_N(\Delta\zeta) = 2 \sum_{m=1}^M \exp[ik\eta/m] \sum_{j=1}^J \exp[ik\bar{W}_m^j] \int_{r_m^{j-1}}^{r_m^j} r dr \quad (41)$$

Fig. 11 Exit pupil, image plane and an axially shifted transverse plane in the image space of an axially symmetric imaging system.

Fig. 12 Shift of image plane by $\Delta\zeta$ gives rise to defocus or “Defect of Focus” aberration [Q”Q’].

The axial shift $O'O'' = \Delta\zeta$ (as in Fig. 12). $\bar{W}_m^j$ is the average value of $W(r)$ over the j th subzone of the m th zone and is given by

$$\overline{W}_m^j = \frac{\int_{r_m^{j-1}}^{r_m^j} W(r) r dr}{\int_{r_m^{j-1}}^{r_m^j} r dr} = \frac{W_{20}}{2T} [2(m-1)J + (2j-1)] \quad (42)$$

and

$$\int_{r_m^{j-1}}^{r_m^j} r dr = \Re_j = \left[\frac{(r_m^j)^2}{2} - \frac{(r_m^{j-1})^2}{2} \right] = \left[\frac{1}{2T} \right] \quad (43)$$

In Eq. (26) it is seen that the radial Walsh filter $\varphi_k(r)$ can be expressed as

$$\varphi_k(r) = \sum_{m=1}^M e^{ik\psi_m} B_m(r) \quad (44)$$

From the defining relation Eq. (24) the value of $\varphi_k(r)$ over the m -th annular zone with inner and outer radii given by Eq. (28) is either $+1$ or -1 ; value of $e^{ik\psi_m}$ on the m -th annular zone of the corresponding radial Walsh filter is either $+1$ or -1 so that the phase $k\psi_m$ on the m -th zone is either 0 or π , respectively.

From Eqs. (41–44)

$$F_N(a) = \frac{1}{T} \sum_{m=1}^M \exp[ik\psi_m] \sum_{j=1}^J \exp[ik\bar{W}_m^j] \quad (45)$$

Therefore, when the radial Walsh filter $\phi_k(r)$ is used as an optical mask over the exit pupil, the normalized intensity distribution along the axis may be expressed as

$$I_N(a) = |F_N(\Delta\zeta)|^2 = \frac{1}{T^2} \sum_{m=1}^M \sum_{u=1}^M \sum_{j=1}^J \sum_{v=1}^J \cos\left[\{k\psi_m - k\psi_u\} + \{k\bar{W}_m^j - k\bar{W}_u^v\}\right] \quad (46)$$

Illustrative results for variation of normalized axial intensity with the distance from the focal/image plane are presented in Fig. 13 when radial Walsh filters $\phi_k(r)$ are used as optical masks on the exit pupil. The positive and negative values of a represent axial shifts on either side of the focal/image plane. For the radial Walsh filter $\phi_0(r)$, which is same as the Airy pupil, the axial intensity on the image plane is maximum. But for all radial Walsh filters of integral order other than zero, the axial intensity on the

Fig. 13 Normalized intensity distribution along the axis around the transverse image/focal plane with radial Walsh filters $\phi_k(r)$, $k=0,\dots,7$.

image plane is zero. However, for all filters, the intensity along the axis is same for both $+\Delta\zeta$ and $-\Delta\zeta$, where $\Delta\zeta$ represents the distance of the point O'' from O' (Fig. 11).

For Walsh filters of order 0, there is one peak in the axial intensity distribution. In case of radial Walsh filters of lower orders, two distinct peaks are present, and locations and local variation of intensity surrounding the peaks depend on the order of the function. As the order of the radial Walsh filter increases, more peaks of varying intensities appear, but all peaks are located symmetrically with respect to the image plane. Number, location and intensity level in the peaks can be tailored by suitable combination of radial Walsh filters.

Intensity Distribution on Neighboring Transverse Planes Shifted Axially From the Image Plane

Following the analyses presented above, the normalized complex amplitude distribution on a transverse plane located at an axial distance of $\Delta\zeta$ from the image/focal plane (Fig. 11) is given by

$$F_N(p, a) = F_N(\chi, \Delta\zeta) = 2 \sum_{m=1}^M \exp[ik\psi_m] \sum_{j=1}^J \exp[ik\bar{W}_m^j] \int_{r_m^{j-1}}^{r_m^j} I_0(pr) r dr \quad (47)$$

where $\bar{W}_m^j$ is the average value of the wave aberration function over the j th subzone of the m th zone and is given by

$$\bar{W}_m^j = \frac{\int_{r_m^{j-1}}^{r_m^j} W(r) r dr}{\int_{r_m^{j-1}}^{r_m^j} r dr} = \frac{W_{20}}{2T} [2(m-1)J + (2j-1)] \quad (48)$$

and

$$\int_{r_m^{j-1}}^{r_m^j} I_0(pr) r dr = \mathcal{J}_m^j(p) = \left[\frac{r_m^j J_1(pr_m^j) - r_m^{j-1} J_1(pr_m^{j-1})}{p} \right] \quad (49)$$

From Eqs. (47)–(49) it follows

$$F_N(p, a) = 2 \sum_{m=1}^M \exp[ik\psi_m] \sum_{j=1}^J \exp[ik\bar{W}_m^j] \mathcal{J}_m^j(p) \quad (50)$$

When a radial Walsh filter $\phi_k(r)$ is used as an optical mask on the exit pupil, the normalized intensity distribution $I_N(p, a)$ on a neighboring transverse plane located at an axial distance of $\Delta\zeta$ from the image/focal plane is given by squared modulus of $F_N(p, a)$. It follows

$$I_N(p, a) = 4 \sum_{m=1}^M \sum_{u=1}^M \sum_{j=1}^J \sum_{v=1}^J \cos[\{k\psi_m - k\psi_u\} + \{k\bar{W}_m^j - k\bar{W}_u^v\}] \mathcal{J}_m^j(p) \mathcal{J}_u^v(p) \quad (51)$$

A cross section of the three dimensional light distributions around the focal plane produced by some of the radial Walsh filters are presented in Fig. 12. On account of axial symmetry of the imaging system, the intensity distribution is the same along any plane containing the ζ axis. The intensity distribution along (χ, ζ) plane in the focal/image region is presented in Fig. 14 for the radial Walsh filters $\phi_k(r)$, $k=0, 1, 2, \dots, 7$. The elliptical blobs or patches of focussed light seen in the figures are the cross sections of the 3D intensity distributions produced near the focus. Except for the case of $\phi_0(r)$, where a single structure is observed, in all other cases multiple structures are observed. The number and locations of the regions of high light concentration, and the local variation of light intensity in these regions can be tailored by using suitable weighted combination of radial Walsh filters. These regions of high light concentration are effectively multiple optical traps.

Walsh Filters and Self-Similarity

The set of radial Walsh filters can be classified into distinct self-similar groups and subgroups where members of each subgroup possess self-similar structures or phase sequences. The axial and transverse intensity distributions, and also the three dimensional light distribution around the image plane exhibited by one radial filter are similar to the same exhibited by other members of the self-similar group to which the filter belongs. This characteristic of Walsh filters is quite similar to that exhibited by fractal zone plates and other fractal diffracting apertures.

In case of higher order Walsh functions, one or more of the annular zones may become very narrow, so much so that analysis based on scalar diffraction theory may not be valid. Similarly, predictions based on scalar theory are incorrect when optical masks

Fig. 14 Intensity distribution along (χ, ζ) plane in the focal/image region with the radial Walsh filters $\varphi_k(r)$, $k=0,1,2,\dots,7$ on the exit pupil.

using Walsh functions are used in imaging systems of high numerical aperture. Both these challenges can be tackled by using vector diffraction theory.

Introduction

Since the inception of quantum mechanics almost a century ago, a prime activity has been the observation of quantum phenomena in virtually all areas of chemistry and physics. However, the natural evolution of science leads to the desire to go beyond passive observation to active manipulation of quantum mechanical processes. Achieving control over quantum phenomena could be viewed as engineering at the atomic scale guided by the principles of quantum mechanics, for the alteration of system properties or dynamic behavior. From this perspective, the construction of quantum mechanically operating solid-state devices through selective material growth would fall into this category. The focus of this article is principally on the manipulation of quantum phenomena through tailored laser pulses. The suggestion of using coherent radiation for the active alteration of microworld processes may be traced to the early 1960s, almost immediately after the discovery of lasers. Since then, the subject has grown enormously to encompass the manipulation of (1) chemical reactions, (2) quantum electron transport in semiconductors, (3) excitons in solids, (4) quantum information systems, (5) atom lasers, and (6) high harmonic generation, amongst other topics. Perhaps the most significant use of these techniques may be their provision of refined tools to ultimately better understand the basic physical interactions operative at the atomic scale.

Regardless of the particular application of laser control over quantum phenomena, there is one basic operating principle involved: active manipulation of constructive and destructive quantum wave interferences. This process is depicted in Fig. 1, showing the evolution of a quantum system from the initial state $|\psi_i\rangle$ to the desired final state $|\psi_f\rangle$ along three of possibly many interfering pathways. In general, there may be many possible final accessible states $|\psi_f\rangle$, and often the goal is to achieve a high amplitude in one of these states and low amplitude in all the others. The target state might actually be a superposition of states, and an analogous picture to that in Fig. 1 would also apply to steering about the density matrix. The process depicted in Fig. 1 may be thought of as a microscale analog of the classic double-slit experiment for light waves. As the goal is often high-finesse focusing into a particular target quantum state, success may call for the manipulation of many quantum pathways (i.e., the notion of a 'many-slit' experiment). Most applications are concerned with achieving a desirable outcome for the expectation value $\langle\psi_f|O|\psi_f\rangle$ associated with some observable Hermitian operator O .

The practical realization of the task above becomes a control problem when the system is expressed through its Hamiltonian $H=H_0+V_c$ where H_0 is the free Hamiltonian describing the dynamics without explicit control; it is assumed that the free evolutionary dynamics under H_0 will not satisfactorily achieve the physical objective. Thus, a laboratory-accessible control term V_c is introduced in the Hamiltonian to achieve the desired manipulation. Even just considering radiative interactions, the form of V_c could be quite diverse depending on the nature of the system (e.g., nuclear spins, electrons, atoms, molecules, etc.) and the intensity of the radiation field. Many problems may be treated through an electric dipole interaction $V_c=-\boldsymbol{\mu}\cdot\boldsymbol{\varepsilon}(t)$ where $\boldsymbol{\mu}$ is a system dipole moment and $\boldsymbol{\varepsilon}(t)$ is the laser electric field. Where appropriate, this article will consider the interaction in this form, but other suitable radiative control interactions may be equally well treated. Thus, the laser field $\boldsymbol{\varepsilon}(t)$ as a function of time (or frequency) is at our disposal for attempted manipulation of quantum systems.

Before considering any practical issues associated with the identification of shaped laser control fields, a fundamental question concerns whether it is, in principle, possible to steer about any particular quantum system from an arbitrary initial state $|\psi_i\rangle$ to an arbitrary final state $|\psi_f\rangle$. Questions of this sort are addressed by a controllability analysis of Schrödinger's equation

$$i\hbar\frac{\partial|\psi(t)\rangle}{\partial t}=[H_0-\boldsymbol{\mu}\cdot\boldsymbol{\varepsilon}(t)]|\psi(t)\rangle, \quad |\psi(0)\rangle=|\psi_i\rangle \quad (1)$$

Controllability concerns whether, in principle, some field $\boldsymbol{\varepsilon}(t)$ exists, such that the quantum system described by $H_0=H_0-\boldsymbol{\mu}\cdot\boldsymbol{\varepsilon}(t)$ permits arbitrary degrees of control. For finite-dimensional quantum systems (i.e., those described by evolution amongst a discrete

Fig. 1 The evolution of a quantum system under laser control from the initial state $|\psi_i\rangle$ to the final state $|\psi_f\rangle$. The latter state is chosen to have desirable physical properties, and three of possibly many pathways between the states are depicted. Successful control of the process $|\psi_i\rangle \rightarrow |\psi_f\rangle$ by a tailored laser pulse generally requires creating constructive quantum wave interferences in the state $|\psi_f\rangle$ from many pathways, and destructive interferences in all other accessible final states $|\psi_f\rangle \neq |\psi_f\rangle$.

set of quantum states), the formal tools for such a controllability analysis exist both for evaluating the controllability of the wave function, as well as the more general time evolution operator $U(t)$, which satisfies

$$i\hbar \frac{\partial U}{\partial t} = [H_0 - \boldsymbol{\mu} \cdot \boldsymbol{\varepsilon}(t)]U, \quad U(0) = 1 \quad (2)$$

Analyses of this type can be quite insightful, but they require detailed knowledge about H_0 and $\boldsymbol{\mu}$. Cases involving quantum information science applications are perhaps the most demanding with regard to achieving total control. Most other physical applications would likely accept much more modest levels of control and still be categorized as excellent achievements.

Theoretical tools and concepts have a number of roles in considering the control of quantum systems, including (1) an exploration of physical/chemical phenomena under active control, (2) the design of viable control fields, (3) the development of algorithms to actively guide laboratory control experiments towards achieving their dynamical objectives, and (4) the introduction of special algorithms to reveal the physical mechanisms operative in the control of quantum phenomena. Activities (1)–(3) have thus far been the primary focus of theoretical studies in this area, and it is anticipated that item (4) will grow in importance in the future.

A few comments on the history of laser control over quantum systems are relevant, as they speak to the special nature of the currently employed successful closed-loop quantum control experiments. Starting in the 1960s and spanning roughly 20 years, it was thought that the design of lasers to manipulate molecular motion could be achieved by the application of simple physical logic and intuition. In particular, the thinking at the time focused on using cw laser fields resonant with one or more local modes of the molecule, as state or energy localization was believed to be the key to successful control. Since quantum dynamics phenomena typically occur on ultrafast time-scales, possibly involving spatially dispersed wave packets, expecting to achieve high quality control with a light source operating at one or two resonant frequencies is generally wishful thinking. Quantum dynamics phenomena occur in a multifrequency domain, and controls with a few frequencies will not suffice. Over approximately the last decade, it became clear that successful control often calls for manipulating multiple interfering quantum pathways (cf., Fig. 1). In turn, this recognition led to the need for broad-bandwidth laser sources (i.e., tailored laser pulses). Fortunately, the necessary laser pulse-shaping technologies have become available, and these sources continue to expand into new frequency ranges with enhanced bandwidth capabilities. Many chemical and physical applications of control over quantum phenomena involve performing a significant amount of work (i.e., quantum mechanical action), and sufficient laser field intensity is required. A commonly quoted adage is ‘no field, no yield’, and at the other extreme, there was much speculation that operating nonlinearly at high field intensities would lead to a loss of control because the quantum system would effectively act as an amplifier of even weak laser field noise. Fortunately, the latter outcome has not occurred, as is evident from a number of successful high field laser control experiments.

Quantum control may be expressed as an inverse problem with a prescribed chemical or physical objective, and the task being the discovery of a suitable control field $\boldsymbol{\varepsilon}(t)$ to meet the objective. Normally, Schrödinger’s Eq. (1) is viewed as linear, and this perspective is valid if the Hamiltonian is known a priori, leaving the equation to be solved for the wave function. However, in the case of quantum control, neither the wave function nor the control field is known a priori, and the two enter bilinearly on the right-hand side of Eq. (1). Thus, quantum control is mathematically a nonlinear inverse problem. As such, one can anticipate possibly diverse behavior in the process of seeking successful controls, as well as in the ensuing quantum dynamical control behavior. The control must take into account the evolving system dynamics, thereby resulting in the control field being a function (a) of the current state of the system $\boldsymbol{\varepsilon}(\psi)$ in the case of quantum control design, or dependent on the system observations $\boldsymbol{\varepsilon}(\langle O \rangle)$ in the case of laboratory closed-loop field discovery efforts where $\langle O \rangle = \langle \psi | O | \psi \rangle$. Furthermore, the control field at the current time t will depend in some implicit fashion on the future state of the evolving system at the final target time T . It is evident that control field design and laboratory discovery present highly nontrivial tasks.

Although the emphasis in this review is on the theoretical aspects of quantum control theory, the subject exists for its laboratory realizations, and those realizations, in turn, intimately depend on the capabilities of theoretical and algorithmic techniques for their successful implementations. Accordingly, theoretical laser control field design techniques will be discussed, along with algorithmic aspects of current laboratory practice. This material respectively will focus on optimal control theory (OCT) and optimal control experiments (OCEs), as seeking optimality provides the best means to achieve any posed objective. Finally, the last part of the article will present some general conclusions on the state of the quantum control field.

Quantum Optimal Control Theory for Designing Laser Fields

When considering control in any domain of application, a reasonable approach is to computationally design the control for subsequent implementation in the laboratory. Quantum mechanical laser field design has taken on a number of realizations. At one limit is the application of simple intuition for design purposes, and in some special cases (e.g., the weak field perturbation theory regime), this approach may be applicable. Physical insights will always play a central role in laser field design, but to be especially useful, they need to be channeled into the proper mathematical framework. Many of the interesting applications operate in the strong-field nonperturbative regime. In this domain, serious questions arise regarding whether sufficient information is available about the Hamiltonian to execute reliable designs. Regardless of whether the Hamiltonian is known accurately or is an

acknowledged model, the theoretical study of quantum control can provide physical insight into the phenomena involved, as well as possibly yielding trial laser pulses for further refinement in the laboratory.

Achieving control over quantum mechanical phenomena often involves a balance of competing dynamical processes. For example, in the case of aiming to create a particular excitation in a molecule or material, there will always be the concomitant need to minimize other unwanted excitations. Often, there are also limitations on the form, intensity, or other characteristics of the laser controls that must be adhered to. Another goal is for the control outcome to be as robust as possible to the laser field fluctuations and Hamiltonian uncertainties. Overriding all of these issues is merely the desire to achieve the best possible physical result for the posed quantum mechanical objective. In summary, all of these desired extrema conditions translate over to posing the design of control laser fields as an optimization problem. Thus, optimal control theory forms a basic foundation for quantum control field design.

Control field design starts by specification of the Hamiltonian components H_0 and μ in Eq. (1), with the goal of finding the best control electric field $\varepsilon(t)$ to balance the competing objectives. Schrödinger's equation must be solved as part of this process, but this effort is not merely a forward propagation task, as the control field is not known a priori. As an optimal design is the goal, a cost functional $J = J(\text{objectives, penalties, } \varepsilon(t))$ is prescribed, which contains the information on the physical objectives, competing penalties, and any costs or constraints associated with the structure of the laser field. The functional J could contain many terms if the competing physical goals are highly complex. As a specific simple illustration, consider the common goal of steering the system to achieve an expectation value $\langle \psi(T) | O | \psi(T) \rangle$ as close as possible to the target value O_{target} associated with the observable operator O at time T . An additional cost is imposed to minimize the laser fluence. These criteria may be embodied in a cost functional of the form

$$J = \left(\langle \psi(T) | O | \psi(T) \rangle - O_{\text{target}} \right)^2 + \omega \int_0^T \varepsilon^2(t) dt - 2 \Im \int_0^T dt \left\langle \lambda(t) \left| i\hbar \frac{\partial}{\partial t} - H_0 + \mu \cdot \varepsilon(t) \right| \psi(t) \right\rangle \quad (3)$$

Here, the parameter $\omega \geq 0$ is a weight to balance the significance of the fluence term relative to achieving the target expectation value, and $|\lambda(t)\rangle$ serves as a Lagrange multiplier, assuring that Schrödinger's equation is satisfied during the variational minimization of J with respect to the control field. Carrying out the latter minimization will lead to Eq. (1), along with the additional relations

$$i\hbar \frac{\partial}{\partial t} |\lambda(t)\rangle = [H_0 - \mu \cdot \varepsilon(t)] |\lambda(t)\rangle, \quad |\lambda(T)\rangle = 2\sigma O |\lambda(T)\rangle \quad (4)$$

$$\varepsilon(t) = \frac{1}{\omega} \Im \langle \lambda(t) | \mu | \psi(t) \rangle \quad (5)$$

$$\sigma = \langle \psi(T) | O | \psi(T) \rangle - O_{\text{target}} \quad (6)$$

Eqs. (1) and (4)–(6) embody the OCT design equations that must be solved to yield the optimal field $\varepsilon(t)$ given in Eq. (5). These design equations have an unusual mathematical structure within quantum mechanics. First, insertion of the field expression in Eq. (5) into Eqs. (1) and (4) produces two cubically nonlinear coupled Schrödinger-like equations. These equations are in the same family as the standard nonlinear Schrödinger equation, and as such, one may expect that unusual dynamical behavior could arise. Although Eq. (4) for $|\lambda(t)\rangle$ is identical in form to the Schrödinger Eq. (1), only $|\psi(t)\rangle$ is the true wavefunction, with $|\lambda(t)\rangle$ serving to guide the controlled quantum evolution towards the physical objective. Importantly, Eq. (1) is an initial value problem, while Eq. (4) is a final value problem. Thus, the two equations together form a two-point boundary value problem in time, which is an inherent feature of temporal engineering optimal control as well. The boundary value nature of these equations typically leads to the existence of multiple solutions, where σ in Eq. (6) plays the role of a discrete eigenvalue, specifying the quality of the particular achieved control field design. The fact that there are generally multiple solutions to the laser design equations can be attractive from a physical perspective, as the designs may be sorted through to identify those being most attractive for laboratory implementation.

The overall mathematical structure of Eqs. (1) and (4)–(6) can be melded together into a single design equation

$$i\hbar \frac{\partial}{\partial t} |\psi(t)\rangle = [H_0 - \mu \cdot \varepsilon(\psi, \sigma, t)] |\psi(t)\rangle, \quad |\psi(0)\rangle = |\psi_i\rangle \quad (7)$$

The structure of this equation embodies the comments in the introduction that control field design is inherently a nonlinear process. The main source of complexity arising in Eq. (7) is through the control field $\varepsilon(\psi, \sigma, t)$ depending not only on the wave function at the present time t , but also on the future value of the wavefunction at the target time T contained in σ . This structure again reflects the two-point boundary value nature of the control equations.

Given the typical multiplicity of solutions to Eqs. (1) and (4)–(6), or equivalently, Eq. (7), it is attractive to consider approximations to these equations (except perhaps for the inviolate Schrödinger Eq. (1), and much work continues to be done along these lines. One case involves what is referred to as tracking control, whereby a path is specified for $\langle \psi(t) | O | \psi(t) \rangle$ evolving from $t=0$ out to $t=T$. Tracking control eliminates σ to produce a field of the form $\varepsilon(\psi, t)$, thereby permitting the design equations to be explicitly integrated as a forward-marching problem toward the target; the tracking equations are still nonlinear with respect to the evolving state. Many variations on these concepts can be envisioned, and other approximations may also be introduced to deal with special circumstances. One technique appropriate for at least few-level systems is stimulated Raman adiabatic passage (STIRAP), which seeks robust adiabatic passage from an initial state to a particular final state, typically with nearly total destructive interference

occurring in the intermediate states. This design technique can have special attractive robustness characteristics with respect to field errors. STIRAP, tracking, and various perturbation theory-based control design techniques can be expressed as special cases of OCT, with suitable cost functionals and constraints. Further approximation methods will surely be developed, with the rigorous OCT concepts forming the general foundation for control field design.

As the OCT equations are inherently nonlinear, their solution typically requires numerical iteration, and a variety of procedures may be utilized for this purpose. Almost all of the methods employ local search techniques (e.g., gradient methods), and some also show monotonic convergence with respect to each new iteration step. Local techniques typically evolve to the nearest solution in the space of possible control fields. Such optimizations can be numerically efficient, although the quality of the attained result can depend on the initial trial for the control field and the details of the algorithm involved. In contrast, global search techniques, such as simulated annealing or genetic algorithms, can search more broadly for the best solution in the control field space. These more expansive searches are attractive, but at the price of typically requiring more intensive computations. Effort has also gone into seeking global or semiglobal input $\rightarrow$ output maps relating the electric field $\epsilon(t)$ structure to the observable $O[\epsilon(t)]$. Such maps may be learned, hopefully, from a modest number of computations with a selected set of fields, and then utilized as high-speed interpolators over the control field space to permit the efficient use of global search algorithms to attain the best control solution possible. At the foundation of all OCT design procedures is the need to solve the Schrödinger equation. Thus, computational technology to improve this basic task is of fundamental importance for designing laser fields.

Many computations have been carried out with OCT to attain control field designs for manipulating a host of phenomena, including rotational, vibrational, electronic, and reactive dynamics of molecules, as well as electron motion in semiconductors. Every system has its own rich details, which in turn, are compounded by the fact that multiple control designs will typically exist in many applications producing comparable physical outcomes. Collectively, these control design studies confirm the manipulation of constructive and destructive quantum wave interferences as the general mechanism for achieving successful control over quantum phenomena. This conclusion may be expressed as the following principle:

Control field–system cooperativity principle: Successful quantum control requires that the field must have the proper structure to take full advantage of all of the dynamical opportunities offered by the system, to best satisfy the physical objective.

This simple statement of system–field cooperativity embodies the richness, as well as the complexity, of seeking control over quantum phenomena, and also speaks to why simple intuition alone has not proved to be a generally viable design technique. Quantum systems can often exhibit highly complex dynamical behavior, including broad dispersion of the wave packet over spatial domains or multitudes of quantum states. Handling such complexity can require fields with subtle structure to interact with the quantum system in a global fashion to manage all of the motions involved. Thus, we may expect that successful control pulses will often have broad bandwidth, including amplitude and phase modulation. Until relatively recently, laser sources with these characteristics were not available, but the technology is now in hand and rapidly evolving (see the discussion later).

The cooperativity principle above is of fundamental importance in the control of all quantum phenomena, and a simple illustration of this principle is shown in Fig. 2 for the control of wave packet motion on an excited state of the NO molecule.

Fig. 2 Control of wave packet evolution on the electronically excited B state of NO, with the goal of creating a narrow final packet over the excited state well. (a) indicates that the ground-state packet is brought up in two pieces using the coordinated dual pulse in (b). The piece of the packet from the first pulse actually passes through the target region, then bounces off the right side of the potential, to finally meet the second piece of the packet at just the right time over the target location r^* for successful control. This behavior is an illustration of the control field–system cooperativity principle stated in the text.

The target for the control is a narrow wave packet located over the well of the excited Bstate. The optimal control field consists of two coordinated pulses, at early and late times, with both features having internal structure. The figure indicates that the ensuing excited state wave packet has two components, one of which actually passes through the target region during the initial evolution, only to return again and meet the second component at just the right place and time, to achieve the target objective as best as possible. Similar cooperativity interpretations can be found in virtually all implementations with OCT.

The main reason for performing quantum field design is to ultimately implement the designs in the laboratory. The design procedures must face laboratory realities, which include the fact that most Hamiltonians are not known to high accuracy (especially for polyatomic molecules and complex solid-state structures), and secondly, a variety of laboratory field imperfections may unwittingly be present. Notwithstanding these comments, OCT has been fundamental to the development of quantum control, including laying out the logic for how to perform the analogous optimal control experiments. Design implementations and further OCT development will continue to play a basic role in the quantum control field. At present, perhaps the most important contribution of OCT has been to (1) highlight the basic control cooperativity principle above, and (2) provide the basis for developing algorithms to successfully guide optimal control experiments, as discussed below.

Algorithms for Implementing Optimal Control Experiments

The ultimate purpose of considering control theory within quantum mechanics is to take the matter into the laboratory for implementation and exploitation of its capabilities. Ideally, theoretical control field designs may be attained using the techniques discussed above, followed by the achievement of successful control upon execution of the designs in the laboratory. This appealing approach is burdened with three difficulties: (1) Hamiltonians are often imprecisely known, (2) accurately solving the design equations can be a significant task, and (3) realization of any given design will likely be imperfect due to laboratory noise or other unaccounted-for systematic errors. Perhaps the most serious of these difficulties is point (1), especially considering that the best quality control will be achieved by maximally drawing on subtle constructive and destructive quantum wave interference effects. Exploiting such subtleties will generally require high-quality control designs that, in turn, depend on having reliable Hamiltonians. Although various designs have been carried out seeking robustness with respect to Hamiltonian uncertainties, the issue in point (1) should remain of significance in the foreseeable future, especially for the most complex (and often, the most interesting!) chemical/physical applications. Mitigating this serious problem is the ability to create shaped laser pulse controls and apply them to a quantum system, followed by a probe of their effects at an unprecedented rate of thousands or more independent trials per minute. This unique capability led to the suggestion of partially, if not totally, sidestepping the design process by performing closed-loop experiments to let the quantum system teach the laser how to achieve its control in the laboratory. Fig. 3 schematically shows this closed loop process, drawing on the following logic:

1. **The molecular view.** Although there may be theoretical uncertainty about the system Hamiltonian, the actual chemical/physical system under study 'knows' its own Hamiltonian precisely! This knowledge would also include any unusual exigencies, perhaps associated with structural or other defects in the particular sample. Furthermore, upon exposure to a control field, the system 'solves' its own Schrödinger equation impeccably accurately and as fast as possible in real time. Considering these points, the aim is to replace the offline arduous digital computer control field design effort with the actual quantum system under study acting as a precise analog computer, solving the true equations of motion.
2. **Control laser technology.** Pulse shaping under full computer control may be carried out using even hundreds of discrete elements in the frequency domain controlling the phase and amplitude structure of the pulse. This technology is readily available and expanding in terms of pulse center frequency flexibility and bandwidth capabilities.
3. **Quantum mechanical objectives.** Many chemical/physical objectives may be simply expressed as the desire to steer a quantum mechanical flux out one clearly defined channel versus another.
4. **Detection of the control action.** Detection of the control outcome can often be carried out by a second laser pulse or any other suitable high duty cycle detection means, such as laser-induced mass spectrometry. The typical circumstance in point (3) implies that little, if any, time-consuming offline data analysis will be necessary beyond that of simple signal averaging.
5. **Fast learning algorithms.** All of the four points above may be slaved together using pattern recognition learning algorithms to identify those control fields which are producing better results, and bias the next sequence of experiments in their favor for further improvement. Although many algorithms may be employed for this purpose, the global search capabilities of genetic algorithms are quite attractive, as they may take full advantage of the high throughput nature of the experiments.

In linking together all of these components into a closed-loop OCE, it is important that no single operational step significantly lags behind any other, for efficiency reasons. Fortunately, this economy is coincident with all the tasks and technologies involved. For achieving control alone, there is no requirement that the actual laser pulse structure be identified on each cycle of the loop. Rather, the laser control 'knob' settings are adequate information for the learning algorithm, as the only criterion is to suitably adjust the knobs to achieve an acceptable value for the chemical/physical objective. The learning algorithm in point (5) operates with a cost functional J , analogous to that used for computational design of fields, but now the cost functional can only depend on those quantities directly observable in the laboratory (i.e., minimally, the current achieved target expectation value). In cases where a physical understanding is sought about the control mechanism, the laser field structure must also be measured. This additional

Fig. 3 A schematic of the closed-loop concept for allowing the quantum system to teach the laser how to achieve its control. The actual quantum system under control is in a loop with a laser and pulse shaper all slaved together with a pattern recognition algorithm to guide the excursions around the loop. The success of this concept relies on the ability to perform very large numbers of control experiments in a short period of time. In principle, no knowledge of the system Hamiltonian is required to steer the system to the desired final objective, although a good trial design $\varepsilon_0(t)$ may accelerate the process. The i th cycle around the loop attempts to find a better control field $\varepsilon_i(t)$ such that the system response $\langle O(T) \rangle_i$ for the observable operator O comes closer to the desired value O_{target} .

information is typically also not a burden to attain, as it often is only required for the single best control field at the end of the closed-loop learning experiments.

The OCE process in Fig. 3 and steps (1)–(5) above constitute the laboratory process for achieving optimal quantum control, and exactly the same reasons put forth for OCT motivate the desire for attaining optimal performance: principally, seeking the best control result that can possibly be obtained. Seeking optimal performance also ensures some degree of inherent robustness to field noise, as fleeting observations would not likely survive the signal averaging carried out in the laboratory. Additionally, robustness as a specific criterion may also be included in the laboratory cost functional in item (5). When a detailed physical interpretation of the controlled dynamics is desired, it is essential to remove any extraneous control field features that have little impact on the system manipulations. Without the latter clean-up carried out during the experiments, the final field may be contaminated by structures that have little physical impact. Although quantum dynamics typically occurs on femtosecond or picosecond time-scales, the loop excursions in Fig. 3 need not be carried out on the latter time-scales. Rather, the loop may be traversed as rapidly as convenient, consistent with the capabilities of the apparatus. A new system sample is introduced on each cycle of the loop. This process is referred learning control, to distinguish it from real-time feedback control.

The closed-loop quantum learning control algorithm can be self-starting, requiring no prior control field designs, under favorable circumstances. Virtually all of the current experiments were carried out in this fashion. It remains to be seen if this procedure of ‘going in blind’ will be generally applicable in highly complex situations where the initial state is far from the target state. Learning control can only proceed if at least a minimal signal is observed in the target state. Presently, this requirement has been met by drawing on the overwhelmingly large number of exploratory experiments that can be carried out, even in a brief few minutes, under full computer control. However, in some situations, the performance of intermediate observations along the way to the target goal may be necessary in order to at least partially guide the quantum dynamics towards the ultimate objective. Beneficial use could also be made from prior theoretical laser control designs $\varepsilon_0(t)$ capable of at least yielding a minimal target signal.

The OCE closed-loop procedure was based on the growing number of successful theoretical OCT design calculations, even with all of their foibles, especially including less than perfect Hamiltonians. The OCT and OCE processes are analogous, with their primary distinction involving precisely what appears in their corresponding cost functionals. Theoretical guidance can aid in identifying the appropriate cost functionals and learning algorithms for OCE, especially for addressing the needs associated with attaining a physical understanding about the mechanisms governing controlled quantum dynamics phenomena.

A central issue is the rate that learning control occurs upon excursions around the loop in Fig. 3. A number of factors control this rate of learning, including the nature of the physical system, the choice of objective, the presence of field uncertainties and measurement errors, the number of control variables, and the capabilities of the learning algorithm employed. Achieving control is a matter of discrimination, and some of these factors, whether inherent to the system or introduced by choice, may work against

Fig. 4 An illustration of dissociative rearrangement achieved by closed-loop learning control in Fig. 3. The optimally deduced laser pulse broke two bonds in the parent acetophenone molecule and formed a new one to yield the toluene product. The laboratory learning curve is shown for the toluene product signal as a function of the generations in the genetic algorithm guiding the experiments. The fluctuations in the learning curve for optimizing the toluene yield corresponds to the algorithm searching for the optimal yield as the experiments proceed.

attaining good-quality discrimination. At this juncture, little is known quantitatively about the limitations associated with any of these factors.

The latter issues have not prevented the successful performance of a broad variety of quantum control experiments, and at present the ability to carry out massive numbers of closed-loop excursions has overcome any evident difficulties. The number of examples of successful closed-loop quantum control is rapidly growing, with illustrations involving the manipulation of laser dye fluorescence, chemical reactivity, high harmonic generation, semiconductor optical switching, fiber optic pulse transmission, and dynamical discrimination of similar chemical species, amongst others. Perhaps the most interesting cases are those carried out at high field intensities, where prior speculation suggested that such experiments would fail due to even modest laser field noise being amplified by the quantum dynamics. Fortunately, this outcome did not occur, and theoretical studies have indicated that surprising degrees of robustness to field noise may accompany the manipulation of quantum dynamics phenomena. Although the presence of field noise may diminish the beneficial influence of constructive and destructive interferences, evidence shows that field noise does not appear to kill the actual control process, at least in terms of obtaining reasonable values for the control objectives. One illustration of control in the high-field regime is shown in Fig. 4, demonstrating the learning process for the dissociative rearrangement of acetophenone to form toluene. Interestingly, this case involves breaking two bonds, with the formation of a third, indicating that complex dynamics can be managed with suitably tailored laser pulses.

Operating in the strong-field regime, especially for chemical manipulations, also has the important benefit of producing a generic laser tool to control a broad variety of systems by overcoming the long-standing problem of having sufficient bandwidth. For example, the result in Fig. 4 uses a Ti:sapphire laser in the near-infrared regime. Starting with a bandwidth-limited pulse of intensity near $\sim 10^{14}$ W cm $^{-2}$, in this regime, the dynamic power broadening can easily be on the order of ~ 1 eV or more, thereby effectively converting the otherwise discrete spectrum of the molecule into an effective continuum for ready multiphoton matching by the control laser pulse. Operating under these physical conditions is very attractive, as the apparatus is generic, permitting a single shaped-pulse laser source (e.g., a Ti:sapphire system with phase and amplitude modulation) to be utilized with virtually any chemical system where manipulations are desired. Although every desired physical/chemical goal may not be satisfactorily met (i.e., the goals must be physically attainable!), the means are now available to explore large numbers of systems. Operating under closed loop in the strong-field tailored-pulse regime eliminates the prior serious limitation of first finding a physical system to meet the laser capabilities; now, the structure of the laser pulse can be shaped to meet the molecule's characteristics. Strong field operations may be attractive for these reasons, but other broadband laser sources, possibly working at weaker field intensities, might be essential in some applications (e.g., controlling electron dynamics in semiconductors, where material damage is to be avoided). It is anticipated that additional broadband laser sources will become available for these purposes.

The coming years should be a period of rapid expansion, including a thorough exploration of closed-loop quantum control capabilities. As with the use of any laboratory tool, certain applications may be more amenable than others to attaining successful control. The particular physical/chemical questions need to be well posed, and controls need to have sufficient flexibility to meet the objectives. The experiments ahead should be able to reveal the degree to which drawing on optimality in OCE, combined with the performance of massive numbers of experiments can lead to broad-scale successful control of quantum phenomena. One issue of concern is the richness associated with the large numbers of phase and amplitude control knobs that may be adjusted in the laboratory. Some experiments have already operated with hundreds of knobs, while others have restricted their number in a variety of ways, to simplify the search process. Additional technological and algorithmic advances may be required to manage the

Fig. 5 Three possible closed-loop formulations for attaining laser control over quantum phenomena. (a) is a learning control process where a new system is introduced on each excursion around the loop. (b) utilizes feedback control with the loop being traversed with the same sample, generally calling for an accurate model of the system to adjust the controls on each loop excursion. (c) is, at present, a dream machine where the laser and the sample under control are one unit operating without external algorithmic guidance. The closed-loop learning control procedure in (a) appears to form the most practical means to achieve laser control over quantum phenomena, especially for complex systems.

high-dimensional control space searches. Fortunately, for typical applications, the search does not reduce to seeking a needle in a haystack, as generally there are multiple control solutions, possibly all of very good quality.

As a final comment on OCE, it is useful to appreciate the subtle distinction of the procedure from closed-loop feedback experiments. This distinction is illustrated in Fig. 5, pointing to three types of closed-loop quantum control laboratory experiments. The OCE procedure in Fig. 5(a) produces a generic laser tool capable of controlling a broad variety of systems with an emphasis in the figure placed on the point that each cycle around the loop starts with a new sample for control. The replacement of the sample on each cycle eliminates a number of difficulties, principally including concerns about sample damage, avoidance of operating the loop at the ultrafast speed of the quantum mechanical processes, and elimination of the effect that ‘to observe is to disturb’ in quantum mechanics. Thus, learning control provides a generic practical procedure, regardless of the nature of the quantum system. Fig. 5(b) has the same structure as that of Fig. 5(a), except the loop is now closed around the same single quantum system, which is followed throughout its evolution. All of the issues mentioned above that are circumvented by operating through laboratory learning control in Fig. 5(a) must now be directly faced in the setup of Fig. 5(b). The procedure in Fig. 5(b) will likely only be applicable in special circumstances, at least for the reason that many quantum systems operate on time-scales far too fast for opto-electronics and computers to keep up with. However, there are certain quantum mechanical processes that are sufficiently slow to meet the criteria. Furthermore, a period of free evolutionary quantum dynamics may be permitted to occur between one control pulse and the next, to make the time issue manageable. While the learning control process in Figs. 3 and 5(a) can be performed model-free, the feedback algorithm in Fig. 5(b) generally must operate with a sufficiently reliable system Hamiltonian to carry out fast design corrections to the control field, based on the previous control outcome. These are very severe demands, but they may be met under certain circumstances. One reason for considering closed-loop feedback control in Fig. 5(b) is to explore the basic physical issue of quantum mechanical limitations inherent in the statement ‘to observe is to disturb’. It is suggestive that control over many types of quantum phenomena may fall into the semiclassical regime, lying somewhere between classical engineering behavior and the hard limitations of quantum mechanics. Experiments of the type in Fig. 5(b) will be most interesting for exploring this matter. Finally, Fig. 5(c) introduces a *gedanken* experiment in the sense that the closed-loop process is literally built into the hardware. That is, the laser control and quantum system act as a single functioning unit operating in a stable fashion, so as to automatically steer the system to the desired target. This process may involve engineering the quantum mechanical system prior to control in cases where that freedom exists, as well as engineering the laser components involved.

The meaning of such a device in [Fig. 5\(c\)](#) can be understood by considering an analogy with airplane flight, where the aircraft is constructed to have an inherent degree of aerodynamic stability and will essentially fly (glide) on its own accord when pushed forward. It is an open question whether closing the loop in the hardware can be attained for quantum control, and an exploration of this concept may require additional laser technologies.

Conclusions

This article presented an overview of theoretical concepts and algorithmic considerations associated with the control of quantum phenomena. Theory has played a central role in this area by revealing the fundamental principles underlying quantum control, as well as by providing algorithms for designing controls and guiding experiments to discover successful controls in the laboratory. The challenge of controlling quantum phenomena, in one sense, is an old subject, going back at least 40 years. However, roughly the first 30 of these years would best be described as a period of frustration, due to a lack of full understanding of the principles involved and the nature of the lasers needed to achieve success. Thus, from another perspective, the subject is quite young, with perhaps the most notable development being the introduction of closed-loop laboratory learning procedures. At the time of writing this article, these procedures are just beginning to be explored for their full capabilities. To appreciate the young nature of this subject, it is useful to note that the analogous engineering control disciplines presently occupy many thousands of engineers worldwide, both theoreticians and practitioners, and have done so for many years. Yet, engineering control is far from considered a mature subject. Armed now with the basic concepts and proper laboratory tools, one may anticipate a thorough exploration of control over quantum phenomena, including its many possible applications.

Introduction

The experimental control of quantum phenomena in atoms, molecules, and condensed phase materials has been a long-standing challenge in the physical sciences. For example, the idea that a laser beam could be used to selectively cleave a chemical bond has been pursued since the demonstration of the laser in the early 1960s. However, it was not until very recent times that one could realize selective bond cleavage. One key to the rapid acceleration of such experiments is the capability of manipulating the relative phases between two or more paths leading to the same final state. This is done in practice by controlling the phase of two (or two thousand!) laser frequencies coupling the initial state to some desired final state. The present interest in phase-related control stems in part from research focusing on quantum information sciences, controlling chemical reactivity, and developing new optical technologies, such as in biophotonics for imaging cellular materials. Ultimately, one would like to identify coherent control applications having impact similar to linear regime applications like compact disk reading (and writing), integrated circuit fabrication, and photodynamic therapy. Note that in each of these the phase of the electromagnetic field is not an important parameter and only the brightness of the laser at a particular frequency is used. While phase is of negligible importance in any one photon process, for excitations involving two or more photons, phase not only becomes a useful characteristic, it can modulate the yield of a desired process between zero and one hundred percent.

The use of optical phase to manipulate atomic and molecular systems rose to the forefront of laser science in the 1980s. Prior to this there was considerable effort directed toward using the intensity and high spectral resolution features of the laser for various applications. For example, the high spectral resolution character was employed in purifying nuclear isotopes. Highly intense beams were also used in the unsuccessful attempt to pump enough energy into a single vibrational resonance to selectively dissociate a molecule. The current revolution in coherent control has been driven in part by the realization that controlling energy deposition into a single degree of freedom (such as selectively breaking a bond in a polyatomic molecule) can not be accomplished by simply driving a resonance with an ever more intense laser source. In the case of laser-induced photo dissociation, such excitation ultimately results in statistical dissociation throughout the molecule due to vibrational mode coupling. In complex systems, controlling energy deposition into a desired quantum state requires a more sophisticated approach and one scheme involves coherent control.

The two distinct regimes for excitation in coherent control, the time and frequency domain experiments, are formally equivalent. While the experimental approach and level of success for each domain is vastly different, both rely on precisely specifying the phase relations for a series of excitation frequencies. The basic idea behind phase control is simple. One emulates the interference effects that can be easily visualized in a water tank experiment with a wave propagating through two slits. In the coherent control experiment, two or more indistinguishable pathways must be excited that connect one quantum state to another. In either water waves, or coherent control, the probability for observing constructive or destructive interference at a target state depends on the phase difference between the paths connecting the two locations in the water tank, or the initial and final states in the quantum system. In the case of coherent control, the final state may have some technological value, for instance, a desirable chemical reaction product or an intermediate in the implementation of quantum computation.

Frequency domain methods concentrate on interfering two excitation routes in a system by controlling the phase difference between two distinct frequencies coupling an initial state to a final state. Perhaps the first mention of the concept of phase control in the optical regime can be traced to investigations in Russia in the early 1960s, where the interference between a one- and three-photon path was theoretically proposed as a means to modulate a two-photon absorption. This two-path interference idea lay dormant until the reality of controlling the relative phase of two distinct frequencies was achieved in 1990 using gas phase pressure modulation for frequency domain experiments. The idea was theoretically extended to the control of nuclear motion in 1988. The first experimental example of two-color phase control over nuclear motion was demonstrated in 1991. It is interesting that the first demonstrations of coherent control did not, however, originate in the frequency domain approach, but came from time domain investigations in the mid-1980s. This was work that grew directly out of the chemical dynamics community and will be described below.

While frequency domain methods were developed exclusively for the observation of quantum interference, the experimental implementation of time-domain methods was first developed for observing nuclear motion in real time. In the time domain, a superposition of multiple states is prepared in a system using a short duration (~ 50 fs) laser pulse. The superposition state will subsequently evolve according to the phase relationships of the prepared states and the Hamiltonian of the system. At some later time the evolution must be probed using a second, short-time-duration laser pulse. The time-domain methods for coherent control were first proposed in 1985 and were based on wavepacket propagation methods developed in the 1970s. The first experiments were reported in the mid-1980s.

To determine whether the time or frequency domain implementation is more applicable for a particular control context, one should compare the relevant energy level spacing of the quantum system to the bandwidth of the excitation laser. For instance, control of atomic systems is more suited to frequency domain methods because the characteristic energy level spacing in an atom

(several electron volts) is large compared to the bandwidth of femtosecond laser pulses (millielectron volts). In this case, preparation of a superposition of two or more states is impractical with a single laser pulse at the present time, dictating that the control scheme must employ the initial state and a single excited eigenstate. In practice, quasi-CW nanosecond duration laser pulses are employed for such experiments because current ultrafast (fs duration) laser sources cannot typically prepare a superposition of electronic states. One instructive exception involves the excitation of Rydberg states in atoms. Here the electronic energy level spacing can be small enough that the bandwidth of a femtosecond excitation laser may span several electronic states and thus can create a superposition state. One should also note that the next generation of laser sources in the attosecond regime may permit the preparation of a wavepacket from low-lying electronic states in an atom. In the case of molecules, avoiding a superposition state is nearly impossible. Such experiments employ pico- to femtosecond duration laser pulses, having a bandwidth sufficient to excite many vibrational levels, either in the ground or excited electronic state manifold of a molecule. To complete the time-dependent measurement, the propagation of the wavepacket to the final state of interest must be observed (probed) using a second ultrafast laser pulse that can produce fluorescence, ionization, or stimulated emission in a time-resolved manner. The multiple paths that link the initial and final state via the pump and the probe pulses are the key to the equivalence of the time and frequency domain methods.

There is another useful way to classify experiments that have been performed recently in coherent control, that is into either open-loop or closed-loop techniques. Open-loop signifies that a calculation may be performed to specify the required pulse shape for control before the experiment is attempted. All of the frequency-based, and most of the time-based experiments fall into this category. Closed-loop, on the other hand, signifies that the results from experimental measurements must be used to assist in determining the correct parameters for the next experiment, this pioneering approach was suggested in 1992. It is interesting that in the context of control experiments performed to date, closed-loop experiments represent the only route to determining the optimal laser pulse shape for controlling even moderately complex systems. In this approach, no input from theoretical models is required for coherent control of complex systems. This is unlike typical control engineering environments, where closed-loop signifies the use of experiments to refine parameters used in a theoretical model.

There is one additional distinction that is of value for understanding the state of coherent control at the present time. Experiments may be classified into systems having Hamiltonians that allow calculation of frequencies required for the desired interference patterns (thus enabling open-loop experiments) and those having ill-defined Hamiltonians (requiring closed-loop experiments). The open-loop experiments have demonstrated the utility of various control schemes, but are not amenable to systems having even moderate complexity. The closed-loop experiments are capable of controlling systems of moderate complexity but are not amenable to precalculation of the required control fields. Systems requiring closed-loop methods include propagation of short pulses in an optical fiber, control of high harmonic generation for soft X-ray generation, control of chemical reactions and control of biological systems. In the experimental regime, the value of learning control for dealing with complex systems has been well documented.

The remainder of this article represents an overview of the experimental implementation of coherent control. The earliest phase control experiments involved time-dependent probing of molecular wavepackets, and were followed by two-path interference in an atomic system. The most recent, and general, implementation of control involves tailoring a time-dependent electromagnetic field for a desired objective using closed-loop techniques. Since the use of tailored laser pulses appears to be rather general, a more complete description of the experiment is provided.

Time-Dependent Methods

The first experiments demonstrating the possibility of coherent control were performed to detect nuclear motion in molecules in real time. These investigations were the experimental realization of the pump-dump or pulse-timing control methods as originally described in 1985. The experimental applications have expanded to numerous systems including diatomic and triatomic molecules, small clusters, and even biological molecules. For such experiments, a vibrational coherence is prepared by exciting a superposition of states. These measurements implicitly used phase control both in the generation of the ultrashort pulses and in the coherent probing of the superposition state by varying the time delay between the pump and probe pulses, in effect modulating the outcome of a quantum transition. Since the earliest optical experiment in the mid-1980s, there have been many hundreds of such experiments reported in the literature. The motivation for the very first experiments was not explicitly phase control, but rather the observation of nuclear motion of molecules in real time. In such later measurements, oscillations in the superposition states were observable for many cycles, up to many tens of picoseconds in favorable cases, i.e., diatomic molecules in the gas phase. The loss of signal in the coherent oscillations is ultimately due to passage of the superposition state in to surrounding bath states. This may be due to collision with another molecule, dissociation of the system or redistribution of the excitation energy into other modes of the system not originally excited in the superposition. It is notable that coherence can be maintained in solution phase systems for tens of picoseconds and for the case of resonances having weak coupling to other modes, coherence can even be modulated in large biological systems on the picosecond time scale.

Decoherence represents loss of phase information about a system. In this context, phase information represents our detailed knowledge of the electronic and nuclear coordinates of the system. In the case of vibrational coherence, decoherence may be represented by intramolecular vibrational energy transfer to other modes of the molecule. This can be thought of as the propensity of vibrational modes of a molecule to couple together in a manner that randomizes deposited energy throughout the molecule.

Decoherence in a condensed phase system includes transfer of energy to the solvent modes surrounding the system of interest. For an electronically excited molecule or atom, decoherence can involve spontaneous emission of radiation (fluorescence), or dissociation in the case of molecules. Certain excited states may have high probability for fluorescence and would represent a significant decoherence pathway and an obstacle for coherent control. These states may be called 'lossy' and are often used in optical pumping schemes as well as for stimulated emission pumping. An interesting question arises as to whether one can employ such states in a pathway leading to a desired final state, or must such lossy states be avoided at all costs in coherent control. This question has been answered to some degree by the method of rapid adiabatic passage. In this experiment, an initial state is coupled to a final state by way of a lossy state. The coupling is a coherent process and the preparation involves dressed states that are eigenstates of the system. In this coherent superposition the lossy state is employed, but no population is allowed to build up and thus decoherence is circumvented.

Two-Path Interference Methods

Interference methods form perhaps the most intuitive example of coherent control. The first experimental demonstration was reported in 1990 and involved the modulation of ionization probability in Hg by interfering a one-photon and three-photon excitation pathway to an excited electronic state (followed by two-photon ionization). The long delay between the introduction of the two-path interference concept in 1960 and the demonstration in 1990 was the difficulty in controlling the relative phase of the one- and three-photon paths. The solution involved generating the third harmonic of the fundamental in a nonlinear crystal, and copropagating the two beams through a low-density gas. Changing the pressure of the gas changes the optical phase retardance at different rates for different frequencies, thus allowing relative phase control between two colors. The ionization yield of Hg was clearly modulated as a function of pressure. Such schemes have been extended to diatomic molecular systems and the concept of determining molecular phase has been investigated. While changing the phase of more than two frequencies has not been demonstrated using pressure tuning (because of experimental difficulties), a more flexible method has been developed to alter relative phase of up to 1000 frequency bands, as will be described next.

Closed-Loop Control Methods

Perhaps the most exciting new aspect of control in recent years concerns the prospect for performing closed-loop experiments. In this approach a more complex level of control in matter is achieved in comparison to the two-path interference and pump-probe control methods. In the closed-loop method, an arbitrarily complex time-dependent electromagnetic field is prepared that may have multiple subpulses and up to thousands of interfering frequency bands. The realization of closed-loop control over complex processes relies on the confluence of three technologies: (i) production of large bandwidth ultrafast laser pulses; (ii) spatial modulation methods for manipulating the relative phases and amplitudes of component frequencies of the ultrafast laser pulse; and (iii) closed-loop learning control methods for sorting through the vast number of pulse shapes available as potential control fields. In the closed-loop method, the result of a laser molecule interaction is used to tailor an optimized pulse.

In almost all of the experimental systems used for closed-loop control today, Kerr lens mode-locking in the Ti:sapphire crystal is used to phase lock the wide bandwidth of available frequencies (750–950 nm) to create the ultrafast pulse. In this phenomenon, the intensity variation in the short laser pulse creates a transient lens in the Ti:sapphire lasing medium that discriminates between free lasing and mode-locked pulses. As a result, all of the population inversion available in the lasing medium may be coerced into enhancing the ultrashort traveling wave in the cavity in this way. The wide bandwidth available may then be amplified and tailored into a shaped electromagnetic field. Spatial light modulation is one such method for modulating the relative phases and amplitudes of the component frequencies in the ultrafast laser pulse to tailor the shaped laser pulse. Pulse shaping first involves dispersing the phase-locked frequencies on an optical grating, the dispersed radiation is then collimated using a cylindrical lens and the individual frequencies are focused to a line forming the Fourier plane. At the Fourier plane, the time-dependent laser pulse is transformed into a series of phase-locked continuous wave (CW) laser frequencies, and thus Fourier transformed from time to frequency space. The relative phases and amplitudes may be modulated in the Fourier plane using an array of liquid crystal pixels. After altering the spectral phase and amplitude profile, the frequencies are recombined on a second grating to form the shaped laser pulse. With one degree of phase control and 10 pixels there are an astronomic number (360^{10}) of pulse shapes that may be generated in this manner. (At the present time, pulse shapers have up to 2000 independent elements.) Evolutionary algorithms are employed to manage the available phase space. Realizing that the pulse shape is nothing more than the summation of a series of sine waves, each having an associated phase and amplitude, we find that a certain pulse shape can be represented by a genome consisting of an array of these frequency-dependent phases and amplitudes. This immediately suggests that the methods of evolutionary search strategies may be useful for determining the optimal pulse shape for a desired photoexcitation process.

The method of closed-loop optimal control for experiments was first proposed in 1992 and the first experiments were reported in 1997 regarding optimization of the efficiency of a laser dye molecule in solution. Since that time a number of experiments have been performed in both the weak and strong field regime. In the weak field regime, the intensity of the laser does not alter the field free structure of the excited states of the system under investigation. In the strong field, the field free states of the system are altered by the electric field of the laser. Whether one is in the weak or strong field regime depends on parameters including the

characteristic level spacing of the states of the system to be controlled and the intensity of the laser coupling into those states. Examples of weak field closed-loop control include optimization of laser dye efficiency, compression of an ultrashort laser pulse, dissociation of alkali clusters, optimization of coherent anti-Stokes Raman excitation, and optical pulse propagation in fibers. In the strong field, the laser field is used to manipulate the excited states of the molecule as well as induce population transfer among these states. In this sense, the laser is both creating and exciting resonances, in effect allowing universal excitation with a limited frequency bandwidth of 750–850 nm. For chemical applications, it is worth noting that most molecules do not absorb in this wavelength region in the weak field. Strong field control has been used for controlling bond dissociation, chemical rearrangement, photonic reagents, X-ray generation, molecular centrifuges and the manipulation of mass spectral fragmentation intensities. In the latter case, a new sensing technology has emerged wherein each individual pulse shape represents an independent sensor for a molecule. Given the fact that thousands of pulse shapes can be tested per minute, this represents a new paradigm for molecular analysis.

At the time of this writing, the closed-loop method for adaptively tailoring control fields, has far outstripped our theoretical understanding of the process (particularly in the strong field regime). Adaptive control is presently an active field of investigation, encompassing the fields of physics, engineering, optics, and chemistry. In the coming years, there will be as much work done on the mechanism of control as in the application of the methods. Due to small energy level spacings and complexity of the systems, we anticipate the majority of applications to be in the chemical sciences.

Optics of the Human Eye

David A Atchison, Queensland University of Technology, Brisbane, QLD, Australia

Basic Optical Structure

The human eye is shown in Fig. 1. The outer layer consists of the cornea at the front and the sclera at the back. The transparent cornea is approximately spherical with a radius of curvature of about 8 mm. The white, opaque sclera is approximately spherical with a radius of curvature of approximately 12 mm. The middle layer of the eye is the uveal tract, which consists of the iris anteriorly, the choroid posteriorly (not shown), and the intermediate ciliary body. Inside the eye, about 3 mm from the cornea, is the transparent lens. The anterior chamber between cornea and iris, and the posterior chamber between iris, ciliary body and lens, contain fluid called the aqueous humor. The vitreous chamber between the lens and the back of the eye contains a transparent, colorless, gelatinous mass called the vitreous humor.

The inner layer of the eye is the light-sensitive tissue called the retina, which is connected to the brain via the optic nerve. Light passes through the inner retinal layers to reach the photoreceptors, where light is absorbed to initiate the electrical and chemical processes involved in vision. Photoreceptors are of two types: rods and cones. Cones are associated with vision in bright (photopic) lighting conditions; there are three types that absorb at different wavelength ranges and initiate color vision. Rods are associated with vision in low (scotopic) light levels, and there is an intermediate (mesopic) light level range where both cones and rods operate. The cones predominate in the fovea, which is 1.5 mm (5 degree field) wide. The fovea is free of rods in its central 1 degree field. When the eye fixates, or “looks at,” a small object of interest, the retinal image forms at the foveal center. The inner retinal layers contain ganglion cells, whose axons leave the retina at the optic disk. This is functionally blind because there are no cones or rods here. It is approximately 5 degree horizontally and 7 degree vertically, and its center is approximately 15 degree nasally and 1.5 degree upwards from the foveal center.

Light enters the eye through the cornea, and is refracted by the cornea and lens to focus at the retina. The cornea has the greater power, but the lens power in young eyes can change to allow the eye to focus at different distances – the process of accommodation. The hole in the iris is the aperture stop. When we look at the aperture stop, we see it as the pupil, which is closer to the front of the eye and slightly bigger than the aperture stop. The aperture stop controls how much light reaches the retina and the retinal image quality.

In good quality man-made optical systems, the optical axis is the line that joins the centers of curvatures of the refracting surfaces. However, the eye is not rotationally symmetric; surfaces and the aperture stop are tilted and decentered relative to each other. The optical axis can be defined as the line of best fit through the centers of curvature, which in practice is determined by the best alignment of the images formed by reflection from the surfaces. To complicate matters, the fovea center is about 5 degree from the optical axis as measured at the posterior nodal point of the eye. This lack of symmetry has led to a number of axes being required for the eye. For example, the line-of-sight is the line joining an object of interest and the fovea, and which passes through the center of the aperture stop (see Section Axes and Angles).

Ignoring the lack of symmetry, eyes can be treated like many other optical systems with cardinal points and with an equivalent power. Of more importance than equivalent power in a clinical context is refractive error, which is the error in the equivalent power due to an imbalance between equivalent power and eye length.

Fig. 1 Horizontal section of a right eye as seen from above.

Fig. 2 The Le Grand four-refracting surface schematic eye (Atchison and Smith, 2000), showing dimensions in millimeters and refractive indices. R – surface radius of curvature, n – refractive index.

Dimensions of the eye vary greatly between individuals, and alter with age and accommodation. Average values of populations have been used to construct model (schematic) eyes. These can be made of different complexities, with different number of surfaces. The “paraxial” schematic eyes contain centered, spherical surfaces. These are useful for basic properties, such as component powers, positions of cardinal points, and image size and illuminance calculations, but not for subtle optical effects such as higher-order aberrations. One schematic eye is shown in Fig. 2 as representative of dimensions in relaxed (non-accommodating) adult eyes. The equivalent power of this eye is approximately 60 m^{-1} . When dealing with powers, the term diopter with symbol “D” is usually used instead of inverse meters, a practice followed in the rest of this article.

The range of angles from the fovea at which perception is possible is referred to as the field-of-vision. Its limits are determined by anatomical, optical, and sensory factors. Field limits are about 100 degree temporally, 90 degree inferiorly, and 40 degree superiorly and nasally. Rotating the eye to remove the upper brow and nose restrictions increases the superior field to about 80 degree and the nasal field to about 60 degree; the latter is now limited by extent of the temporal sensitive retina.

Humans have two eyes which are separated by approximately 60–70 mm in adults. Binocular vision provides slightly improved contrast sensitivity and vision acuity over monocular vision. The total field-of-view is about 210 degree with a 120 degree binocular overlap. The slightly different sizes and/or shapes of the two retinal images of a close object allow three-dimensional perception known as stereopsis. Presenting different images to the two eyes is exploited in a number of circumstances such as enabling near vision at a range of distances where this would otherwise not be possible by putting lenses of different power in front of the two eyes, and having aspects of the object which can only be seen by one eye through filters placed in front of the eyes (e.g., 3-D effects in cinemas). When the eyes accommodate to focus for a near object, they rotate inwards (convergence) to fixate the object.

Cornea

The cornea has about 40 D of power, which about two-thirds of the power of the unaccommodated eye. It contains a tear film (about 4–7 μm thick) at the front, an epithelium, Bowman’s membrane, the stroma, Descemet’s membrane and the endothelium. The tear film has oily, aqueous and mucous layers, but they are mixed to variable extents during the blinking cycle. Because the tear film is thin and conforms to the shape of the underlying cornea, it is sometimes treated as being optically inert; however it is important in compensating for the roughness of the outer epithelial cells and there are circumstances in which it cannot be ignored optically such as fitting of rigid contact lenses. The stroma has about 90% of the corneal thickness. It contains about 200–250 layers (lamellae) of cylindrical fibrils. The fibrils within a lamella lie parallel to each other and fibrils within a lamella are inclined at large angles to fibrils in adjacent lamellae. While the different layers of the cornea have different refractive indices, the cornea is usually assigned a constant value which of about 1.376.

Estimates of the anterior and posterior surface radii of curvature of the cornea are about 7.8 and 6.3 mm (Atchison and Smith, 2000), respectively, but there are wide ranges. On average males have flatter corneas than females. Corresponding powers for these radii of curvature are approximately 48 and -6 D ; the much smaller power for the posterior cornea is because of the much lower refractive index (0.04) between aqueous and cornea than between cornea and air (0.376). The two radii of curvature are highly correlated (Dunne *et al.*, 1992; Lowe and Clark, 1973; Patel *et al.*, 1993). Some instruments determine a corneal power based on the anterior radius of curvature and an equivalent index such as 1.3375.

The surfaces are not perfectly spherical; they have both toricity and asphericity. Toricity means that the radius of curvature varies with meridian and produces the optical defect of astigmatism (see Section Refractive anomalies/Astigmatism). Most cornea surfaces are also aspheric and are often represented as conics in two dimensions or as conicoids in three dimensions. One way of

Fig. 3 The Y-Z section of conicoids, showing the influence of asphericity on conicoid shape. All surfaces have the same vertex radius of curvature.

expressing a conicoid is

$$z = \frac{c(x^2 + y^2)}{1 + \sqrt{1 - (1 + Q)(x^2 + y^2)}}$$

where the coordinates at a point on the surface are (x, y, z) with the z -axis corresponding to the optical axis, c is the vertex curvature (the inverse of the vertex radius of curvature), and Q is the surface asphericity giving different types of conicoids (**Fig. 3**):

- $Q < -1$ hyperboloid
- $Q = -1$ paraboloid
- $-1 < Q < 0$ prolate ellipsoid (z -axis is major axis)
- $Q = 0$ sphere
- $0 < Q$ ellipsoid with the major axis in the xy plane

Other forms of representing corneal shape include bi-conicoids, in which there are separate x -direction and y -direction vertex curvatures.

Most anterior corneal surfaces can be describe as prolate ellipsoids, i.e., they flatten away from the vertex, with the mean asphericity being about -0.20 ([Atchison and Smith, 2000](#)). One consequence of this is that the aberration known as spherical aberration is reduced from that which would occur for spherical corneas. There are fewer estimates of asphericity of the posterior corneal surface than of the anterior corneal surface. Mean estimates of the posterior cornea are negative. These are less likely to be accurate than the anterior corneal estimates because of the issue of imaging the posterior cornea through the anterior cornea.

Corneal thickness is about 0.5 mm near the center, and increases into the periphery because the posterior surface is more curved than the anterior surface.

Aperture Stop and Pupils

The iris forms the aperture stop of the eye. Iris color varies considerably, and this depends upon the amount of pigmentation. The stop position varies between individuals, and with age and accommodation. In young adults it is about 3.5 mm behind the anterior cornea. The aperture size is determined by the balance between the sphincter pupillae and dilator pupillae muscles. The former is a ring around the inner margin of the iris, and its contraction causes the stop to constrict. The latter consists of cells that extend radially from the sphincter, and its contraction causes the stop to dilate.

The entrance pupil is the image of the aperture stop formed in object space by the cornea, and the exit pupil is the image of the aperture stop formed by the lens (**Fig. 4**). Paraxial ray tracing through model eyes, in which it is assumed that the aperture stop lies in the anterior vertex plane of the lens, gives approximate positions and sizes of pupils. While varying between different eyes and with accommodation, the entrance pupil is approximately 13% bigger and 0.5 mm closer to the cornea than the aperture stop, while the exit pupil is about 3% bigger and 0.1 mm behind the aperture stop.

Because the entrance pupil is what we see when we look into the eye, the aperture stop is usually referred to loosely as the pupil. Compared with the entrance pupil, the exit pupil has little significance, and for the rest of this article the term “pupil” will refer to the entrance pupil.

Illumination level is the most important factor affecting pupil size, and pupil diameter may vary between 2 mm at high illuminations to 8 mm in the dark. [Watson and Yellott \(2012\)](#) provided a comprehensive description of the dependence of pupil size on illumination and how this is affected by factors of age, size of adapting field, and whether one of both eyes are adapted. The influence of age on pupil size will be discussed later. Other factors that are important are accommodation and convergence, which usually occur together, and state of arousal. Sometimes effects of these are transient, for example, accommodating from distance to a near target will produce constriction that is usually not sustained.

Fig. 4 The aperture stop, the entrance pupil and the exit pupil of the eye. The paraxial pupil ray is directed toward the center of the entrance pupil, by refraction reaches the center of the aperture stop, and is refracted by the lens so that it appears to come from the center of the exit pupil. In a similar fashion, the marginal pupil ray shows the top edges of the aperture stop and the pupils.

Fig. 5 Pupil diameter ratio as a function of horizontal visual field angle θ for one subject. The data are fitted by $1.009 \cos \left[\frac{(\theta+3.936)}{1.121} \right]$. Unpublished data from the study of Mathur *et al.* (2013).

Drugs can affect pupil size and some are intended for this purpose. Mydriatics cause pupil dilation by either stimulating the sympathetic division of the autonomic nervous system (sympathomimetics) or by blocking its parasympathetic division (parasympatholytics). Miotics cause pupil constriction by either stimulating the parasympathetic division (parasympathomimetics) or by blocking the sympathetic division (sympatholytics).

When the pupil is viewed along the line-of-sight it appears circular in most eyes. When the eye is viewed eccentrically along the horizontal visual field meridian, it becomes elliptical. This is described by a cosine function, flatter by about 12% than the cosine of the viewing angle and decentered by a few degrees into the temporal visual field (Mathur *et al.*, 2013) (Fig. 5).

The pupils of most eyes are decentered relative to the center of the limbus, the line demarking the clear cornea from the surrounding sclera. This decentration is about 0.5 mm nasally, and usually becomes more nasal as the pupil constricts. Mean pupil decentration shift across a large range of illuminances is about 0.12 mm, but with individual shifts of up to 0.5 mm (e.g., Mathur *et al.*, 2014).

The pupil size and decentration, particularly the former, have considerable effects on vision. Pupil diameter affects retinal light level and subsequently light adaptation. However, this is not a large effect considering the pupil area can change by a factor of only 16, which is much smaller than the million times range over which the eye operates. The diameter affects the depth-of-focus, which is the range of distances over which the eye cannot detect any change in focus, with the depth-of-focus usually narrowing as pupil size increases. Retinal image quality and visual performance are influenced by pupil size; for large pupil diameters optical defects of the eye known as aberrations cause deterioration in retinal image quality, while for small pupil diameters diffraction limits retinal image quality. Pupil decentration interacts with diameter to affect image quality.

Lens

The lens is a mass of cellular tissue contained within an elastic capsule. An epithelial cell layer underneath the capsule extends from the anterior vertex to the equator. Throughout life, new epithelial cells form near the equator and elongate forwards and backwards as fibers between the epithelium and capsule. These join other fibers at junctions called sutures.

The capsule is attached to the ciliary body by suspensory ligaments called zonules. Contraction of the ciliary body's muscle causes the ciliary body to move forwards and inwards. This reduces tension on the zonules, which in turn reduce tension on the lens and allow the lens to take up a more curved form under the influence of the capsule. Lens power increases because the surfaces increase in power and because of changes of refractive index distribution within the lens. This allows the eye to change focus from distant to close objects. This process is reversible. The ability of the eye to focus on objects at different distances is known as accommodation. This is usually measured as a change in inverse of distances from the eye, rather than change in lens power. As an example if the eye changes its focus from an object 1 m away to 25 cm away, the change in accommodation is $1/0.25 - 1/1 = 3.0$ D. The magnitude of possible accommodation is called the amplitude of accommodation. Its peak of about 10 D occurs in the second decade of life, with corresponding "unaccommodated" and "accommodated" equivalent lens powers of about 19 and 30 D, respectively. From the peak, amplitude declines steadily to become zero in about the mid-50s. This is described further in the Section Changes with Age/Accommodation and Presbyopia.

The biometric parameters of the lens vary considerably between people, and with age and accommodation. Some values will be given here which are reasonable estimates for young adults in the unaccommodated state. The radii of curvature for the anterior and posterior surfaces are about 10 mm and -6 mm, respectively, and the central thickness of the lens is about 3.6 mm. The lens diameter is 9–10 mm. During accommodation the radii of curvature decrease, more so for the front surface than for the back surface. This is combined with increase in the axial thickness, most of which occurs in the nucleus of the lens. Both the anterior and vitreous chambers are reduced in depth, and the diameter decreases.

One of the most intriguing things about the lens is its gradient refractive index. There is a plateau of high index (about 1.41) in the central (nucleus) region, but the index reduces toward the periphery where it is about 1.38. This index variation produces continuous refraction of rays, so that there are both surface and internal contributions to the power of the lens. Many model eyes have a constant refractive index rather than a gradient index, and to adequately account for the loss of gradient index power this "equivalent" index must be made higher (e.g., 1.42) than the maximum index of the lens. Gullstrand (1924) referred to the contribution of changes in gradient index during accommodation to changes in power as the "intracapsular mechanism of accommodation."

Axes and Angles

Several axes are required to fully describe the optical properties of the eye, because of a lack of symmetry and the departure of the fovea from a best fit optical axis. The validity of some axes is dependent on idealized eye properties. As well as the axes, names are given to the angles between them. A full treatment of these axes is outside the scope of this article (see Atchison (2017a)).

The most important axes are the optical axis, the line-of-sight, the visual axis and the pupillary axis (Fig. 6). The optical axis does not truly exist, but it can be considered to be the line of best fit through the centers of curvature of the intraocular surfaces. The line-of-sight is the line joining the fixation point T and the foveal center T' through the center of the pupil E . This is usually on

Fig. 6 Some axes and angles of the eye. The object has been shown very close to the eye and the angles are exaggerated for clarity. Adapted from Atchison, D.A., 2017a. Axes and angles of the eye. In: Artal, P. (Ed.), *Handbook of Visual Optics*. vol. I. Boca Raton, FL: Francis & Taylor Group (Chapter 17).

the nasal side of the optical axis in object space. Because the pupil center moves with accommodation and luminance, this quantity is not fixed. The visual axis is the line joining the fixation point and the fovea center through the nodal points N and N' ; it is usually close to the line-of-sight. The pupillary axis is the line passing through the center of the entrance pupil and which is normal to the anterior corneal surface. Usually this lies between the optical axis and the line-of-sight.

The angle between the optical axis and the visual axis is called alpha (or α) and is approximately 5 degree horizontally and 2 degree vertically (visual axis nasal to and above optical axis in object space). The angle between the pupillary axis and line-of-sight is called lambda (or λ) and the angle between the pupillary axis and the visual axis is called kappa (or κ). The angles are of some diagnostic significance, particularly λ which is used to diagnose eccentric fixation and heterotropia (turned eye).

Schematic Eyes

Schematic eyes are models that show optical related biometry of eyes. These have a variety of uses, such as calculating retinal image size, estimating retinal light levels, determining how refractive errors arising from variations in eye dimensions, calculating appropriate powers of intraocular lenses in cataract surgery, estimating aberrations and retinal image quality, and designing ophthalmic instrument and ophthalmic corrections.

Schematic eyes are available in a range of complexity. The paraxial schematic eyes have spherical refractive surfaces that are centered on a common optical axis. Some are not anatomical accurate, for example, the reduced eyes have only one refractive surface. These schematic eyes can describe optics of real eyes accurately only within the paraxial region for which rays are close to the optical axis and subtend small angles to it.

Finite, or wide angle, schematic eyes provide better predictions of aberrations and retinal image quality than the paraxial schematic eyes. They can have various features, such as aspheric surfaces, gradient refractive index, surface tilts and misalignments, media whose refractive indices vary with wavelength, and curved retinas. These eyes require more elaborate calculations than paraxial schematic eyes. Like the paraxial eyes, they are usually based on average values of population values, but can be customized to more accurately describe individual eyes.

An example of a paraxial schematic eye is the Le Grand full theoretical eye (Fig. 7). This contains four-refracting surfaces. It is available in both relaxed and accommodated (7.1 D) forms, but only the former is shown here. It has served as a basis for several paraxial and finite schematic eyes. The figure shows the three pairs of cardinal points. Light leaving the anterior focal point F passes into the eye and is imaged toward infinity. Light passing into the eye from infinity and parallel to the optical axis is imaged at the posterior focal point F' . For light traveling into the eye, the object position can be considered relative to the anterior principal point P and refraction can be treated as if it occurred at the posterior principal point P' . The reverse is true for light traveling from the retina out of the eye. Light traveling into the eye toward the anterior nodal point N appears to pass through the posterior nodal point N' on the image side without the angle of inclination changing.

The constant lens index can be placed by a continuously varying index $N(r)$ described by

$$N(r) = c_0 + c_1 r^2 + c_2 r^4 + c_3 r^6$$

or

$$N(r) = c_0 + c_1 r^p$$

where r is the relative distance from the center of the lens to its edge, and c_0 , c_1 , c_2 , c_3 , and p are coefficients. Different levels of sophistication of such modeling have been proposed (Atchison, 2017b).

Fig. 7 The unaccommodated version of the Le Grand four-refracting surface schematic eye, showing the cardinal points.

The change in refractive index with wavelength, or chromatic dispersion, of media has been incorporated into some schematic eyes using equations such as Cauchy dispersion equation

$$n(\lambda) = A + B/\lambda^2 + C/\lambda^4 + D/\lambda^6 \dots$$

and the Cornu dispersion equation

$$n(\lambda) = n_\infty + K/(\lambda - \lambda_0)$$

Here λ is wavelength and A, B, C, D, n_∞, K , and λ_0 are constants for a particular medium.

Most of the well-known schematic eyes are representative of average values in particular populations at the times and places the eyes were devised. Many variations of the common schematic eyes have been proposed to account for changes with age in children and adults, with accommodation and with particular ocular conditions. With increased ocular biometry available, personalized eye models are being developed.

When deciding upon which schematic eye might be employed for one of the applications described in the first paragraph of this section, a good principle is to use the simplest model that is adequate, even if this is anatomically inaccurate.

Light and the Eye

Many regions of the electromagnetic spectrum are important to the eye because they may cause damage to various parts of the eye, but the main region in which we are interested is that producing a visual response and to which we refer as light. The wavelength range of light is approximately 390 to 800 nm, for which the spectral colors we see are violet (~390–450 nm), blue (~450–500 nm), green (~500–560 nm), yellow (~560–600 nm), orange (~600–620 nm), and red (~620–800 nm). The eye response within this range depends upon the luminance. Fig. 8 shows the relative luminous efficiencies under photopic and scotopic conditions, with respective peak sensitivities at 555 and 507 nm. The change in peak between these two values, that occurs under the intermediate mesopic conditions of approximately 3–0.03 cd m⁻², is referred to as the Purkinje shift.

Radiometric quantities (radiant flux, radiant intensity, radiance and irradiance) can be converted into the corresponding photometric quantities (luminous flux, luminous intensity, luminance and illuminance) by simple equations that weight the radiometric values at any wavelength by the appropriate relative luminous efficiency.

Passage of Light Into Eye

Not all of light entering the eye reaches the retina. Some is lost by specular reflection at the surfaces of the cornea and lens, by scattering, and by absorption.

The specular reflections are image forming: the virtual images formed by single reflection and by transmission out of the eye are called the Purkinje-Sanson I, II, III and IV images, and correspond to the anterior cornea, posterior cornea, anterior lens and posterior lens surfaces, respectively. These images can be used to estimate lens equivalent refractive index, lens surface radii of

Fig. 8 The relative luminous efficiency functions in photopic and scotopic lighting levels.

curvature, and axes of the eye. Image I is by far the brightest because of the large refractive index between air and the cornea (strictly its tear film) and is located about 3.9 mm inside the eye. Image II is difficult to see because it is in a similar location to image I and is much dimmer because of the low refractive index difference (0.04) between cornea and aqueous. In the unaccommodated eye, Image III is about twice as big as image I and is about 10 mm inside the eye, while image IV is about 4 mm inside the eye, about three-quarters the size of image I and inverted. Both images III and IV change with accommodation, with image III becoming much smaller and moving closer to the cornea.

Transmittance of the eye and its components is highly dependent upon wavelength and age. Of particular interest is the protection given to internal structures from ultraviolet radiation (<380 nm). Considering natural radiation, most ultraviolet below about 288 nm is absorbed by the oxygen and ozone in the atmosphere; 288 nm corresponds approximately to the wavelength at which the cornea starts passing radiation through to the lens. In turn, the lens absorbs nearly all radiation up to 380 nm. Absorption for wavelengths beyond 600 nm is dominated by water, while for shorter wavelengths the spectral absorption is far more absorbing than occurs for water (Atchison and Smith, 2000).

Scatter is caused by spatial variations of refractive index within a medium, usually at the microscopic level, and is a combination of diffraction, reflection, and reflection. The angular distribution of scatter may be complex. Distinction can be made between forward-scattered light which affects retinal imagery and is sometimes called straylight, and back-scattered light directed out of the eye. The forward scatter produces a veiling glare that reduces the contrast of the retinal image and reduces visibility of objects. The backward-scattered light is important for observing intraocular structures in techniques such as slit-lamp biomicroscopy. Given that the cornea and lens contain inhomogeneities on the scale of the wavelength of light, their transparencies in healthy eyes are remarkably high.

An interesting phenomenon related to transmittance is birefringence. This occurs when the velocity of light depends not only on the direction of light travel but also on orientation of the electric field. This results in two refractive indices in a material, and the birefringence is quantified by their difference. Estimates of birefringence have been made for the cornea and retina.

Light at the Retina

Probably about 50–90% of light entering the eye reaches the retina to form images, but there is considerable age and wavelength dependence. Ignoring these factors, a simple measure of retinal illuminance is the troland. The retinal illuminance E_t in trolands is the product of the area A of the pupil in mm^2 and object luminance L in cd m^{-2} :

$$E_t = LA$$

In terms of pupil diameter in millimeter, this is

$$E_t = \pi LD^2/4$$

The luminous efficiency of a beam of light depends upon the entry point of the pupil. This is known as the Stiles–Crawford effect of the first kind (Stiles and Crawford, 1933). This is due to the wave-guide properties of the photoreceptors and can be considered both as an optical and neural phenomenon. A convenient equation for this is

$$\eta/\eta_{\max} = e^{-\rho(r-r_{\max})^2}$$

where $\eta/\eta_{\max}$ is relative luminous efficiency for which η is sensitivity at position r from pupil center and $\eta_{\max}$ is peak sensitivity at $r_{\max}$, and with ρ the retinal directionality parameter (Fig. 9(a)). The fit can be extended to two dimensions to allow for non-rotational symmetry. Mean foveal ρ is $0.12 \pm 0.03 \text{ mm}^{-1}$ with horizontal and vertical components for $r_{\max}$ of 0.5 ± 0.7 mm nasal and 0.2 ± 0.6 mm superior (Atchison and Smith, 2000). The Stiles–Crawford effect is sometimes factored into retinal illuminance determinations and image quality determinations as a photometric efficiency $S(D)$ for a pupil diameter D as it were a filter at the pupil, which from the previous equation and ignoring the offset of the peak from the pupil center is

$$S(D) = \frac{4 \left[1 - e^{-\frac{\rho D^2}{4}} \right]}{\rho D^2}$$

A smaller, but equivalent pupil of diameter D_e without a Stiles–Crawford effect is given by

$$D_e = D \sqrt{[S(D)]}$$

This is shown in Fig. 9(b).

The ρ value of 0.12 mm^{-1} is applicable for subjective measurements not far from the middle of the vision spectrum, and under photopic conditions. It will vary with wavelength and reduce as luminance decreases. Objective methods give much higher values. The Stiles–Crawford effect reduces the effects of aberrations on retinal image quality, although the influence of this is probably small.

Light Interaction With the Back of the Eye

In addition to the absorption of light by the photoreceptors discussed above, there are other interactions with the back of the eye in the retina, choroid and sclera, collectively called the fundus. There are important absorbing pigments: macula pigment in the retina called xanthophyll, the visual pigments in the photoreceptors responsible for initiating the neural process of vision, melanin

Fig. 9 The Stiles–Crawford effect. (a) Relative sensitivity as a function of position in the pupil, with data fitted by $e^{-0.116(x-0.46)^2}$ and (b) the photometrically equivalent pupil diameter as a function of pupil diameter for a ρ value of 0.12 mm^{-1} .

in the retinal pigment epithelium and choroid, and hemoglobin mainly in the choroid. The sclera backscatters light strongly so that most light reaching it passes back to the retina.

Fundus reflectance, the light reflected and scattered at the fundus and which passes back out of the eye, is used for diagnostic evaluation. Reflectance is low at short wavelengths and gradually increases with increase in wavelength, largely attributable to blood in the choroid. Some of the scattered light will contribute to veiling glare; it is thought that an important role of the Stiles–Crawford effect is to reduce the luminous efficiency of this light.

Refractive Anomalies

When the eye fixates an object of interest, ideally the image is focused at the retina. This may require some accommodation effort of the eye so that the object lies within the far and near points corresponding to minimum and maximum accommodation, respectively.

An eye whose far point is at infinity is referred to as an emmetropic eye, and this is considered the normal eye provided that it has appropriate accommodative amplitude. A refractive anomaly, or refractive error, occurs when the far point is not at infinity. Eyes with far points that are not at infinity are referred to as ametropic eyes. Emmetropia and ametropia might be regarded as opposites, but emmetropia is part of the ametropia distribution.

The departure from emmetropia is often considered to be an error of refraction, and ametropias are referred to also as refractive errors. Refractive anomalies can be corrected with ophthalmic lenses in the form of spectacle, contact, and intraocular lenses. Ophthalmic practitioners do not distinguish between the terms of refractive error and refractive correction, although from a purist perspective they are opposites.

While emmetropia may be defined in terms of the far point being at infinity, within the precision of refractive correction and ophthalmic lens manufacture this is not a practical definition. People with corrections within a range such as -0.25 D to $+0.50 \text{ D}$ may be considered to be emmetropic, but some authorities may give slightly different ranges.

If the range of accommodation is reduced with age so that near objects of interest cannot be seen clearly, it gives a refractive anomaly called presbyopia.

Spherical Refractive Anomalies

In spherical refractive anomalies, the refraction is unaffected by the meridian in the pupil of the eye. These are categorized according to the far point position (the spherical refractive errors) or to the near point position (presbyopia).

For a myopic eye, the far point is in front of the eye (Fig. 10(a)). An object at infinity is focused at the eye's posterior focal point F' , which is in front of the retina and consequently the retinal image is blurred. There is a mismatch between the length of the eye and its power, so the eye can be considered as being too powerful for its length or as being too long for its power, although the latter is the better point of view as most myopic eyes have excessive length compared with emmetropic eyes. Clear focus on a distant object can be achieved by placing an ophthalmic lens of appropriate negative power at the front of the eye (Fig. 11(a)). This lens works by forming a virtual image at its back focal plane, which coincides with the far point of the eye.

Myopia has been classified by magnitude (e.g., low, moderate, high), and age of onset (e.g., early onset or late onset). Uncorrected myopes complain of blurred distance vision, which is most noticeable at night when pupils are large and there is a small depth-of-focus. If the level of myopia is sufficient, they may complain that close objects also appear blurred.

Fig. 10 (a) Myopic and (b) hyperopic eyes, showing the far points at R , retinas at R' , and posterior focal points at F' .

For a hyperopic (also hypermetropic) eye, the far point is behind the eye and the posterior focal point F' is behind the retina (Fig. 10(b)). An object at infinity is focused toward this point, and the retinal image is blurred unless the eye has sufficient accommodation amplitude to bring the image into sharp focus. As for myopia, hyperopia can be considered as a mismatch between the length of the eye and its power, but now with the eye being too weak for its length or too short for its power. Clear focus on a distant object can be achieved by placing an ophthalmic lens of appropriate positive power at the front of the eye (Fig. 11(b)). This lens forms a real image at its back focal plane, coinciding with the far point of the eye.

Young hyperopes may have difficulty relaxing accommodation, with residual ciliary muscle tonus producing latent hyperopia. Total hyperopia consists of manifest and latent components, with the portion of the former that can be compensated by accommodative effort being referred to as facultative hyperopia and the remainder as absolute hyperopia. Taking into account the loss of accommodation with age, this can be expressed as

$$\text{Total} = (\text{Facultative} \downarrow + \text{Absolute} \uparrow) + \text{Latent} \downarrow = \text{Manifest} \uparrow + \text{Latent} \downarrow$$

with the directions of the arrows indicating whether a component increases or decreases with aging.

Because uncorrected hyperopes must make more accommodative effort than emmetropes or myopes to view close objects, they tend to complain of sore eyes and headaches associated with effort in near visual tasks. Depending on the level of hyperopia, they may complain of blurred near vision and blurred distance vision, with the former being worse than the latter.

Presbyopia (from the Greek for “old eye”) is the difficulty people have in performing near tasks because of the age-related decrease in accommodative amplitude. The near point moves away from the eye to be beyond the near task position. Age of onset is related to the sign and magnitude of refraction, with uncorrected hypermetropes having problems earlier in life than uncorrected myopes. Presbyopia is corrected by ophthalmic lenses that are more positively, or less negatively, powered than the distance correction. Of course, uncorrected presbyopes’ main complaint is difficulty performing close tasks.

Astigmatism

Astigmatic refractive errors occur when the refractive error depends upon meridian (Fig. 12). It is usually due to one of more of the refracting surfaces, and particularly the anterior corneal surface, having a toroidal shape. However, it may be due to one or more surfaces being tilted or displaced. The level of astigmatism is the difference being the least and most powerful meridians. Astigmatism is corrected by lenses which have different powers in these meridians, with the power difference being referred to as a cylinder. The cylinder can be given as either positive or negative power, depending upon how the difference is determined. The axis of a positive cylinder will be at 90 degree to its corresponding negative cylinder axis. The axis of a cylinder is specified by an anticlockwise rotation from the right side of an observer looking at the lens in front of a patient’s face, to a maximum of 180 degree. The vertical meridian is usually given as 180 degree rather than 0 degree.

Fig. 11 Ophthalmic corrections for (a) myopia and (b) hyperopia. The posterior focal planes of the correcting lenses coincide with the far points of the eyes at R .

Fig. 12 Astigmatism in the eye. Far points R_α and $R_{\alpha+90}$ are imaged at retinal point R' .

There are different subclassifications of astigmatism. In myopic astigmatism, the eye is too powerful for its length in one (simple myopic astigmatism) or both (compound myopic astigmatism) principal meridians. In hyperopic astigmatism, the eye is too weak for its length in one (simple hyperopic astigmatism) or both (compound hyperopic astigmatism) principal meridians. Mixed astigmatism occurs when one principal meridian is myopic and the other is hyperopic.

Astigmatism may also be classified by axis. With-the-rule astigmatism requires a correcting negative cylinder with an axis within ± 30 degrees of the horizontal meridian; it is usually associated with an anterior cornea that is steeper along the vertical than along the horizontal meridian. Against-the-rule astigmatism requires a correcting negative cylinder lens with an axis within ± 30 degrees of the vertical meridian; it is usually associated with an anterior cornea that is steeper along the horizontal than along the vertical meridian. Oblique astigmatism occurs if the axes are beyond 30 degree from the horizontal and vertical meridians.

Astigmatism causes blurred vision at all distances, although, depending on the type of astigmatism, this may be worse at distance or near. Astigmatism may complain of tired and sore eyes and headaches associated with demanding visual tasks.

Ophthalmic lenses to correct astigmatism usually have one spherical surface and one toroidal surface, with the latter generally being the back surface, but are often referred to as sphero-cylindrical lenses. They have the specification

$$S/C \times \alpha$$

where S and C are spherical and cylindrical powers and α is the cylindrical axis. Another specification that is becoming popular is

$$M, J_{180}, J_{45}$$

where M is the mean sphere (also equivalent sphere) and J_{180} and J_{45} are regular and oblique astigmatism components. The two specifications are related by

$$M = S + C/2, J_{180} = -C \cos(2\alpha)/2, J_{45} = -C \sin(2\alpha)/2$$

and, using negative power cylinders,

$$C = -2\sqrt{(J_{180}^2 + J_{45}^2)}, \alpha = \tan^{-1}(J_{45}/J_{180})/2, S = M - C/2$$

Some rules have to be used to ensure that α is calculable and is correctly within the range of 0–180 degrees. For calculations of α that do not retain information about signs of J_{180} and J_{45} :

$$\text{If } J_{180} = 0, J_{45} < 0, \alpha = 135 \text{ degree}$$

$$\text{If } J_{180} = 0, J_{45} \geq 0, \alpha = 45 \text{ degree}$$

$$\text{If } J_{180} < 0, \alpha = \alpha + 90 \text{ degree}$$

This should give an angle between -90 and 90 degrees. To put the angle between 0 and 180 , 180 degrees must be added to negative angles to place them in the range 90 to 180 degrees. Either add 180 degree to negative angles or apply the rule:

$$\text{If } J_{180} \geq 0 \text{ and } J_{45} \leq 0, \alpha = \alpha + 180 \text{ degree}$$

The M, J_{180}, J_{45} form is useful for averaging a number of readings or for analyzing population data. Such calculations are not valid using the $S/C \times \alpha$ form.

Anisometropia

Here the refractive errors of fellow eyes of a person are different. Subclassifications include anisomyopia when fellow eyes are myopic, anisohyperopia when fellow eyes are hyperopic and antimetropia when one eye is myopic and its fellow eye is hyperopic. Subclassification could extend to consideration of astigmatism. Usually a threshold is set for anisometropia, for example, a person might be considered to have clinically significant anisometropia if it exceeds 1.0 D.

Correction of Refractive Anomalies

As mentioned before, refractive anomalies may be corrected by spectacle, contact and intraocular lenses. Nonsurgical and surgical procedures for the cornea are also available. The former occurs in orthokeratology in which rigid contact lenses are worn overnight to alter the shape of the anterior cornea. Surgical procedures involve removal of tissue from the cornea to alter anterior corneal shape. Future approaches are in development for the noninvasive alteration of the cornea's refractive index, thereby correcting refractive anomalies without the removal of tissue.

Several procedures have been adopted for the correction of presbyopia, where the challenge is to correct vision for different distances. For spectacles, this has meant having different powers in different parts of the lens in the form of multifocal or progressive addition lenses. This approach has also been attempted in contact lenses relying on pressure from the bottom eyelid to move lenses upwards relative to the cornea on downwards eye movement during near tasks. Usually contact lenses and intraocular lenses, and even corneal surgery, use simultaneous vision in which the best compromise between the demands of different distances is attempted; this will reduce image contrast compared with in-focus monofocal corrections as some light must always be out of focus ([Fig. 13](#)). Modalities include aspheric designs and annuli with different powers. Vision at different distances is highly dependent on pupil size. This dependence is overcome to some extent by using diffractive optics so that light from the entire pupil is concentrated into two orders.

Another modality for correcting presbyopia is a form of simultaneous vision, called monovision, in which different corrections are applied to fellow eyes, for example, one eye corrected for distance tasks and the other for near tasks. This relies on the brain being able to pay attention only to the eye with the clearer image for a particular task. This can be used with contact lenses, intraocular lenses, and corneal refractive surgery.

Another approach to presbyopia is not to modify refraction but to increase depth-of-focus by the use of small apertures in contact lenses, intraocular lenses or in disks implanted into the cornea.

All these correction types come with side effects, for example, spectacle lenses correcting myopia will minify the size of the retinal image. As mentioned above simultaneous vision lenses cannot provide crisp vision at any distance. Spectacle lens correction of anisometropia results in different retinal image sizes and different prismatic effects when looking through lens peripheries, and these may compromise binocular vision.

Fig. 13 Imagery with a bifocal contact lens with inner distance and outer near zones. Effects are exaggerated.

Corrections have aberrations that interact with those of the eye. Spectacle lenses do not move with the eye, and their important aberrations are associated with foveal vision and oblique incidence of light on the lens as the eye rotates behind it. Aberrations highly dependent on pupil size, such as spherical aberration, are not important for spectacle lenses as the surface curvatures are too small to affect aberrations. Contact lenses and intraocular lenses move with the eye and have high surface curvatures, and aberrations highly dependent on pupil size are important.

Some ingenious arrangements have been considered for the restoration of accommodation involving moving or altering the shape of intraocular lenses under the influence of the ciliary body during accommodative effort; these rely on the ciliary body's accommodative apparatus being intact. One surgical proposal relies on a maverick theory of accommodation and presbyopia in which the action of the ciliary body is to increase the lens diameter with age, at odds with the argument given here (see Section Changes With Age, Accommodation and Presbyopia), and this is made more difficult by a supposed increase in lens diameter with age. The surgery involves increase in the diameter of the eye so that the ciliary body can once again influence lens shape. At this time, none of these methods has been able to restore more than 2–3 D of accommodation, and usually any improvement is transient.

Aberrations

The refractive anomalies can be considered as optical aberrations of the eye. They reduce retinal image quality, prevent the image from being a perfect replica of an object (disregarding size and luminance effects), and adversely affect visual performance (e.g., visual acuity when reading letter charts). There are other aberrations which can interact with the refractive anomalies. Some of these aberrations become important when the refractive anomalies are corrected. These additional aberrations can be classified as monochromatic aberrations and the chromatic aberrations. Monochromatic aberrations are present at any wavelength and indeed change with wavelength. The chromatic aberrations occur when there is multi-wavelength light, and result from the varying refractive index of a transparent material with wavelength. This latter produces the separation of white light into its colored components known as chromatic dispersion.

Monochromatic Aberrations

There are three common ways of representing monochromatic aberrations (**Fig. 14(a)**). A wave aberration is the departure of the wavefront from the ideal waveform, as measured at the exit pupil. Transverse aberration is the departure of a ray from its ideal location at the image surface. Longitudinal aberration is the departure of the intersection of a ray with a reference axis (the pupil ray) from its ideal intersection; this may not always exist. The monochromatic aberrations must be measured in object space, with the exit pupil becoming the entrance pupil in this description (**Fig. 14(b)**).

In vision science, aberrations are specified as wave aberrations using the ophthalmic optics OSA variant of a Zernike polynomial function series (**ANSI, 2010; ISO, 2008**). The wave aberration $W(\rho, \theta)$ has the polar representation

$$W(\rho, \theta) = \sum_{n=0}^k \sum_{m=2i-n}^n c_n^m Z_n^m(\rho, \theta) \quad (1)$$

where Z_n^m is a particular Zernike polynomial and c_n^m is its coefficient (weighting). ρ is the relative distance from the center of the pupil and ranges from 0 to 1 (**Fig. 15**). θ is a meridian in radians and ranges from 0 to 2π . It is measured from the positive X-axis (to an observer's right when he or she looks at an eye) with an anticlockwise angle, as for the cylindrical axis scheme given earlier.

Fig. 14 Wave, transverse and longitudinal aberrations: (a) general optical system and (b) determined in object space as they must be for the eye.

Fig. 15 Pupil coordinate system for specifying ocular aberrations.

i is counted from 0 to n , and k is the maximum order of the polynomial series. The Zernike polynomial function Z_n^m is defined as

$$Z_n^m(\rho, \theta) = N_n^m R_n^{|m|}(\rho) \cos(m\theta), \text{ for } m \geq 0 \text{ and}$$

$$Z_n^m(\rho, \theta) = N_n^m R_n^{|m|}(\rho) \sin(m\theta), \text{ for } m < 0$$

where $R_n^{|m|}$ is a radial polynomial that is a function of ρ and $N_n^{|m|}$ is a normalization term. $R_n^{|m|}$ is given by

$$R_n^{|m|}(\rho) = \sum_{s=0}^{(n-|m|)/2} \frac{(-1)^s (n-s)!}{s! [0.5(n+|m|)-s]! [0.5(n-|m|)-s]! \rho^{n-2s}}$$

where the index n is the highest power of the radial polynomial and the index m describes the meridional frequency of the sinusoidal component of the Zernike polynomial. The normalization term N_n^m is given by

$$N_n^m = \sqrt{n+1}, \text{ for } m = 0 \text{ and } N_n^m = \sqrt{2(n+1)}, \text{ for } m \neq 0$$

The normalization means that the variance of each Zernike polynomial function is 1, and so the square of the coefficient of the Zernike polynomial function becomes the contribution of that polynomial function to the variance of the wave aberration.

Fig. 16 Three-dimensional representation of the first five orders of the Zernike polynomial functions pyramid.

Summing the squares of the coefficients for Zernike polynomial functions of a particular order n gives the contribution of that order to the wave aberration variance. For the total variance, it is usual to disregard the piston coefficient, whose value is arbitrary, and the tilt coefficients which do not contribute to quality (at least in monochromatic light). The root-mean-square (RMS) of the wave aberration (the square root of its variance) can be used as a measure of image quality. This is given by

$$\text{RMS} = \sqrt{\sum_{n>1, \text{ all } m} (c_n^m)^2}$$

The coefficients c_n^m are relative to the size of the pupil, and must alter with pupil size. The change is not simple because a Zernike polynomial function of a particular order contains lower order terms, for example, the primary spherical aberration polynomial is $Z_4^0 = \sqrt{5}(6\rho^4 - 6\rho^2 + 1)$. There are various ways by which Zernike coefficients can be recalculated at a new pupil size. Comparing aberration of different eyes, or the aberrations of a particular eye at different times, is valid only if this is done at the same pupil size.

The Zernike polynomial function series is sometimes represented as a pyramid in which order n changes vertically and frequency m changes horizontally **Fig. 16** shows Zernike aberration functions against pupil position for terms up to the 4th-order.

The first row order is $n=0$. The single function is called piston. Its coefficient is usually manipulated to make the wave aberration zero at the pupil center.

The second row order is $n=1$. The terms are tilts or prisms, Z_1^{-1} in the (vertical) y -direction and Z_1^{+1} in the (horizontal) x -direction. They are rotated functions of one another. This rotational nature continues down the pyramid, so that in any row a function with a negative value of the index m is a rotated form of the function with the same, but positive number for m .

The third row order is $n=2$. The terms are the refraction terms. The rotationally symmetric center term is called defocus (Z_2^0). The side terms are the astigmatisms. Oblique astigmatism (Z_2^{-1}) with $m=-2$ is on the left; it has a maximum value of $+\sqrt{6}$ along the 45 degree meridian and a minimum value of $-\sqrt{6}$ along the 135 degree meridian. Horizontal/vertical astigmatism (Z_2^{+1}) with $m=+2$ is on the right; it is rotated by -45 degree from oblique astigmatism to have a maximum value along the horizontal meridian of $+\sqrt{6}$ and a minimum value along the vertical meridian of $-\sqrt{6}$.

The fourth row order is $n=3$. The terms are the first of what are called the higher-order polynomial functions. The two middling terms are the comas, one vertical (Z_3^{-1}) and one horizontal (Z_3^{+1}). The fifth-row order is $n=4$, and its rotationally symmetric center term is called spherical aberration (Z_4^0).

Even order Zernike coefficients can be converted into refraction in the M, J_{180}, J_{45} classification given in the Section Refractive Anomalies according to

$$\begin{aligned} M &= -\frac{4\sqrt{3}c_2^0 - 12\sqrt{5}c_4^0 + 24\sqrt{7}c_6^0 \dots}{R^2} \\ J_{180} &= -2\frac{\sqrt{6}c_2^{-2} - 6\sqrt{10}c_4^{-2} + 12\sqrt{14}c_6^{-2} \dots}{R^2} \\ J_{45} &= -2\frac{\sqrt{6}c_2^{+2} - 6\sqrt{10}c_4^{+2} + 12\sqrt{14}c_6^{+2} \dots}{R^2} \end{aligned}$$

where is the pupil semidiameter for which coefficients apply. Converting from an error into a correction requires the initial negative signs on the right hand sides of the equations. When doing these calculations, it is convenient to have the coefficients in micrometers and the pupil size in millimeters so that the corrections are in diopters. A lens power minimizing the RMS of the wavefront is determined by using only the first terms on the right hand sides of the equations. As additional terms are added, we come closer to a paraxial refraction, in which we are determining the refraction based on rays traced into/out of the eye for a central part of the pupil.

Most instruments for measuring aberrations use near infrared wavelengths where fundus reflection is much higher than for visible light. This requires corrections ΔM and Δc_2^0 to the spherical equivalent refraction and defocus wave aberration coefficient, respectively. A schematic eye such as the Indiana Chromatic eye can be used for this purpose (Thibos *et al.*, 1992). For the infrared wavelength 840 nm and visible wavelength 550 nm, ΔM is approximately -0.87 D, and from the previous equation for M ,

$$\Delta c_2^0 = -\Delta M \cdot \frac{R^2}{4\sqrt{3}} = -0.144\Delta M \cdot R^2$$

Several investigations have been conducted on the magnitudes and distributions of the higher-order aberrations including how they vary with pupil size, age and refraction, eye side (right versus left), following refractive surgery, in various disease conditions, and the corneal and lenticular contributions to eye aberrations. Concerning pupil size, aberrations increase as pupil size increases and the relative contribution of the higher-order aberrations increases. There is considerable between-eye symmetry, with many higher-order terms being highly correlated between fellow eyes (Hartwig and Atchison, 2012). For on-axis vision, the most important higher-order aberrations are the comas and spherical aberrations. It cannot be overemphasized that the higher-order aberrations become important only when the lower order aberrations are largely corrected.

Aberrations associated with peripheral vision have become of considerable interest in recent years. The eye has very high peripheral levels of defocus and astigmatism, and there is a shift in the pattern of the former with hyperopia and emmetropia tending toward myopia in the periphery (relative peripheral myopia) and myopes tending toward hyperopia in the periphery (relative peripheral hyperopia), at least along the horizontal vision field (Atchison, 2012). This has led to a consideration that hyperopes and emmetropes with relative peripheral hyperopia might have a tendency to develop myopia, and that compensating for the peripheral refraction might slow the progression of myopia. An alternative view is that the change in peripheral refraction pattern is a consequence rather than a cause of developing myopia.

Accompanying peripheral changes in the second order aberrations are changes in the higher-order aberrations. Most notably, horizontal coma changes approximately linearly with horizontal visual field angle and vertical coma changes approximately linearly with vertical visual field angle.

Chromatic Aberrations

Chromatic dispersion produces two types of aberration, longitudinal and transverse.

Longitudinal chromatic aberration of the eye is shown in Fig. 17(a). A beam of multiwavelength light from an axial target O enters the eye. The refractive indices inside the eye vary with wavelength, so the path followed by a ray depends upon its wavelength. Refractive indices decrease with increase in wavelength, so the eye power decreases as wavelength increases. If the eye is focused at the target for a yellow light, rays of longer wavelength (such as reds) are focused behind the retina and rays of shorter wavelength (such as blues) are focused in front of the retina.

Longitudinal chromatic aberration can be quantified as a “chromatic difference of power” $\Delta F(\lambda)$, which is the difference in power of the eye between a wavelength λ and the reference wavelength $\bar{\lambda}$, i.e.,

$$\Delta F = F(\lambda) - F(\bar{\lambda})$$

It can also be quantified as a “chromatic difference of refraction” $\Delta R_x(\lambda)$, which is the difference between vergences for which a target is focused at the retina for different wavelengths, or more simply is the change in refraction with wavelength; the second way is how the aberration is measured experimentally (Fig. 17(b)). In mathematical terms

$$\Delta R_x(\lambda) = L(\lambda) - L(\bar{\lambda})$$

where $L(\lambda)$ and $L(\bar{\lambda})$ are the object vergences required at λ and $\bar{\lambda}$, respectively. For the situation shown in the figure, these vergences are both negative.

The relationship between chromatic difference of refraction and chromatic difference of power is (Atchison and Smith, 2000)

$$\Delta R_x(\lambda) = \frac{[n'(\lambda) - n'(\bar{\lambda})] [F(\bar{\lambda}) + L(\bar{\lambda})]}{n'(\bar{\lambda})} - \Delta F(\lambda)$$

where $n'(\lambda)$ and $n'(\bar{\lambda})$ are vitreous refractive indices at λ and $\bar{\lambda}$, respectively.

For an emmetropic eye focused at infinity, $L(\bar{\lambda}) = 0$, and the equation reduces to

$$\Delta R_x(\lambda) = \frac{[n'(\lambda) - n'(\bar{\lambda})] F(\bar{\lambda})}{n'(\bar{\lambda})} - \Delta F(\lambda)$$

The range of chromatic difference of refraction is about 2.1 D between 400 and 700 nm, and is slightly higher than that for a reduced eye filled with water. There are minor differences between studies and between participants within studies. Despite the

Fig. 17 Longitudinal chromatic aberration (greatly exaggerated). (a) Imagery at the eye for blue, yellow and red lights when the yellow light is focused at the retina and (b) determining chromatic difference of refraction. Object distances are specified relative to the anterior principal plane of the eye.

large magnitude, longitudinal chromatic aberration has little deleterious effect on vision, largely because its effects are attenuated by the variable sensitivity of the eye to different wavelengths (Fig. 8).

Transverse chromatic aberration of the eye is shown in Fig. 18(a) for an eye which is a centered optical system and for off-axis object point Q. The different wavelength images are at different depths because of the longitudinal chromatic aberration. Also, because the power is less for long wavelengths than for short wavelengths, longer wavelength rays are deviated less than shorter wavelength rays to reach the retina further away from the optical axis.

Like longitudinal chromatic aberration, transverse chromatic aberration must be measured outside the eye, where it is quantified as a "chromatic difference of position" (Fig. 18(b)). Rays of wavelength λ and $\bar{\lambda}$ originate from different positions in object space, but pass through the same point in the pupil to intersect at the retina. The chromatic difference of position $t(\lambda)$ for height h of the rays in the pupil, relative to the visual axis ray (ray passing through the nodal points) is

$$t(\lambda) = a_\lambda - a_{\bar{\lambda}}$$

where a_λ and $a_{\bar{\lambda}}$ are angles subtended by the rays with the visual axis in object space.

The transverse chromatic aberration and longitudinal chromatic aberration, or more specifically the chromatic difference of position and the chromatic difference of refraction, are related by the equation (Atchison and Smith, 2000)

$$t(\lambda) \approx h \Delta R_x(\lambda)$$

Because the eye is a decentered optical system, there is transverse chromatic aberration associated with foveal vision, and the foveal chromatic difference of position is

$$t(\lambda) \approx d \Delta R_x(\lambda)$$

where d is the departure of the line-of-sight, the axis joining the fixation target and the center of the pupil, from the visual axis (Fig. 18(b)).

The range of foveal chromatic difference of position across the visible spectrum can be higher than 1 min of arc. Usually the line-of-sight is nasal to the visual axis in object space (Fig. 6). In binocular vision, this can give rise to the phenomenon of chromostereopsis in which reddish objects appear to be closer than bluish objects at the same distance. Potentially transverse chromatic aberration can have deleterious effects on vision because it produces wavelength-dependent changes in spatial phase of images. This may be a problem for highly decentered natural or artificial pupils. Two-thirds loss of resolution may result for 3 mm displacement of small artificial pupils (Green, 1967; Thibos *et al.*, 1991).

Retinal Image Quality

Retinal image quality can be determined in different ways. One way is to use the wave aberrations themselves or a metric based on them such as the root-mean-squared aberrations. Another common quality measure is the point spread function, which is the shape and dimension of the image of a point object. The optical transfer function measures changes, from object to image, in the contrast and phase of sinusoidal varying luminance patterns. The wave aberration is related to the point spread function and optical transfer function by Fourier transforms, but this overestimates the quality of the retinal image as it does not take into account scatter within the media and the fundus. The point spread function can be measured by a double pass method (light

Fig. 18 Transverse chromatic aberration (greatly exaggerated). (a) Centered pupil and an off-axis object and (b) determining chromatic difference of position (for simplicity, the nodal points are assumed to be at a common point).

passes into the eye and is reflected out), and the contrast aspect of the optical transfer function can be estimated by comparing contrast sensitivities of the eye obtained with screen-based equipment and with an interferometric method in which the optics are effectively by-passed (Archison and Smith, 2000).

Several metrics based on wave aberrations have been used to estimate objective refractions. They involve manipulating refraction to minimize or maximize some aspect of the aberrations or of image quality, for example, maximizing the Strehl intensity ratio which is the height of the point spread function relative to its aberration-free height.

Changes With Age

Pathological changes that occur in the optics of the eye with age, such as cataract, will not be considered here.

Cornea

As age increases, there is fiber degeneration, decreased spacing between collagen fibrils of the stroma, and increases in the cross-sectional area of collagen fibers. Descemet's membrane increases in thickness with age and the size of endothelial cells becomes more variable. Endothelial function may become impaired, with the aqueous humor seeping into the cornea, disrupting structural order and increasing light scatter.

The anterior surface radius of curvature is usually greater along the horizontal than along the vertical meridian in young eyes, but this trend reverses with age. There is little variation in transmittance with age, but Boettner and Wolter (1962) found a decrease in the direct (non-scattered) light with increased age.

Aperture Stop and Iris

The natural pupil becomes smaller with increase in age, a process known as senile miosis, and this is accompanied by decreases in speed and magnitude of pupil reactions.

Lens

The human lens grows throughout life with considerable changes in size, shape, mass, and stiffness. The young lens is soft and easy to deform, while the old lens is stiff and unable to be deformed. With age, the lens becomes thicker along its axis with

corresponding decrease in anterior chamber depth. Its surfaces become more curved, with greater change for the anterior than for the posterior surface. Equatorial thickness either does not change or increases slowly with age. There are changes in refractive index distribution such that the refractive index change is restricted to a smaller proportion of the peripheral lens, accompanied by a reduction in the equivalent index (Kasthurirangan *et al.*, 2008).

Light Loss at the Retina

Retinal illumination decreases with age due to senile miosis and decrease in ocular transmittance. Decrease is much more rapid for shorter than for longer wavelengths (e.g., van de Kraats and van Norren, 2007) (Fig. 19). As a consequence, the lens becomes more yellow with increase in age. With aging, there is increase in both forward and backward-scattered light.

Refraction

The distribution of refraction is strongly age-dependent. Newly-born children have a normal distribution whose mean is considerably hyperopic with a distribution range to approximately ± 10 D (Grosvenor, 2002). The growth of ocular components is coordinated so that emmetropia can be achieved by 6 years of age, a process known as emmetropization, but emmetropia is not always subsequently maintained. By 6–8 years the mean refraction is slightly hyperopic and the distribution is steeper than a normal distribution (leptokurtosis). A pronounced tail in the myopic direction develops after this and is observed in data of 20-year olds. The distribution is stable between the ages of 20 and 40 years, after which the distribution becomes less leptokurtic and then there is usually a hyperopic shift (Grosvenor, 2002). The age-related formation of cataracts can alter the refraction.

Most studies of refraction have been cross-sectional, meaning the measurements of people of different ages occurred within a limited time span. These can mask intergenerational (longitudinal) changes. In particular they do not pick up changes in the direction of myopia that have been occurring in the last few decades (e.g., Edwards and Lam, 2004) (Fig. 20). Myopia prevalence is correlated with increasing urbanization (Ip *et al.*, 2008; Zhan *et al.*, 2000) and its prevalence in East Asian countries is now in excess of 80% by early adulthood (He *et al.*, 2004; Lin *et al.*, 2004; Wu *et al.*, 2001). Myopia is a leading cause of blindness in later life, as having severe myopia doubles the risk of developing serious eye problems, such as cataract and retinal detachment. There is no “safe” level of myopia, with even low levels increasing the risk of other ocular diseases (Flitcroft, 2012).

The age-related changes mentioned above for corneal toricity affect astigmatism of the eye. Considerable astigmatism, usually against-the-rule, exists in the first year, but decreases quickly during early infancy. Astigmatism is usually with-the-rule up to 40 years, after which the prevalence of against-the-rule astigmatism increases.

Accommodation and Presbyopia

Presbyopia is the name given to the loss of clear and comfort near vision which occurs because of the age-related loss of accommodation amplitude. Onset for most people is the early to mid-40s, but is affected by the amplitude, the nature and duration of close work, and other refractive conditions. The decline in amplitude of accommodation might be affected by a number of factors including diet, race, exposure to ultraviolet radiation, and temperature. As an example of the influence of refractive conditions, in the absence of a distant correction, a low myope would need a lesser amplitude of accommodation than a hyperope to perform near tasks and would become presbyopic later in life.

Previously it was mentioned that, after peaking early in life, accommodation amplitude gradually reduces to become zero by mid-50s. Many clinically related studies suggest that some accommodation remains into older age (Fig. 21). This is an artefact of subjective measurement (the participants’ judgement is involved) involving depth-of-focus.

Fig. 21 Subjective amplitude of accommodation as a function of age from the study of Ungerer (1986).

Aberrations

Taking into account normal age-related pupillary miosis, there is reduction in higher-order aberrations with increase in age (Applegate *et al.*, 2007). Considering fixed pupil sizes, total higher-order aberrations increase throughout adulthood and spherical aberration becomes more positive with increase in age (Applegate *et al.*, 2007).

Measuring Retinal Blood Flow

Alberto de Castro and Stephen A Burns, Indiana University School of Optometry, Bloomington, IN, United States

Introduction

The retina of the eye, in addition to being one of our most vital sensory organs, is the most accessible portion of the central nervous system (CNS). This has led to an array of noninvasive approaches to measuring its structure and function. It is uniquely accessible for optical measurements, since evolution has resulted in an optical window that lets us probe more than 2 cm into the body. While early optical measurements of the retina were primarily structural and based on photography, it was quickly realized that the blood supply of the retina, which enters and exits the eye through the optic nerve head and courses across the surface, provides a unique window into the CNS. The retina has the added advantage that the circulation is laid out in a layered form, with most of the vessels lying in a series of layers parallel to the walls of the eye (Snodderly *et al.*, 1992), an arrangement which parallels the neural layers of the retina. This arrangement allows ready optical access to the vessels and is simpler than the layout in the cortex, which can be quite complex. Thus the eye was an early target for measurements of blood flow and its regulation. The techniques used included measures of the flow of fluorescein dye (Wessing, 1974; Jung *et al.*, 1983; Wolf *et al.*, 1989, 1990), speckle decorrelation (Fercher and Briers, 1981; Suzuki *et al.*, 1991), and laser Doppler velocimetry (Riva *et al.*, 1972, 1979; Feke and Riva, 1978) or Doppler optical coherence tomography (OCT) (Chen *et al.*, 1997; Westphal *et al.*, 2002). Measurements have included blood velocity, total flow, and have incorporated the regulation of blood flow, allowing measures of both the metabolic demands of the retina and body, as well as how the oxygen supply is driven by neuronal tissue. That is, when a visual stimulus is presented to the eye, the blood flow must change to meet the increased metabolic demand of the neural tissue, a process referred to as neurovascular coupling (Riva *et al.*, 2001; Pournaras *et al.*, 2008; Kur *et al.*, 2012). Some retinal diseases, such as diabetic retinopathy (DR), have a severe impact on both the structure of the retinal vasculature and the regulation of blood flow (Grunwald *et al.*, 1986, 1990; Kohner *et al.*, 1995; Garhöfer *et al.*, 2004; Deak and Schmidt-Erfurth, 2013).

Most of the blood flow in the posterior pole of the eye is supplied by the central retinal artery and exits the eye through central retinal vein, both of which traverse the optic nerve. For this reason measurements near the optic nerve can capture a large proportion of the blood supply to the neural retina as it enters and exits the eye. These measurements therefore can provide a tool for understanding the total retinal metabolic demand. These vessels are relatively large, typically on the order of 100 μm or larger, and thus are easily resolved and carry large volumes of blood, providing a high signal:noise ratio (SNR) for measurements. However, vascular control (Villringer and Dirnagl, 1995; Riva *et al.*, 2001, 2005; Pournaras *et al.*, 2008) is performed at a more local level (Zhong *et al.*, 2012), and in fact it is not known how local the control of retinal blood flow is, nor the area over which it is regulated. In recent years there has been increasing interest in making more local measurements of retinal blood flow driven in part by the growing availability of adaptive optics in retinal imaging.

This article provides a brief overview of current optical techniques for measuring retinal blood flow and then concentrates on approaches to measure the cell velocity in the capillaries of the human retina.

Total Retinal Blood Flow

Early measurements of blood flow depended on injecting fluorescein into the body and then using photographic and video techniques to measure the transit time (Jung *et al.*, 1983). These dye methods improved with the development of techniques based on the scanning laser ophthalmoscope (SLO) (Wolf *et al.*, 1989, 1990) and because they measured the transit of blood moving from the central retinal artery to the draining veins, they gave an estimate of the total transit time of the retina. By combining this with the approximate size of the vessels, and making assumptions about the nature of the flow based on parabolic velocity distribution (Pouisselle's law), an estimate of total blood delivered to the eye could be obtained. These techniques are mostly based on plasma velocity, since fluorescein is a small molecule and is present in the plasma fraction of the blood. The advent of the laser allowed development of laser Doppler velocimetry measurements (Feke and Riva, 1978; Riva *et al.*, 1979), and by making these measurements from two points in the pupil, variations due to angle and bulk movements could be accounted for, improving the accuracy. More recently, OCT has been used to make Doppler measurements (White *et al.*, 2003; Leitgeb *et al.*, 2004; Dai *et al.*, 2013; Doblhoff-Dier *et al.*, 2014; Aschinger *et al.*, 2015). In both techniques the Doppler shift arising from red blood cells is used to provide a measurement of the velocity of the cells. Typically the centerline velocity has been measured, since this provides a maximum frequency shift on the impinging light. It is becoming increasingly apparent that the flow in the retina is not parabolic (Bishop *et al.*, 2001; Logean *et al.*, 2003; Zhong *et al.*, 2011; Willerslev *et al.*, 2014) and the advances in both axial and lateral resolution are allowing more accurate estimates of total blood flow (Baumann *et al.*, 2011).

The movement of cells in the vasculature can also be used to generate flowmetry estimates. In these it is the variation over time, rather than the Doppler shift, that is used to estimate perfusion of the tissue. This was first attempted using speckle decorrelation (Fercher *et al.*, 1985) and flowmetry (Riva *et al.*, 1992) and the motion alone has been used to qualitatively separate vessels according to their speed (Ferguson *et al.*, 2004). OCT also can be combined with this technique, and this is generally called OCT

angiography (or OCT-A) although there are a number of variants (Makita *et al.*, 2006; Wang *et al.*, 2007; Tokayer *et al.*, 2013). Finally the motion can be directly tracked by imaging a single line repeatedly over a larger vessel with an adaptive optics scanning laser ophthalmoscope (AOSLO). In this method, by stopping the slow scanner, streaks created by the erythrocytes passing through are visible in the spatiotemporal image and its slope can be related directly to speed (Zhong *et al.*, 2008, 2011).

Capillary Blood Flow

Why Measure Blood Flow in Capillaries

Noninvasive access to capillaries and capillary flow is of increasing interest in the retina. Capillary velocities have mainly been measured in the area surrounding the fovea, where there is one or two capillary layers and one can easily assume that these are perpendicular to the retina, i.e., in the imaging plane. There are a number of purposes for such measurements, ranging from the understanding of the local control of blood flow, to biological parameters governing flow, such as the interaction of blood with the vascular walls, to the impact of disease on both the physical properties of the vascular system and the regulation of flow. Techniques for measuring flow at the capillary level depend on the ability to measure the movement of cells on an individual basis. A number of techniques have been devised for this, including psychophysics, fluorescent detection techniques, and, most recently, adaptive optics (Fig. 1). Some general patterns emerge from these techniques, however, it is important to note that different techniques measure different aspects of the blood, ranging from the relatively large leukocytes (psychophysics and recently, AO imaging), to cell aggregates interspersed with plasma (fluorescein), to red blood cells (direct imaging with adaptive optics). Because of this heterogeneity in the measuring techniques, differences in velocities obtained using different techniques are not surprising. The small diameters of the capillaries and the need for cells to deform as they move through them can cause differences in velocity for different blood fractions. However, understanding the differences between the methods and the velocities being measured remains an important topic of research as will be an understanding of the variability of the normal retina, since this provides the background upon which clinical measurements need to be compared. The next section of this article compares results obtained with six different methods, most having very different assumptions.

Blue Field Entoptic Phenomenon

The retina itself can be used as a detector for measuring retinal blood flow. This is what is done with the blue field entoptoscope (Kato, 1952; Riva and Petrig, 1980). When looking at a relatively bright blue field (including a clear blue sky), bright dots can be observed moving in an erratic manner in the observer's visual field. These dots are believed to be white blood cells moving in the capillaries of the eye. White blood cells do not absorb blue light and thus, when crossing over a region of retina the cells are detected by the photoreceptors giving the appearance of a bright dot. By comparing the perceived motion of these dots to a simulation on a computer monitor the apparent speed can be matched (Riva and Petrig, 1980). The blue field technique gives an average velocity of 0.77 mm s^{-1} and this varies with exercise (Kato, 1952). Velocity estimates are pulsatile, changing with the heart beat (Riva and Petrig, 1980) and the mean velocity decreases with age by 20% (Grunwald *et al.*, 1993). The measured pulsatility, defined as $(V_{\text{max}} - V_{\text{min}})/V_{\text{mean}}$, is 0.98 (Riva and Petrig, 1980). The impact of diabetes on capillary flow is non-monotonic; in diabetics with no retinopathy, Fallon *et al.* (1986) observed average velocities similar to those in non diabetics

Fig. 1 Adaptive optics scanning laser ophthalmoscope (AOSLO) images of capillaries in the perifoveal area of a healthy subject. The use of multiply scattered light has allowed direct visualization of leukocytes (passing through the capillary marked with the white arrow) and erythrocytes (black arrow) in the capillaries in the retina (individual video frames).

(0.51 and 0.54 mm s⁻¹, respectively), but reported an increase of velocity in patients with background retinopathy (0.74 mm s⁻¹), and a decrease in the preproliferative stage (0.37 mm s⁻¹), to increase again after photocoagulation (0.42 mm s⁻¹). Additionally, the velocity of the leukocytes is sensitive to neural activity, increasing in the presence of flickering background lights. This velocity increase (Scheiner *et al.*, 1994) occurs about 15 s after the onset of the flickering stimulus and under the conditions used increased more than 50% (from 0.60 to 1.01 mm s⁻¹). In general, velocities measured with the blue field entoptoscope are some of the lower velocity values obtained (Table 1), but it is important to note that these are almost certainly leukocytes moving through the capillaries near the foveal avascular zone, which are some of the smallest capillaries, and the slower values may reflect the mechanical constraints on fitting large cells through small capillaries.

Fluorescein Angiography

Fluorescein angiography is a common clinical technique for investigating the health of the retinal vasculature. During fluorescein angiography the fluorescein dye is injected (typically in the arm) and arrives as a dye front at the eye. Because the early phases of the fluorescein angiogram have high contrast it is possible to obtain excellent images of the vascular network. If fluorescein angiograms are collected using video techniques, segments of low and high fluorescence can be observed moving through the capillaries in the parafoveal region of the retina. The segments of low fluorescence are thought to correspond to erythrocytes in rouleaux formation (that is strings of red blood cells closely packed to each other). The cells are not stained by the fluorescein and thus are dark and the more fluorescent segments then correspond to cell-free plasma (Arend *et al.*, 1994). The velocity of the hypofluorescent segments, which are sparse enough to be readily identified, can be determined by measuring

the distance traveled between two frames. Using videos captured with a SLO, an average speed in the perifovea of 3.28 mm s^{-1} was obtained in normal subjects and a lower value (2.89 mm s^{-1}) was observed in diabetics (Arend *et al.*, 1991; Wolf *et al.*, 1991).

While the hypofluorescent segments were assumed to be rouleaux, Yang *et al.* (1997) made measurements on two types of hyperfluorescent signals: hyperfluorescent dots and hyperfluorescent segments. He considered the dots to be leukocytes and measured a speed of 1.37 mm s^{-1} and, similar to Wolf *et al.* (1991), hypothesized that the segments might be the plasma gaps located between erythrocyte rouleaux. The segments moved at a lower velocity than the dots, consistent with the size difference of the particles being tracked. The velocities measured with fluorescein angiography are higher than those obtained with the blue field entoptoscope. This could be because they measure slightly different parts of the retina since with an SLO measurements can be performed at higher eccentricity than when using the blue field entoptic phenomenon (Arend *et al.*, 1995), or perhaps because the visual backgrounds are different leading to a different demand on retinal blood flow. Both techniques provided a background, but that of the SLO is very bright and is actually flickering due to the sequential scan with local intensity varying at approximately 30 frames per second.

Fluorescently Stained Leukocytes

A variant of the fluorescein method involves the use of labeled leukocytes. In this method blood is withdrawn from a subject, leukocytes are separated from the plasma and erythrocytes by centrifugation, and they are stained with fluorescein. When reinjected into the same patient from whom they were extracted the externally stained leukocytes can be observed passing through the capillaries of the retina, providing a very high contrast signal. The velocity can be determined without the risk of aliasing due to the sparse number of stained cells. Thus a single cell can be followed as it changes position over several frames of a video. Yang *et al.* (1997) measured leukocyte velocity using an SLO and measured an average value of 1.41 mm s^{-1} . Paques *et al.* (2000) used a similar method and reported a mean velocity of 1.43 mm s^{-1} in the macula and 1.82 mm s^{-1} in the peripapillary area. This technique is very powerful, and since the subject's own cells are used as a low risk of complications, however, it is not possible in some regions to obtain approvals for its use in humans.

Leukocyte Imaging With AOSLO

Adaptive optics has now enabled imaging at cellular scale in the living human retina (Liang *et al.*, 1997). The first applications to measuring blood flow with adaptive optics used a confocal AOSLO focused on the cone photoreceptors. Under these conditions, dark shadows can be visualized moving across the retina. This motion is most evident in the capillaries close to the fovea. Martin and Roorda (2005) argued that they should be leukocytes and calculated their speed by measuring the distance traveled between several frames giving an average velocity of 1.37 mm s^{-1} , similar to previous studies of leukocytes velocity as discussed above. The velocity of these shadows varies with the cardiac pulse (Martin and Roorda, 2009) with an average minimum speed of 1.0 mm s^{-1} and an average maximum speed of 1.58 mm s^{-1} , resulting in a pulsatility of 0.45. The speed of the leukocytes was also determined by computationally straightening the capillaries and calculating the slope of the changes of intensity along a capillary as a function of time (Tam *et al.*, 2011). In this spatiotemporal plot thick, high contrast and sparse traces and thin, low contrast and dense traces were observed. This pattern of results is consistent with the thick traces being leukocytes and the thin traces corresponding to erythrocytes or plasma gaps between erythrocytes. However, contrary to expectations, the velocity of the leukocytes was found to be higher than the velocity found in plasma gaps (1.80 vs. 1.30 mm s^{-1}) suggesting that either these traces are not a good proxy for erythrocyte velocity or that leukocytes and erythrocytes travel at similar velocities when restricted to single-file capillaries (Tam *et al.*, 2011).

Erythrocyte Imaging With AOSLO

Adaptive optics also allows directly imaging cells in the retinal vessels. If a confocal AOSLO is focused on the small vessels and capillaries, bright moving dots are seen. These can move quite quickly. It is possible to sample these moving cells more densely by momentarily halting the slow direction of the scan. The retinal image at this point becomes a position versus time image, and the cells are seen as diagonal streaks, with the angle of the streak representing the component of the cell's velocity in the direction of the scan (Zhong *et al.*, 2008). This approach works well for vessels ranging in size from about $15\text{--}20 \mu\text{m}$ in diameter upwards, but at the small end is limited by eye movements, since to capture the entire cardiac cycle the scanning line should remain on the vessel for about 1 s, and micro-saccades and ocular drift can move it off. In animals under anesthesia this or similar techniques (Guevara-Torres *et al.*, 2016) work relatively well, and the advent of highly stabilized AOSLO's hold promise for capillary measurements (Vogel *et al.*, 2006; Burns *et al.*, 2007; Yang *et al.*, 2014). In addition to the eye movements there are other disadvantages of this technique in that not all of the cells are easily seen. Visibility of the cells in a confocal imaging mode is highly dependent on the orientation of the cells and thus brightness can vary rapidly. In addition, there are so many cells that great care needs to be taken to avoid aliasing. The contrast issue can be dealt with by imaging using multiply scattered light imaging (Elsner *et al.*, 2000). This form of imaging improves contrast of vasculature and allows red blood cells to be directly imaged, while traveling through the capillaries (Chui *et al.*, 2012). The potential for aliasing has recently been solved by using two image wavelengths and a scanning system to collect images from the two channels with a slight offset between them

Fig. 2 The erythrocyte position was detected in one of the channels (a) and when studying the same region in the other channel (b) the one with the temporal shift, a displaced image of the same cell was observed. In the figure, the shift of the image of the average cell is used to calculate the velocity at different times (c).

Fig. 3 Using a dual channel scanning laser ophthalmoscope, the velocity of the red blood cells passing through three capillaries was measured simultaneously.

(de Castro *et al.*, 2016). This spatial offset is equivalent to a temporal separation, because the same retinal region is imaged at slightly different times in each channel. By varying the spatial misalignment, the temporal offset can be varied over a wide range of values to match the imaging task. If the displacement is made in a pupil conjugate plane, then it becomes possible to rapidly adjust the temporal separation between channels. Thus by using multiply scattered light imaging and a separation of 71 lines (which corresponds to 4.7 ms, since the frequency of the fast scan was 15.1 kHz), de Castro *et al.* (2016) were able to measure the velocity of the red blood cells in the capillaries of the foveal and parafoveal region (Fig. 2). The velocity measurements were pulsatile, with peak values ranging from 0.70 to 3.98 mm s⁻¹. The average velocities of three different subjects, 10 capillaries each, ranged from 0.30 to 2.23 mm s⁻¹ with a mean value of 1.14 mm s⁻¹, similar to estimates of other methods although lower than the fluorescein methods (Table 1).

To obtain a better signal to noise ratio de Castro *et al.* averaged cell images from three consecutive frames, i.e., one measurement every 107 ms. They were able, under good conditions to determine the velocity at the frame rate of the imaging system, 36 ms. The technique also allowed simultaneous measurements of multiple capillaries within a single field of view, typically between 1.2 and 1.8 degrees. One striking feature of the measurements is that different capillaries within the same video and of the same size have different red blood cell velocities (Fig. 3).

Erythrocyte Imaging With Flood Illuminated Adaptive Optics. Particle Image Velocimetry

Adaptive optics can also be used in non-scanning system. Using a flood illuminated adaptive optics ophthalmoscope with a high temporal resolution camera, Bedggood and Metha (2012) were successful in imaging erythrocytes traveling through the capillaries and velocities could be determined with particle image velocimetry methods. To achieve a frame rate of 460 frames per second, the vertical extent of the imaged regions was reduced to 70 μm and images were captured during sequences of 130 ms (60 frames). They found a wide range of velocities (from 0.3 to 3.3 mm s⁻¹, mean 1.3 mm s⁻¹) and a general increase in velocity during the captured time sequences. They reported that the same capillary segments showed different velocities when

imaged several times and also that, within the same sequence, while some capillary segments increased their velocity, others did not. The authors argued that the reason for the increase in velocity during imaging was not neurovascular coupling, since the reaction time in capillaries in animal models as well as the human eye is typically longer (Scheiner *et al.*, 1994) than their imaging time. The advantage of the flood illuminated approach is that image rates can be very high, and corrections for timing arising from the nature of scanning systems are not needed. However, image quality is not as good as with the AOSLO methods due to the lower contrast, and the applicability of this approach to image blood cells in clinical or older populations is not yet known.

Discussion

The literature on blood velocity and blood flow in the eye is very large, and as we have shown, interpretation requires understanding not only the measurement technology, but the biophysical properties of blood flow within different size blood vessels and indeed under different physiological and pathological conditions. However, because flow measurements can be combined with other optical measurements such as oximetry (Delori, 1988) to determine metabolic activity (Blair *et al.*, 2016) the promise to use these techniques for understanding both the normal and abnormal properties of the CNS is great. It is also important to note that most of the techniques have different advantages and disadvantages, and so one particular method may not be ideal to answer all questions.

The different techniques do seem to give different estimates of velocity, and some of these differences may reflect the different components of the blood being used to measure velocity as well as where in the retina they are measured. However, many of the techniques use leukocytes, and while these can be expected to move more slowly through capillaries, since they are much larger, the values found in erythrocytes (Bedggood and Metha, 2012; de Castro *et al.*, 2016) are comparable to those measured on leukocytes using the entoptic phenomenon (Kato, 1952; Riva and Petrig, 1980; Fallon *et al.*, 1986; Grunwald *et al.*, 1993), labeling with fluorescein (Yang *et al.*, 1997; Paques *et al.*, 2000), or direct imaging with AOSLO (Martin and Roorda, 2005, 2009; Tam and Roorda, 2011). However, the peak velocities found with higher temporal resolution using the dual channel AOSLO (de Castro *et al.*, 2016) are only comparable to those obtained injecting intravenous fluorescein (Arend *et al.*, 1991, 1995; Wolf *et al.*, 1991).

Finally, it is clear that there is a lot of variability in the measurements. Table 1 summarizes measurements of capillary blood velocity. And within any cell class the variability in the velocity measurements is large and this may reflect more than measurement variability, since different capillaries have different speeds and composition of cells (Tam *et al.*, 2011; de Castro *et al.*, 2016; Guevara-Torres *et al.*, 2016).

This natural variation may place a fundamental limit on the simple application of these techniques to clinical measurements, since it will be necessary to obtain sufficient sample sizes to understand the cause of differences. However, it should not be a problem when testing the response of the retina to different conditions within an eye (such as exercise or visual stimulation) since in this case the response of several individual vessels can be compared. Finally, it is important to note that the eye now provides a tissue in which it is possible to measure the entire vascular tree ranging from vessels larger than 100 μm to the smallest capillaries. This will allow improved understanding of the biophysical properties of the entire vascular network and how it responds to stress and disease.

Adaptive Optics Retinal Imaging Techniques and Clinical Applications

Jessica IW Morgan, University of Pennsylvania, Philadelphia, PA, United States

Introduction

Ophthalmoscopy is a fundamental part of a fundus exam, because it allows observation of the retina through the natural optics of the eye. Since the first fundus photograph was taken in 1886 (Jackman and Webster, 1886), numerous modalities for ocular imaging have been developed. However, the overarching goal of these imaging techniques remains stationary: to understand the structure and function of the normal visual system and to assist in the diagnosis, prognosis, and treatment of the diseased visual system. The purpose of this current article is to describe state-of-the-art adaptive optics (AO) high-resolution ophthalmic imaging, the detection schemes used in different AO imaging modalities, the current analysis methods utilized for interpreting high-resolution AO images of the outer retina, and a brief discussion of the current and future clinical applications for this technology.

Optical Limitations for Imaging in the Eye

One can think of retinal imaging in the same terms as imaging with a microscope, where the retina is the sample to be imaged and the optical components of the eye provide the final objective lens in front of the sample. All optical systems, including the eye, are limited in resolution by their point spread function (psf), which is defined as the volume of space over which a focused point of light extends. Therefore the resolution of a retinal image, regardless of which imaging modality or detection scheme is employed, will be limited by the size of the eye's psf. The eye's psf in turn is dependent upon the quality of the optical components of the eye (the cornea and lens) as well as the limiting aperture of the eye (the pupil). For an ideal, aberration-free eye, the psf would be determined by diffraction through the pupil. In the diffraction limit, the spatial extent of the psf decreases with increasing pupil diameter, leading to the resolution limit:

$$l_{\text{transverse}} = \frac{1.22f\lambda_0}{D}$$

where f is the focal length of the eye, λ is the central imaging wavelength, and D is the pupil diameter. Unfortunately, the cornea and lens of the real eye are not ideal optical elements; these elements impose optical aberrations on light entering (or reflected out of) the eye, and thereby increase the size of the psf beyond that of the diffraction limit. For real eyes with pupil diameters that are 2 mm or smaller, the size of the psf is dominated mainly by diffraction. However, for pupil diameters larger than 2 mm, ocular aberrations become the dominant factor for determining the extent of the psf (Packer and Williams, 2003). In theory, eliminating the optical aberrations imposed on light entering or exiting the eye by the cornea and lens would reduce the size of the psf to that observed in the diffraction limiting case, even at large pupil sizes. Optically compensating for the eye's optical aberrations thus becomes the main concept behind high-resolution AO ophthalmoscopy.

AO

AO is a technique first proposed by astronomers to measure and correct for optical aberrations imposed by turbulence in earth's atmosphere (Babcock, 1953). Incorporating this technique into ground-based telescopes resulted in improvements in transverse resolution and contrast of astrological images. The same concept was applied to ophthalmoscopy by Liang *et al.* (1997). The goal of AO ophthalmoscopy is straightforward: first measure, then correct for the optical aberrations of the living eye in order to attain diffraction limited resolution through large pupil sizes.

Ophthalmic AO systems typically use a Shack–Hartman wavefront sensor to measure the optical aberrations of the eye. This consists of a lenslet array and a two-dimensional (2D) camera. The lenslet array is placed at a plane optically conjugate with the eye's pupil. Each lenslet of the array focuses a small section of the wavefront to a single spot on the camera. For an ideal, aberration-free optical system, the result is a perfectly spaced 2D grid of focused spots, called the reference. For an aberrated system, such as the real eye, the arrangement of focused spots will be distorted from the perfectly spaced reference grid, and the x and y displacement of each focused spot from its ideal reference location allows a direct calculation of the wave aberration at the location of the lenslet within the pupil plane (Liang *et al.*, 1994).

After the wavefront sensor, the second critical component for an AO system is the wavefront corrector. This optical element also is placed optically conjugate with the eye's pupil and therefore the lenslet array of the Shack–Hartman wavefront sensor. Ophthalmic AO systems typically use a deformable mirror for this purpose, but other techniques, such as liquid crystal spatial light modulators, also can be used. The shape of the deformable mirror is adjusted to be one half of the amplitude of the wave

Fig. 1 Schematic diagram of wavefront measurement and adaptive optics (AO) correction. Reprinted from Carroll, J., Gray, D.C., Roorda, A., Williams, D.R., 2005. Recent advances in retinal imaging with adaptive optics. *Optics and Photonics News* 16, 36–42 with permission from Joseph Carroll.

aberration at each point in the pupil, such that the imposed phase delay at each point in the pupil results in a (close-to) aberration-free wavefront that when measured using the Shack–Hartman wavefront sensor approaches the reference grid of focus spots. This AO correction yields an aberration corrected psf for the eye, which is thus close to that of the diffraction limit, even for dilated pupils. A schematic diagram of wavefront measurement and AO correction is shown in [Fig. 1](#) ([Carroll et al., 2005](#)). Most state-of-the-art AO systems run in closed loop with real-time AO correction occurring multiple times per second, as has been shown to provide improved AO quality in comparison with open loop systems ([Hofer et al., 2001](#)). Retinal imaging with a visible or near infrared light source (400–900 nm) incorporating AO correction over a dilated pupil (7 mm) provides sufficient transverse resolution for observing individual cells in the living retina, noninvasively.

AO Retinal Imaging

It is important to note that AO on its own is not a method of retinal imaging. Rather, AO is a tool used to increase the transverse resolution of a given imaging modality by correcting the optical aberrations of the eye. To obtain an AO retinal image, AO must be incorporated with technologies that encompass retinal image acquisition techniques. Here we describe three such retinal imaging modalities, AO flood-illuminated ophthalmoscopy, AO scanning laser/light ophthalmoscopy (AOSLO), and AO-optical coherence tomography (AO-OCT), and discuss applications of these three imaging techniques for studying the structure and function of the normal and diseased retina.

AO Flood-Illuminated Ophthalmoscopy

The first application of AO to ophthalmoscopy occurred when Liang, Williams, and Miller incorporated AO correction into a flood-illuminated fundus camera ([Liang et al., 1997](#)). A fundus camera system involves using a light source to uniformly illuminate a patch of retina and a 2D science camera to record the backscattered light from that same retinal patch. Considerations for imaging include ensuring investigators use only non-phototoxic (ocularly safe) amounts of light to illuminate the retina and a camera sensitive enough to capture the low reflective signal returning back from the retina and through the pupil of the eye. The first report of AO corrected fundus photography showed improvement in both contrast and resolution in images of the cone photoreceptors in comparison to non-AO corrected images of the same retinal patch. Since this early work, improvements in both light sources and the speed of digital cameras have made possible high frame acquisition rates using AO corrected flood-illumination retinal imaging.

An important consideration for flood-illuminated retinal imaging systems is the image exposure time. One property of flood-illuminated systems is that all pixels within the 2D image are acquired at the same time. This is an advantage in that the retinal

image incorporates few distortions and thus the spatial relationship between features in the image represents true retinal anatomy. On the other hand, the eye is continually undergoing fixational eye motion, and thus, any eye motion that occurs during the image exposure/acquisition time will result in a blurring of retinal features. For imaging microscopic features, such as the individual cones in the photoreceptor mosaic, even small eye movements can result in blurring out the contrast between neighboring cones. By limiting the exposure time of a single image to less than 10 msec, [Rha et al. \(2006\)](#) found most retinal images exhibited cone mosaic structure, and thus concluded that blurring from fixational eye motion was minimal when using this short exposure duration. Early applications of AO flood-illumination ophthalmoscopy demonstrated the arrangement and variability of the three cone classes in the trichromatic cone mosaic ([Roorda and Williams, 1999](#)) and loss of waveguiding cones in a dichromat ([Carroll et al., 2004](#)) and in patients with inherited retinal degenerations ([Wolfing et al., 2006](#)). In addition, AO flood-illumination ophthalmoscopy has been used to examine the reflectance of cones over time both in the absence and presence of visual stimuli ([Pallikaris et al., 2003](#); [Jonnal et al., 2007](#)).

AO Scanning Laser/Light Ophthalmoscopy

Scanning laser/light ophthalmoscopy (SLO) was the second retinal imaging modality to incorporate AO correction ([Roorda et al., 2002](#)). SLO operates by focusing a point source of light (a laser or super-luminescent diode) to the retina, and using a point detector, such as a photomultiplier tube (PMT), to detect the backscattered (or emitted) light from that point. The point source on the retina is then repeatedly raster scanned in 2D, and the time-sync between the scanners and the point detector is used to construct a 2D image sequence based on the x, y position of the scanned beam on the retina. A feature of this image collection paradigm is that each pixel of the image sequence is obtained at a different point in time, yielding real-time movies of the retina, but including in the raw data all eye movements. Even when asked to hold the eye perfectly still, subjects experience involuntary eye movements; this involuntary motion exists not only between frames of the image sequence (inter-frame motion), but also within frames of the image sequence (intra-frame motion). Intra-frame motion complicates the registration and averaging of multiple frames together, but results in precise measurements of fixational eye motion ([Sheehy et al., 2015](#)). Again, the transverse resolution of an SLO is limited by the eye's psf, which is improved when using AO aberration correction.

Most AOSLO imaging systems place a pinhole in front of the photodetector that is confocal with the retinal layer of interest in order to reduce the amount of backscattered light detected from retinal layers other than the plane of focus. This results in improved contrast in the retinal image in comparison with flood-illuminated AO systems. Using a confocal pinhole also provides coarse axial sectioning through the retinal layers. While the psf provides the transverse resolution, the size of the confocal pinhole provides the axial resolution for an AOSLO system. Close-to diffraction limited systems with just over 1 Airy disk-sized confocal pinholes have demonstrated axial resolutions of $\sim 50 \mu\text{m}$ ([Venkateswaran et al., 2004](#)). The first application of confocal AOSLO by [Roorda et al. \(2002\)](#) demonstrated the coarse axial sectioning obtained by imaging waveguiding photoreceptor reflectance, blood flow through the retinal capillaries, and reflectance of the nerve fiber layer at the same retinal location. Confocal AOSLO imaging is the most often applied AO imaging modality to date. Among numerous other applications, this imaging paradigm has enabled routine observation of the cone and rod photoreceptor waveguiding reflectance mosaic in normal sighted individuals ([Fig. 2](#)) and

Fig. 2 Confocal adaptive optics scanning laser/light ophthalmoscopy (AOSLO) image of the foveal cone mosaic from a normal sighted control.

in patients with retinal disease, visualization of the parafoveal capillaries, the retinal vascular network and blood flow in normal sighted individuals and in patients with diabetes, and examination of the lamina cribrosa (for a recent review describing AOSLO image findings in disease, see [Morgan, 2016](#)).

Again, the AOSLO is analogous to a scanning microscope, so just as in microscopy, one can manipulate the illumination and the detection beams in the system to attain different views of the retinal structure other than those obtained from confocal reflectance. One demonstration of this came from combining autofluorescence imaging with AOSLO to visualize the retinal pigment epithelium (RPE) in human and nonhuman primates ([Morgan *et al.*, 2009](#)). The RPE cytoplasm contains inherently fluorescent lipofuscin, a byproduct of the natural processes of phototransduction and phagocytosis. Lipofuscin granules consist of a conglomeration of multiple molecules that when excited with a short wavelength in the visible spectrum (blue/green) emit with a longer visible wavelength (red). Unfortunately, the autofluorescence signal from lipofuscin is low – too low to observe cellular structure in an individual autofluorescence AOSLO frame and too low for using the autofluorescence signal to register multiple frames together. Safety limits for ocular light exposures prevent simply increasing the excitation irradiance until a usable signal is obtained. To overcome these problems, [Morgan *et al.* \(2009\)](#) used simultaneous autofluorescence and confocal reflectance imaging to obtain two temporally and spatially synced retinal images, one with the low signal to noise autofluorescence signal and the other with the high signal to noise confocal reflectance signal. The high signal to noise reflectance images were used to determine the fixational eye motion present from frame to frame, and thus the lateral translation required to stabilize the image sequence. Since the autofluorescence image was acquired simultaneously, the fixational eye motion present in the autofluorescence image sequence was the same as the fixational eye motion present in the reflectance image sequence. Morgan *et al.* then applied the same lateral translations needed to stabilize the reflectance image to the autofluorescence image sequence and integrated the autofluorescence signal over the full image series. This novel image processing technique enabled visualization of the RPE cell mosaic in living humans ([Fig. 3](#)) and nonhuman primates and is routinely used to co-register simultaneously captured image sequences regardless of signal strength.

Autofluorescence imaging of the RPE lipofuscin was a natural extension from confocal AOSLO reflectance imaging because of the intrinsic contrast provided by the autofluorescent material in the retina. However, fluorescent imaging in the retina is not limited to autofluorescence of lipofuscin, but rather can be extended to other fluorescent markers as well. The general technique is to use the appropriate excitation and emission wavelengths for the fluorophore of interest, and attain a signal with enough spatial contrast to allow observation of the feature of interest in the final image. Fluorescence imaging with AOSLO has been demonstrated using both fluorescein ([Chui *et al.*, 2014](#)) and indocyanine green (ICG), both of which are fluorescent dyes approved for injection to the bloodstream, and which are generally used in ophthalmic imaging to elucidate abnormalities in the retinal and choroidal blood vessels. ICG has also been shown to provide additional contrast for viewing RPE cells ([Tam *et al.*, 2016](#)). Other fluorophores in the retina can provide the needed signal and contrast; fluorescence of cells tagged with fluorescent markers have been demonstrated in nonhuman primates and rodents ([Geng *et al.*, 2012](#)), two photon fluorescence has been demonstrated in nonhuman primates ([Sharma *et al.*, 2016](#)), and single photon intrinsic infrared autofluorescence of melanin in humans and other species holds promise. Regardless of the fluorophore being excited, successful AOSLO (or AO flood illumination) fluorescence imaging requires: (1) the presence of a fluorophore with spatial contrast; (2) an excitation and emission spectra that will pass

Fig. 3 Autofluorescence image of the retinal pigment epithelium (RPE) mosaic at approximately 20 degrees superior to fixation in a normal sighted control.

through the optics of the eye; (3) safe (non-phototoxic) excitation; and (4) sufficient quantity of emitted signal which is captured by the detector.

For more than the first decade following the invention of AOSLO, both reflectance and fluorescence imaging was done using a confocal pinhole in front of the point detector as described above. Then, in 2012, [Chui et al. \(2012\)](#) published a study in which the authors offset the pinhole from its central position, effectively blocking confocal reflectance and capturing a portion of the non-confocal multiply scattered light from the retina. This study demonstrated the advantage of this method for imaging retinal vasculature, and became the first of a series of imaging innovations using non-confocal AOSLO detection techniques ([Fig. 4](#)), each of which showed distinct advantages for elucidating various retinal structures. The second non-confocal AOSLO detection technique described, termed dark-field ([Scoles et al., 2013](#)), involved excluding the light that would normally pass through the confocal pinhole and detecting the light passing through an annulus surrounding the blocked pinhole. This technique captured the non-confocal multiply scattered light in the retina, and allowed visualization of the RPE cells in normal retina at some locations without using fluorescence techniques ([Fig. 5](#)). Non-confocal “split detection” shortly followed in which the dark-field signal was split in half using a knife edge and two images (one from each side of the knife edge) were captured simultaneously using two separate detectors. The two images were then recombined using the following equation:

$$I_{x,y,\text{split}} = \frac{I_{x,y,\text{det}_1} - I_{x,y,\text{det}_2}}{I_{x,y,\text{det}_1} + I_{x,y,\text{det}_2}} + 128$$

Fig. 4 Adaptive optics scanning laser/light ophthalmoscopy (AOSLO) detection schemes showing the spatial extent of the retinal plane over which light is blocked from (black) or captured by (white) the point detector. (A) Confocal. (B) Offset pinhole. (C) Dark-field. (D) Non-confocal split detection, where two point detectors are used and the two images are recombined using their difference divided by their sum to form the non-confocal split detection image.

Fig. 5 Dark-field adaptive optics scanning laser/light ophthalmoscopy (AOSLO) image of the retinal pigment epithelium (RPE) mosaic from a normal sighted control.

Fig. 6 Confocal (A) and non-confocal split detection (B) adaptive optics scanning laser/light ophthalmoscopy (AOSLO) image of the photoreceptor mosaic from a normal sighted control.

where $I_{x,y}$ is the image intensity at each pixel in the images from the two non-confocal detectors. This detection scheme resulted in the first in vivo images of the photoreceptor inner segment mosaic (Fig. 6; Scoles *et al.*, 2014). The technique also showed improvements in contrast of vasculature, with greater improvements visible in blood vessels running parallel to the direction of the knife edge. Noteworthy is that the denominator of the split detection equation above is simply the dark-field image. Thus one significant advantage of combining non-confocal split detection with confocal AOSLO imaging is that by using three separate point detectors, the confocal, non-confocal split detection, and dark-field images all can be acquired simultaneously. In theory, this allows investigators to observe the photoreceptor waveguided reflectance mosaic, the inner segment mosaic, and the RPE mosaic at the same location at the same time. In practice, slight differences in the optimal focus level for each cell class sometimes requires sequential imaging of the multiple retinal layers. In addition, RPE imaging with dark-field to date has not proven 100% successful, since there can be significant cross-talk between the photoreceptor mosaic images and the RPE (Scoles *et al.*, 2013). Regardless, the technique of simultaneously collecting multiple images under these difference detection configurations holds promise for studying retina structure at the cellular level in normal sighted individuals and in patients with retinal disease. Finally, other configurations of knife edge and offset pinhole arrangements have led to the first in vivo images of inner retinal neurons in mice (Guevara-Torres *et al.*, 2015), nonhuman primates and humans (Rossi *et al.*, 2017). Innovation surrounding AOSLO illumination and detection schemes have clearly provided methods to elucidate contrast between cells that are transparent under standard reflectance and confocal detection techniques. Undoubtedly, investigators will continue to explore novel methods for noninvasive imaging of additional retinal cell types, and work to optimize imaging conditions to allow routine observation of multiple cell types in the presence and absence of disease.

AO-OCT

While AO provides high transverse resolution as described above, optical coherence tomography (OCT) provides high axial resolution. Time-domain OCT (without AO) was first demonstrated by Huang *et al.* (1991). In time-domain OCT, interference signals are measured between the retina and reflections from a reference arm of an interferometer as it is translated in depth. The inference signal generated using this paradigm is used to create a one-dimensional (1D) cross-sectional image (A-scan) showing the relative depth of each backscattering layer in the retina. Following the acquisition of a single A-scan, the OCT beam is laterally translated on the retina so that the location of the subsequent A-scan is adjacent to the previous one, thereby creating a 2D cross-sectional image (B-scan) of the retina, built up over time. Raster scanning the location of the A-scan in 2D creates a three-dimensional (3D) volumetric OCT data set.

Applications for time-domain OCT were limited by the A-scan acquisition rate, which in turn was limited by the time needed to physically move the reference arm through the depth corresponding to the dimension of each A-scan. Keeping the reference arm static during the A-scan acquisition would in part overcome the limitation imposed by acquisition time but required further technological innovation within the OCT imaging technique. Spectral domain OCT and swept source OCT provided this needed innovation by operating in the spectral regime and utilizing a stationary detector (using a spectrometer to detect the OCT signal or

a tunable light source that is rapidly swept through a broad band, respectively). State-of-the-art OCT systems all take advantage of the increased imaging speeds and higher sensitivity afforded by spectral domain OCT methods in comparison to time-domain OCT (Choma *et al.*, 2003).

The properties governing the transverse and axial resolution in OCT are independent, making OCT a perfect complement for AO. As described above, the transverse resolution of OCT is governed by the eye's psf. The axial resolution, however, is dependent only on the central imaging wavelength (λ_0) and the bandwidth of the imaging source ($\Delta\lambda$).

$$l_{\text{axialOCT}} \propto \frac{\lambda_0^2}{\Delta\lambda}$$

Combining AO with OCT yields subcellular resolution in all dimensions, in theory enabling subcellular volumetric imaging in the living retina. The first application of AO-OCT was by Hermann *et al.* (2004). Since that time numerous groups have utilized AO-OCT to acquire volume data sets of the retina with increased resolution, in particular, showing axial reflections arising from the inner/outer segment junction (also termed ellipsoid layer) and cone/rod outer segment tips. More recently, improvements in software to allow intra-scan registration and hardware to use multiple synchronized detectors to further increase scan acquisition speed (Kocaoglu *et al.*, 2014) have led to AO-OCT images showing the inner/outer segment junctions of the cones, the cone outer segment tips, the RPE mosaic, and the choriocapillaris (Kocaoglu *et al.*, 2016; Liu *et al.*, 2016). AO-OCT imaging has also enabled visualization of the individual cells within the retinal volume corresponding to the ganglion cell bodies, showing not only the individual ganglion cells in a monolayer, but also the individual ganglion cells piled on top of each other in depth (Liu *et al.*, 2017). Applications for AO-OCT imaging abound, especially now that the technology has reached a point where the inner retinal cells can be visualized. To date, however, AO-OCT technology has not been as widely adopted as the AOSLO or AO flood-illumination imaging techniques.

Post Processing and AO Image Analysis

Each of the AO imaging modalities described above results in the acquisition of a retinal image with cellular resolution. Regardless of the imaging modality used, the signal to noise ratio of the retinal image can be improved by averaging multiple images together. Other applications gain an increase in contrast (e.g., motion contrast) by comparing retinal features between sequentially acquired images. Both averaging and comparing sequential images require co-registration of the images. Further, the images obtained using AO imaging systems generally span a field of view of two degrees per side or less (with some exceptions, that then sacrifice sampling density by enlarging pixel size). To cover a larger field of view, investigators typically acquire multiple images adjacent to one another, and in post-processing analysis stitch them together to observe a larger portion of the retina. The result of both multi-frame averaging and multi-image location montaging, means that post processing of AO images regularly occurs. While the concept of averaging and montaging is valid for all the imaging modalities discussed, the image processing steps undertaken must take into account the nature and properties of the acquisition modality being used. For example, a series of frames acquired using a flood-illuminated system at nominally the same retinal location may show translation and rotation between frames, though each frame individually should be free from motion artifacts (assuming the involuntary eye motions of the subject are minimal over the acquisition time of the image as was shown for most images acquired in less than 10 ms). Thus co-alignment of multiple images can be accomplished by finding the optimal transformation to account for the translation and rotation between individual frames using cross-correlation or other comparative algorithms, such as the scale invariant features transform (SIFT). Once the individual images are transformed to be co-aligned, a simple average of the aligned frames provides a higher signal to noise retinal image than an individual frame, and this averaged image from flood-illuminated AO systems is mostly free of motion artifacts.

In comparison, the image processing for both AOSLO and AO-OCT images is more involved, since both techniques are acquired over a period of time throughout which the eye is continually undergoing involuntary eye motions. This results not only in the inter-frame/inter-scan translation and rotation motion described in the flood illumination acquisition condition but also motion within a frame/scan, considered intra-frame/intra-scan motion. An added complication for scanning systems comes from any nonlinearities in the scanner velocity. For example, most AOSLO systems use a fast resonant scanner with a sinusoidal velocity. Evenly sampled pixels in time then result in a sinusoidal distortion in the pixel scale across the frame along the direction parallel to the scanner motion, with pixels on the edges of the image elongated in comparison with pixels closer to the middle of the frame, which are more compressed. These same types of lateral distortions are present in OCT images acquired with systems that also use a nonlinear scanner. The first step of image post-processing is to de-warp the images to remove any effect from a nonlinear scan velocity. The second step is to average together multiple dewarped frames. This is routinely done using an intra-frame registration algorithm, which involves first choosing a reference frame (in the ideal case free from intra-frame motion), second dividing the remaining frames into strips (along the fast scan direction), and third, registering each of these strips to the reference frame (Dubra and Harvey, 2010). The product of this intra-frame 2D registration is to allow averaging of multiple frames to increase the signal to noise ratio of the final registered image, while removing the intra-frame motion from frames other than the reference, which would otherwise blur the features in the image. Unfortunately, this technique does not correct intra-frame motion contained within the selected reference image, and thus the final averaged image will necessarily contain the same spatial distortions that exist within the reference image. At present there is no widely accepted technique for correcting the intra-frame motion within the reference frame, though solutions for using multiple reference frames to identify the ground truth for the image have been proposed

(Cooper *et al.*, 2016a,b; Bedggood and Metha, 2017). In comparison with AOSLO, AO-OCT image registration and averaging has the added complication that the retina is moving in 3D, so registering adjacent A-scans to account for axial movements throughout a B-scan and volumetric data set is also required.

Following multi-frame registration and averaging, adjacent images or volumetric data sets must be montaged to expand the field of view from the small field acquired over a single imaging location to a larger field covering a bigger portion of the retina. Most montaging to date has been done manually, however, an automated montaging algorithm was recently described and validated at the cellular level by Chen *et al.* (2016). The automated algorithm was based on feature matching between images using a combination of SIFT and random sample consensus (RANSAC) functions and the resultant automated montage was of comparable quality to manual montages made from the same image sets. While the software was only validated using images acquired from an AOSLO, the authors speculated that the algorithm would also work on *en face* images acquired under other AO imaging modalities.

Metrics to Analyze Cell Mosaics

AO imaging has enabled visualization of many layers and cell types in the retina, and with this visualization comes the desire to quantify metrics within the image to assess retinal health. To date the most studied feature of AO images remains the waveguided reflectance of the cone photoreceptors. As a result, the most quantification of AO images has been done on the cone mosaic. The discussion of AO metrics below describes what has been done to date and therefore is heavily focused on analysis of the cone mosaic. However, the techniques described here could be applied to any cell mosaic visualized, and almost assuredly will be applied to other cell classes beyond the cone mosaic as they become imaged more routinely.

As described above, AO ophthalmoscopy has enabled routine imaging of the cone mosaic both in normal sighted individuals and in patients with retinal disease. With the ability to observe waveguiding cones, comes the ability to identify cone locations and then quantify parameters of the cone mosaic as a function of retinal eccentricity. Numerous metrics have been used to quantify the structure of the cone mosaic including: cone density, average cone spacing, cone size, mosaic regularity, number of neighbors, nearest/farthest neighbor spacing, cone orientation, and others (Cooper *et al.*, 2016a,b). Each metric has its own set of advantages and disadvantages, and thus the best characterization of a mosaic may be a combination of multiple metrics. However, all mosaic metrics share one thing in common: prior to quantification, investigators must first determine the location of each cone in the mosaic. In addition, regardless of which metric is used, all contiguous cones within the analyzed region must be identified in order to obtain the most accurate results.

Determining the cone locations is many times done in a semi-automated fashion. Initially, cone locations are found by automated algorithms, such as the one described by Li and Roorda (2007), which identify local intensity maxima in an image, while also imposing restrictions on the location of the local maxima (such as a minimum spacing between maxima to eliminate false positives from noise and multiple counts for a single cone). Generally, automated cone selections are then manually reviewed to allow an operator to add cone locations (correct false negatives from the automated algorithm), and remove or move cone locations (correct false positives from the automated algorithm). To date, no automated cone identification software has proven itself superior enough to eliminate the need for manual review. In addition, there are many times when automated algorithms currently will fail, in particular, in cases of disease where cones may not exhibit normal reflectance or spacing patterns. Since automated algorithms are just searching for local maxima within an image, the algorithms at present will find “cones” in any image, so operators must inspect images prior to using automated cone selection algorithms and must review the algorithm’s output in order to maintain high quality cone identifications. Automated algorithms have also been presented for identifying the cone inner segments in split detection images and the RPE cells in autofluorescence images. Regardless of the imaging modality or automated algorithm, manual inspection of the results remains necessary. Manually/semi-automated grading of normal cone locations has been shown to be repeatable and reliable between graders (Fig. 7).

Once cone (or other cell) locations are identified, a number of metrics can be applied to determine parameters of the mosaic at a given retinal location, both in normal and diseased eyes. The two most commonly used mosaic parameters are cone density and cone spacing. Cone density simply counts the number of cells identified over a given area. Typically, cell spacing is found by the density recovery profile (DRP) algorithm, which first measures the distance between each pair of identified cones in an image, second determines a histogram of distances by placing the paired distances into bins, and third identifies the distance at which the first peak of the histogram occurs. Distances between cells can also be used to identify the average nearest/farthest neighbor spacing. In a perfectly regular triangularly packed mosaic, the nearest, farthest, and DRP cone spacing would all be the same. Thus the width of the DRP histogram, or the variability in any of the cell spacing metrics gives information regarding the regularity of the cell mosaic.

Regularity can also be assessed through calculation of the Voronoi diagram, which assigns each pixel in the image to its nearest cell center; boundaries of the Voronoi diagram correspond to midpoints between cell locations and vertices correspond to locations equidistant to three cell centers. This type of analysis allows quantification of the average and standard deviation of the number of Voronoi neighbors, where in a perfectly regular triangularly packed mosaic all cells have exactly six neighbors. Each Voronoi cell area is the inverse of cell density at a particular cell location, and the average Voronoi cell area is the inverse of the cell density over the image.

Regardless of which mosaic metric is used (density, spacing, regularity, or other), the Voronoi diagram is useful for identifying the boundaries over which a metric should be calculated (Fig. 8). Cone/cell metrics are currently only calculated over small regions

Fig. 7 Confocal adaptive optics scanning laser/light ophthalmoscopy (AOSLO) image of a normal sighted control (left). Three-trained observers manually identified cones (colored points overlaid on the cone mosaic image, right). Mean $\pm$ standard deviation of the cone density measurements from the three observers is shown.

Fig. 8 Voronoi diagram overlaid on a confocal adaptive optics scanning laser/light ophthalmoscopy (AOSLO) image of the cone mosaic (A). The edge of the image shows the cells that are not bounded within the Voronoi diagram. Image metrics should be calculated over only bound Voronoi cells (B) to reduce edge effect errors. Even within the bound Voronoi mosaic, error from edge effects are still present, for example, the bound but pointed Voronoi cells at the top of the image (B).

of interest selected throughout the larger montage, and the borders of those regions of interest can lead to errors in mosaic metrics (As an example, consider a border cell, whose nearest/farthest neighbor is outside of the region of interest and therefore is not identified.). To reduce boundary error, only cells who are fully bound within the Voronoi diagram (i.e., have no open Voronoi edges) should be included in summary metrics from an image.

One of the advantages of *in vivo* imaging is that the same cells can be followed over time. AO imaging has enabled longitudinal tracking of cells, though despite two decades of research, the number of studies that evaluate longitudinal cone mosaic metrics is

Fig. 9 Longitudinal confocal and non-confocal split detection AOSLO images at baseline and 1 year in a patient with Choroideremia, an X-linked inherited retinal degeneration. The cone photoreceptor mosaic is visible in both the confocal and split detection images, though the confocal reflectance from the cones of the Choroideremia patient appears “smudged” in comparison to the confocal reflectance of normal cones as seen in Figs. 1 and 5(A). Cell-by-cell alignment is demonstrated over the 1 year time period, with the red arrows showing the same cells visible in each imaging modality at each time point. The yellow asterisk marks the sharp border between intact retina and atrophy in this patient. Mild inward progression of the border can be observed over the 1 year time period.

limited. This is in part due to the complicated analysis process of ensuring that the same cells are followed. First, the small field of view of most AO imaging systems requires that longitudinal montaging be performed. For patients, this means any change in the preferred location of fixation will complicate longitudinal alignment. Second, the reflectance profiles of cones changes on time scales of minutes, hours, and days. Thus while cones are expected to remain stationary in the mosaic, the reflectance pattern over the mosaic will change from time point to time point. This means intensity matching will not successfully align images from different time points, and that pattern matching between time points will be more difficult. Third, for scanning systems, any distortions caused by eye motion will be different between images from different time points. This will further complicate alignment between images from different imaging sessions. Finally, in cases of pathology, true changes in retinal structure may make cell-by-cell alignment impossible. Despite these difficulties, longitudinal imaging can be performed and alignment with cellular precision can be achieved (Fig. 9). At present this process is tedious and time-consuming, and more robust and reliable algorithms are needed before the technique will be widely used.

Applications to Clinical Trials

Before any new technology is accepted into routine medical care, it must demonstrate clinical utility by changing currently accepted standards of care. Investigators have long touted the potential for AO to influence patient care, both by enabling earlier detection of disease and by assessing treatment outcomes. However, to date most clinical studies utilizing AO imaging have been limited to cross-sectional studies investigating affected patients’ cone densities (or other metric/AO feature) in comparison to

normal. Nonetheless, AO imaging is now entering a phase where investigators are increasingly including AO imaging as a secondary/exploratory outcome measure in clinical trials testing the safety and efficacy of experimental interventions.

There are at least two conceivable mechanisms through which AO imaging could influence clinical trials. First, AO imaging could identify patients most amenable to a particular treatment. Second, AO could inform assessments of the safety and efficacy of treatment at the cellular level. As just one example, recent advances have led to an era where gene therapy approaches are conceivable for treating inherited retinal degenerations. Gene therapy aims to restore cellular function to dysfunctional or non-functional cells but its success requires that the target cells are present prior to treatment. Therefore, in theory, AO imaging could identify which patients, and which areas of their retinas, structurally retain dysfunctional cells that would be amenable to gene therapy treatment. In addition, longitudinal AO imaging of the treated patients could provide evidence of retinal changes (either positive or negative) following intervention at the same cellular scale. This type of clinical application for AO is not limited to gene therapy, but could also benefit any treatment option that targets cellular structure or function, including stem cell therapies, small molecular therapies and optogenetics.

Despite the high potential for AO to provide cellular level insight to the treatment of retinal disease, there remains only one study utilizing AO imaging to assess an experimental therapy. [Talcott et al. \(2011\)](#) applied AOSLO imaging to assess longitudinal changes in cone density in eyes treated with ciliary neuro-trophic factor (CNTF) implants in comparison to sham-treated fellow eyes in three patients (two with retinitis pigmentosa and one with Usher's syndrome). The authors found that eyes treated with CNTF retained higher cone densities over 2–3 years than sham-treated control eyes. Despite this AO finding, the larger Phase 2 trial investigating the efficacy of CNTF found no visual acuity or visual field benefit for CNTF-treated eyes compared to sham-treated eyes ([Birch et al., 2013](#)). Together these results beg the question: is cone density an earlier biomarker of CNTF treatment efficacy than visual acuity or visual fields? One possibility is that longer trials assessing visual acuity and visual fields might show a benefit from CNTF implants, as better visual acuity and/or larger visual fields would ultimately be expected in eyes that retain more cones. Alternatively, retaining visible cones in AO images might not correspond to a functional benefit in these tested patients.

The study by [Talcott et al. \(2011\)](#) for CNTF implants highlights critical considerations for clinical trials. As a practical matter, the structure and economics of clinical trials for experimental therapies mean that a high value is placed on outcome measures that can reveal safety and efficacy (or lack thereof) reasonably soon after application of a therapy. Such outcome measures are best formulated in the context of the most precise characterizations of disease presentation and progression. Because of its increased resolution, cellular imaging capabilities and quantifiable analysis, AO retinal imaging has high potential to yield this precise characterization. Here, AO imaging is already playing a clinical role, and numerous studies have characterized retinal diseases at the cellular level ([Morgan, 2016](#)). However, before AO metrics can become accepted outcome measures for therapeutic clinical trials, investigators must transition from cross-sectional observational studies to longitudinal studies, which utilize cellular metrics to investigate the effect a given treatment has on the natural progression of a disease. Subsequently, the investigators must relate altered disease progression found from AO imaging to altered disease progression measured clinically. While it seems intuitive that patients who retain more cone structure will experience higher visual function, this correlation remains to be demonstrated in a treated patient population.

Functional Assessment in Conjunction With AO Imaging

As described above, most clinical applications of AO have been cross-sectional observational studies, intended to characterize diseased retinal structure. However, interest abounds and capabilities exist for measuring cellular function at the same resolution with which investigators image the retina. There are two methods for investigating function at the cellular level: psychophysical measures and physiological measures.

Psychophysical measures of vision involve recording a patient's subjective response to the presentation of a visual stimulus, such as is done in clinical microperimetry. AO-assisted microperimetry enables the presentation of visual stimuli to the retina with the same cellular resolution (same spatial extent of the psf) as attained for retinal imaging. This, in combination with retinal tracking through AOSLO imaging, has allowed repeated presentations of a visual stimulus targeted to the same photoreceptor or group of photoreceptors, thereby enabling measurements of single cell visual thresholds ([Harmening et al., 2014](#)). For a full review on AO psychophysical testing, see [Tuten et al. \(2012\)](#).

While psychophysical testing remains the gold standard for assessing visual function, measuring function one cell at a time is not practical for testing either high volumes of cells within a patient or for testing high volumes of patients. Instead, objective, validated, and high-throughput biomarkers of function are needed. Physiological biomarkers of cellular function through imaging could provide this high-throughput alternative to single cell psychophysical measures. As one example, investigators have shown that cone near infrared reflectance ([Jonnal et al., 2007](#); [Grieve and Roorda, 2008](#); [Rha et al., 2009](#)) and optical path length ([Hillmann et al., 2016](#)) can change following a visible stimulus. These stimulus-evoked intrinsic reflectance responses hold promise as biomarkers for cone function, though further study demonstrating that these measures correlate with functional vision are needed.

Conclusions

AO is a tool through which investigators can measure and correct for the optical aberrations of the living eye and thereby improve the resolution of retinal imaging devices. AO in combination with numerous retinal imaging modalities and detection schemes

has enabled observation of single cells in the living retina. Clinical applications abound, especially as investigators transition from cross-sectional observational studies to longitudinal studies of retinal disease and its treatment.

Introduction

Early diagnosis and timely therapeutic intervention is critical to avoid blindness in retinal disease. While clinical symptoms often manifest late in the disease course, structural changes are visible on a microscopic scale long before onset of clinical disease. State-of-the-art adaptive optics scanning light ophthalmoscopes (AOSLO) capture reflected or scattered light from the fundus of the eye and provide exquisite resolution in *en face* dimensions ($<2\ \mu\text{m}$), which is suited to observe changes in cellular structure (Roorda and Duncan, 2015). In unhealthy retina, cellular metabolism and function are altered prior to structural changes and cell death. Detecting these early changes may provide an opportunity for treatment to prevent vision loss. The most promising imaging modalities are those that can interrogate the retina's molecular composition and biochemical pathways, providing thus information on the tissue's anatomy and physiology.

Fluorescence imaging has great potential because it can spectrally target particular fluorophores, either endogenous or exogenous, offering the possibility of high contrast imagery of specific molecular species. A milestone for biological imaging was achieved in 1990, when Denk and colleagues applied two-photon excited fluorescence (TPEF) to microscopy (Denk *et al.*, 1990). TPEF microscopy is based on the fact that two photons arriving at a fluorescent molecule closely in time can behave like a single photon of half the wavelength (Göppert-Mayer, 1931; Göppert, 1929). Great strides have been made since in cell biology and neuroscience thanks to the technique's optical sectioning capability in highly scattering tissue and its ability to provide structural and functional information (Campagnola *et al.*, 1999; Denk and Detwiler, 1999; Denk *et al.*, 1995; Helmchen, 2009; Svoboda *et al.* 1997; Svoboda and Yasuda, 2006; Yuste and Denk, 1995). TPEF offers yet another advantage when applied to the eye: a host of endogenous fluorophores excitable in the ultraviolet (UV) can be studied in the living primate eye for the first time. Fluorophores with valuable diagnostic potential, such as NAD(P)H (Huang *et al.*, 2002; Shuttleworth, 2010; Zipfel *et al.*, 2003) and all-*trans*-retinol (Imanishi *et al.*, 2004; Kaplan, 1985), are normally inaccessible because their excitation requires UV light that is blocked by the cornea and crystalline lens (Boettner and Wolter, 1962). However, as illustrated in Fig. 1, infrared (IR) light is readily transmitted by the eye's optics and can excite these fluorophores via two-photon absorption. Fluorescence is emitted in the visible spectrum, which exits the eye relatively unattenuated and can be collected for image formation.

This article reviews the current state of *in vivo* nonlinear retinal imaging. It treats the theory of nonlinear ophthalmoscopy, which is generally performed with a nonlinear microscope where the anterior optics of the eye is used instead of an optimized microscope objective to investigate the back of the eye. Further, it discusses its practical implementation as well as light safety aspects. Finally, an outlook on promising future research is given. Due to the fast growth of this area and the multidisciplinary nature of it, this chapter is not intended to be self-contained. Other reviews on nonlinear microscopy (Diaspro, 2002; Diaspro and

Fig. 1 Many key fluorophores are only excitable in the UV outside the ocular transmission window (Boettner and Wolter, 1962). However, infrared photons can excite these molecules via two-photon absorption.

Chirico, 2003; Diaspro *et al.*, 2005; Masters and So, 2008; Svoboda and Yasuda, 2006; Xu and Webb, 1997) and multiphoton imaging of the eye (Imanishi *et al.*, 2007; Sharma and Hunter, 2017) are highly recommended.

In Vivo Multiphoton Retinal Imaging With Adaptive Optics

By nature the retina is a multilayered tissue that is highly transparent for visible light. While this property is beneficial for vision, it becomes a challenge when the goal is to visualize individual retinal layers. Photoreceptors, nerve fiber layer and retinal vessels can readily be imaged in the visible or IR by capturing reflected light in a confocal detection scheme. Visible or IR light also excites single-photon fluorescence from lipofuscin or melanin, which can be harnessed to reveal the retinal pigment epithelium (Delori *et al.*, 1995; Granger *et al.*, 2017; Morgan *et al.*, 2009). Other retinal layers have so far been impossible to visualize with confocal reflectance or single-photon fluorescence methods, although offset aperture techniques show promise (Scoles *et al.*, 2014; Guevara-Torres *et al.*, 2016; Rossi *et al.*, 2017). Advantageously, autofluorescent molecules, which in the living eye are excitable via multiphoton absorption in the UV, are present throughout the retina. The occurrence and distribution of these molecules may be directly associated with retinal health and physiology. Valuable information can be gained by capitalizing on the fluorescence properties of these molecules, such as the absorption and emission spectra, the fluorescence lifetime, anisotropy, etc. By measuring these characteristics, cells and their organelles can be studied and information about the composition of the cells themselves as well as their surrounding environment can be gained.

Structural In Vivo Multiphoton Ophthalmoscopy

The retina contains many UV-excitabile fluorophores that are abundant in different cell classes or cell compartments: Photoreceptors and retinal pigment epithelial cells contain retinoids (Chen *et al.*, 2005; Imanishi *et al.*, 2004; Kaplan, 1985) that take part in the visual cycle. Lipofuscin accumulates within the retinal pigment epithelium (Bindewald-Wittich *et al.*, 2006), especially at advanced age (Kennedy *et al.*, 1995a). Collagen is present in basement membranes and extracellular matrix and is, along with elastin, an integral component of vessel walls (Zoumi *et al.*, 2002, 2004). As precursor molecules for hemoglobin, porphyrins are present in blood and tissue fluids (Zheng *et al.*, 2011). Additionally, all living cells contain NAD(P)H (Chen *et al.*, 2005) and flavoproteins (Zhao *et al.*, 2007), because these molecules are involved in cellular metabolism. NAD(P)H is highly concentrated in the mitochondria, but is also present in the cytosol in the cell. Flavoproteins are almost exclusively present in the mitochondria.

These fluorophores provide intrinsic optical contrast from cells throughout the retina (Gualda *et al.*, 2010), even though their efficiency is relatively poor compared to specifically designed exogenous fluorophores. Nowadays two-photon excited fluorescence ophthalmoscopy (TPEFO) can be performed routinely in the living eye of mouse (Palczewska *et al.*, 2010, 2014a) and primate (Hunter *et al.*, 2011). Fig. 2 shows near-foveal cones in the living macaque eye imaged in 730 nm confocal reflectance and TPEF modality. While the reflectance of single cones differs considerably between cones, the amount of emitted fluorescence is similar. Using an AOSLO, cellular mosaics in many retinal layers other than the photoreceptor layer have been imaged non-invasively at 730 nm and ~900 nm excitation wavelength (Sharma *et al.*, 2016b). RPE cells appeared dark in the center and bright along the cell wall. At the nerve fiber layer, bright streaks, probably the Müller cells, were visible between the darker nerve fibers. Fluorescence was also captured from vessel walls. A major breakthrough was the visualization of cell layers that are invisible in confocal reflectance imaging methods, such as the nuclear layers (Sharma *et al.*, 2016b). Of particular interest are thereby the ganglion cells because these are the primary output neurons of the retina, which degenerate in glaucoma, the second leading cause of blindness worldwide (Quigley, 2011). Capitalizing on experience gained with two-photon ophthalmoscopy in monkey to find the best focal depth and retinal location for ganglion cell imaging, parameters could be optimized to obtain the first in vivo

Fig. 2 Reflectance (left) and TPEF (right) image of near-foveal cones in the living macaque eye.

images of ganglion cells with offset aperture reflectance imaging at light levels that are safe for use in the living human eye (Rossi *et al.*, 2017).

Functional In Vivo Multiphoton Ophthalmoscopy

Recording autofluorescence from retinoids and NADH over time has the potential to track functional activity at a cellular scale (Chen *et al.*, 2005; Imanishi *et al.*, 2004; Kaplan, 1985). TPEF from photoreceptors has been shown to increase in response to photopigment bleaching and decline again in the dark (Sharma *et al.*, 2016a), offering the possibility of monitoring photoreceptor function in vivo. The prevailing view is that the dominant source of time-varying TPEF from photoreceptor outer segments is all-*trans*-retinol, an intermediate component of the visual cycle (Ala-Laurila *et al.*, 2006; Chen *et al.*, 2005; Kaplan, 1985; Liebman, 1969, 1973; Tsina *et al.*, 2004). The visual cycle (see Fig. 3 for a schematic of the canonical visual cycle) occurs in several steps involving numerous enzymes and chaperone proteins (Kiser *et al.*, 2012, 2014; Lamb and Pugh, 2004; Saari, 2000). TPEF imaging quantifies an intermediate step or steps inside the visual cycle and might therefore prove to be a valuable tool for optically dissecting the normal visual cycle. The kinetics of the normally functioning visual cycle in nonhuman primates have been characterized in rod photoreceptors using TPEF (Sharma *et al.*, 2017). Fig. 3 shows the time course of TPEF during adaptation to the imaging laser and the response to a brief flash intended to instantaneously bleach the visual pigment with subsequent recovery.

Insufficiencies can occur in any step of the visual cycle due to genetic mutation, dietary factors, or age, which will result in slowed pigment regeneration or even blindness (Lamb and Pugh, 2004). Multiphoton retinal imaging could thus give diagnostic and prognostic insight into retinal diseases such as Stargardt macular dystrophy, retinitis pigmentosa, Leber congenital amaurosis, fundus albipunctatus, Sorsby fundus dystrophy, and Bothnia dystrophy (Lamb and Pugh, 2004; Thompson and Gal, 2003; Travis *et al.*, 2007). Previous techniques to quantify visual cycle kinetics by measuring dark adaptation and/or rhodopsin densitometry have relied on psychophysics, the electroretinogram, or rhodopsin densitometry. There are a number of limitations to using these methods: Psychophysical measurements are subjective and time consuming. Electroretinograms, although objective, are based on global voltage variations generated by many circuits in the retina and are thus highly susceptible to eye movements. While rhodopsin densitometry estimates the kinetics of rhodopsin regeneration directly, it is subject to artifacts such as reflectance changes associated with neural responses or vascular changes (Grieve and Roorda, 2008; Masella *et al.*, 2014a). So far, such contamination from intrinsic optical signals has not been observed in TPEF ophthalmoscopy, and only further experimentation will reveal whether there are important additional components to the TPEF signal.

In addition to endogenous fluorophores, TPEF of extrinsic fluorophores, such as genetically encoded calcium indicators (GECIs) can provide important functional information at the cellular scale. GECIs can be delivered to specific cells or cell compartments within living animals via transgenesis or viral constructs. Fig. 4 shows a retinal ganglion cell labeled with GCaMP5 that was imaged with a two-photon AOSLO in the living macaque eye. For GECIs in retinal cells, the advantage of two-photon over single-photon excitation lies in the use of near-infrared light, which provides reduced visual stimulation and the intrinsic optical sectioning of TPEF. In addition, at these long wavelengths, extrapolating from the trend at 900 nm, axial chromatic aberration and ocular dispersion is expected to be minimal (Atchison and Smith, 2000) which can improve efficiency and further reduce visual interference from the imaging beam. In mouse, in vivo functional responses to visible stimulation have been recorded using TPEF imaging (without adaptive optics correction) of the GECI GCaMP6 (Bar-Noam *et al.*, 2016).

Fig. 3 (left) Schematic of the canonical visual cycle regenerating bleached rhodopsin. All-*trans*-retinol is the strongest candidate for fluorescence changes in response to stimulation. (right) Time course of TPEF. The initial fluorescence increase is due to stimulation by the imaging laser. After an instantaneous full bleach, fluorescence increases abruptly and gradually declines.

Fig. 4 Retinal ganglion cell labeled with GCaMP5 in the living macaque eye. The highly fluorescent cell nucleus is visible as well as the large dendritic arbor. In collaboration with Robin Sharma, Lu Yin, and William Merigan.

Fig. 5 Jablonski diagram illustrating the excitation of a fluorophore via a single-photon and a two-photon process.

Theory of Multiphoton Retinal Imaging

A number of books and articles on the theory of multiphoton imaging have been published over the years (Denk *et al.*, 2006; Diaspro, 2002; So *et al.*, 2000; Xu and Webb, 1997). Only the most important aspects for retinal imaging are specified here.

The mechanisms of single-photon excitation (SPE) and two-photon excitation (TPE) are illustrated in the Jablonski diagrams in Fig. 5. In single-photon excitation, a fluorescent molecule absorbs a photon and is raised to an excited electronic state. The photon energy must match the energy gap between ground and excited state. As the molecule relaxes back to the ground state, energy can be lost through fluorescence, that is, emission of photons. The emitted photons are of longer wavelength (less energy) than the photons used for excitation due to non-radiative energy loss in the form of heat or vibration within the molecule. The energy difference between fluorescence excitation and emission is referred to as Stokes shift.

Fluorescent molecules can also be excited via a multiphoton process, where two or more photons are absorbed quasi-simultaneously (Göppert-Mayer, 1931; Göppert, 1929). The total energy of the absorbed photons must equal the energy required for conventional single-photon excitation. For two-photon excited fluorescence, the excitation wavelength is approximately twice the wavelength for single-photon excitation.

$$\lambda_{SPE} \approx \left(\frac{1}{\lambda_1} + \frac{1}{\lambda_2} \right)^{-1} \approx \frac{\lambda_{TPE}}{2}$$

The temporal window for two-photon absorption can be calculated via the energy-time uncertainty (Louisell, 1973), taking into account the photon energy $\Delta E = \frac{h \cdot c}{\lambda_{TPE}}$ at the wavelength for two-photon excitation λ_{TPE} in the UV or visible range

$$\Delta t \approx \frac{\hbar}{2\Delta E} = \frac{\lambda_{TPE}}{4\pi c} \approx 10^{-16} \text{ s}$$

where $\hbar = \frac{h}{2\pi}$ with Planck's constant $h \approx 6.63 \times 10^{-34} \frac{\text{m}^2 \text{kg}}{\text{s}}$ and the speed of light $c \approx 3 \times 10^8 \frac{\text{m}}{\text{s}}$.

For multiphoton excitation, ultrafast lasers emitting very short pulses ($\sim \text{fs}$) are required. Such lasers produce high peak powers, while the average power is low. The peak power can be calculated via

$$P_{\text{peak}} = \frac{\langle P(t) \rangle}{f_{\text{rep}} \cdot \tau_p} = g^{(1)} \cdot \frac{P_{\text{avg}}}{f_{\text{rep}} \cdot \tau_p}$$

where P_{avg} is the average power, f_{rep} is the pulse repetition frequency and τ_p the pulse duration. The factor $g^{(1)}$ depends on the pulse shape and is 0.94 and 0.88 for Gaussian and Hyperbolic-secant-squared pulse shapes respectively.

Because time and frequency domain are related via the Fourier transform, pulse duration and spectral bandwidth are linked. This behavior is expressed in the time-bandwidth product. The time-bandwidth product of a non-chirped, transform-limited Gaussian pulse is $\tau_p \cdot \Delta\lambda = \frac{2\ln 2 \cdot \lambda^2}{\pi \cdot c}$. It can be derived by calculating the FWHM of the Fourier transform of a Gaussian function as $\tau_p \cdot \Delta f = \frac{2\ln 2}{\pi} \approx 0.44$, where $\Delta f = \frac{c \cdot \Delta\lambda}{\lambda^2}$ with λ being the center wavelength. The shorter the pulse durations, the broader is the spectral bandwidth, and the more challenging it becomes to focus the beam in both space and time.

The response of fluorescent molecules to excitation depends on two parameters: The absorption cross section δ_2 quantifies the affinity to absorb photons at a certain wavelength λ and the quantum yield η specifies the efficiency in the conversion of absorbed energy into light emission. The quantum yield is preserved in single-photon and multi-photon excitation; however, absorption cross sections differ. Two-photon absorption cross sections are usually broader and blue shifted from what would be expected from single-photon absorption cross sections (Huang *et al.*, 2002). One advantage of the broader absorption cross sections for two-photon excitation is that a single laser can simultaneously excite multiple fluorophores. In honor of Maria Göppert-Mayer, the widely used yet unofficial unit of the two-photon absorption cross section is the GM, corresponding to $10^{-50} \text{ cm}^4 \text{ s}^{-1} \text{ photon}^{-1}$. Two-photon absorption cross sections are about two orders of magnitude greater for exogenous than endogenous fluorophores. For instance, the two-photon absorption cross section is ~ 6 GM for GFP (Diaspro *et al.*, 2005) and 0.02 GM for NADH (So *et al.*, 2000) at a wavelength of 700 nm.

The fluorescence intensity of molecules that are excited via a two-photon effect is proportional to the absorption cross section δ_2 , the quantum yield η and the intensity I squared of incident light (Diaspro and Chirico, 2003):

$$I_f(t) \propto \delta_2(\lambda_{TPE}) \cdot \eta \cdot I^2(t) = \delta_2(\lambda_{TPE}) \cdot \eta \cdot \frac{P^2(t) \cdot NA^4}{\pi^2 \cdot \lambda_{TPE}^4}$$

taking into account that intensity is defined as power per area $I(t) = \frac{P(t)}{A}$ and the illuminated area at the focal plane of a diffraction-limited system in the paraxial approximation $A \approx \pi \frac{\lambda_{TPE}^2}{NA^2}$ (Born and Wolf, 1999). For lasers with pulse repetition rate f_{rep} and pulse width τ_p , the time-averaged power squared depends on the peak power P_{peak} and the pulse shape $\langle P^2(t) \rangle = g^{(2)} \cdot \langle P(t) \rangle^2 = g^{(2)} \cdot \frac{P_{\text{avg}}^2}{\tau_p \cdot f_{\text{rep}}}$. The factor $g^{(2)}$ is related to the energy contained within one pulse and is 0.66 and 0.59 for Gaussian and Hyperbolic-secant-squared pulses respectively. The average number of photons that the fluorescing medium emits per second is therefore:

$$\langle n_f(t) \rangle \propto \delta_2(\lambda_{TPE}) \cdot \eta \cdot g^{(2)} \cdot \frac{P_{\text{avg}}^2}{\tau_p \cdot f_{\text{rep}}} \left(\frac{NA^2}{\pi \cdot h \cdot c \cdot \lambda_{TPE}} \right)^2$$

where, P_{avg} is the time-averaged laser power, λ_{TPE} is the two-photon excitation wavelength, NA is the numerical aperture of the objective, τ_p is the pulse duration and f_{rep} is the laser repetition rate, h is Planck's constant and c the speed of light. It can be seen that the efficiency of TPEF is dependent on the spatial focusing as well as the temporal pulse shape. These parameters must be optimized for successful TPEF imaging.

If the excitation rate exceeds the de-excitation rate, ground state depletion occurs. In other words, if the fluorescence lifetime of the fluorescent molecule ($\sim 10^{-9} \text{ s}$ for biological molecules) is greater than the fluorescence emission rate $\frac{1}{\langle n_f(t) \rangle}$, fluorescence emission eventually saturates. This means that increasing the imaging laser power is only beneficial up to a certain value. For greater laser powers, it is likely that the targeted molecules are raised to even higher excited states.

Second harmonic generation (SHG) is also a second order nonlinear process but differs from two-photon absorption in several aspects. In contrast to two-photon absorption, SHG involves an electron transition to a virtual (not a real) state, energy is conserved, and the SHG pulses are temporally synchronous with the laser excitation pulses. The emitted photon has twice the energy (half the wavelength) of the absorbed photons. SHG can only arise from media lacking a center of symmetry. In biological samples, SHG imaging has proven valuable for visualization of highly ordered structural proteins such as collagen without the need for exogenous fluorophores (Campagnola *et al.*, 2001). SHG and TPEF imaging can be performed with the very same microscope or ophthalmoscope. Both techniques provide complementary information.

Considerations, Artifacts and Implementation of Two-Photon Excited Fluorescence Ophthalmoscopy

Any imaging system is fundamentally limited in the smallest detail it can resolve. The resolution of an optical system is related to the full width at half maximum (FWHM) of its intensity point spread function (PSF) (Born and Wolf, 1999). The intensity I in the focal region of an aberration-free lens of circular aperture and numerical aperture $NA = n \sin \alpha$ is given as

$$I(u, v) = \left| 2 \int_0^1 J_0(v\rho) \exp\left(\frac{1}{2}iu\rho^2\right) \rho d\rho \right|^2$$

where J_0 is the zero-order Bessel function of the first kind, ρ is the radial coordinate in the pupil plane and u and v are axial and radial normalized coordinates given by

$$u = \frac{8\pi}{\lambda} z n \sin^2\left(\frac{\alpha}{2}\right) \text{ and } v = \frac{2\pi}{\lambda} r n \sin \alpha$$

where λ is the imaging wavelength, and z and r are the axial and lateral distance from the focus.

Intensity PSFs in the paraxial approximation are listed for different types of microscopes in Table 1 (Gu and Sheppard, 1995; Sheppard and Gu, 1990).

For simplicity, we consider that detection in a single-photon microscope occurs at a wavelength that is greater than the excitation wavelength $\lambda_{SPEF} = g \cdot \lambda_{SPE}$ ($g > 1$) and that the illuminating light in a two-photon microscope is of twice the wavelength of that used in a single-photon microscope $\lambda_{TPE} = 2\lambda_{SPE}$ to image the same fluorophore.

In a conventional single-photon microscope, the entrance aperture of the objective lens is uniformly illuminated and the detection is performed pointwise. The imaging PSF is only determined by the illumination PSF: $I_{SP} = I(u, v)$.

In a confocal single-photon microscope, both illumination and detection are performed pointwise. The imaging PSF is determined only by the illumination and the detection PSF: $I_{SP} = I^2(u, v)$.

To increase signal detection efficiency, most two-photon microscopes are built in the conventional, not the confocal configuration. Due to the quadratic dependence of a two-photon event on the excitation intensity, the PSF of such a conventional two-photon microscope is: $I_{TP} = I^2\left(\frac{u}{2}, \frac{v}{2}\right)$.

The lateral resolution for point-like objects can be calculated from the intensity distributions in the focal plane $z=0$, whereas the axial resolution for such objects is calculated from the intensity distribution along the optical axis ($r=0$).

Based on this assessment, the shorter the imaging wavelength and the greater the numerical aperture of the objective, the better is the resolution. For in vivo ophthalmoscopy, the NA is limited by the maximum diameter of the dilated pupil of the eye and therefore small compared to common microscope objectives. When the pupil has been dilated, the human and macaque eye has a numerical aperture of ~ 0.2 , whereas the mouse eye has a numerical aperture of ~ 0.5 (Geng et al., 2011). Therefore, the small angle approximation holds for ophthalmoscopy.

The lateral resolution of a conventional single-photon microscope is:

$$d_{SP,r} = \frac{3 \cdot 83}{2\pi} \frac{\lambda}{NA} \approx 0.61 \frac{\lambda}{NA}$$

The axial resolution is:

$$d_{SP,z} = \frac{\lambda}{2 n \sin^2 \frac{\alpha}{2}} = \frac{\lambda}{n(1 - \cos \alpha)} = \frac{\lambda}{n(1 - \sqrt{1 - \sin^2 \alpha})} \approx \frac{2\lambda n}{NA^2}$$

With the Taylor series for $\sin^2 \alpha < 1$, $\sqrt{1 - \sin^2 \alpha} \approx 1 - \frac{1}{2} \sin^2 \alpha$ and $NA = n \sin \alpha$. From the given PSFs in Table 1, it can be easily seen that spatial resolution when imaging point-like objects in a confocal single-photon microscope is improved by factor of $\frac{1}{\sqrt{2}}$, whereas in a conventional two-photon microscope it is worse by a factor of $\sqrt{2}$ with respect to a conventional single-photon microscope.

For a typical excitation wavelength of 365 nm when targeting retinol and the numerical aperture of the human eye, the spatial resolution limits for an optically-perfect eye would be 1.1 μm in a conventional and 0.8 μm in a confocal single-photon ophthalmoscopy and 1.6 μm in a two-photon ophthalmoscopy. Taking into account the refractive index of the vitreous of

Table 1 Comparison of PSFs for different types of microscopes.

	Conventional single-photon microscope	Confocal single-photon microscope	Conventional two-photon microscope
PSF	$I_{SP} = I(u, v)$	$I_{cSP} = I^2(u, v)$	$I_{TP} = I^2\left(\frac{u}{2}, \frac{v}{2}\right)$
Radial PSF ($z=0$)	$I_{SP,r}(v) = \left[\frac{2J_1(v)}{v}\right]^2$	$I_{cSP,r}(v) = \left[\frac{2J_1(v)}{v}\right]^4$	$I_{TP,r}(v) = \left[\frac{2J_1\left(\frac{v}{2}\right)}{\frac{v}{2}}\right]^4$
Axial PSF ($r=0$)	$I_{SP,a}(u) = \left[\frac{\sin\left(\frac{u}{4}\right)}{\frac{u}{4}}\right]^2$	$I_{cSP,a}(u) = \left[\frac{\sin\left(\frac{u}{4}\right)}{\frac{u}{4}}\right]^4$	$I_{TP,a}(u) = \left[\frac{\sin\left(\frac{u}{8}\right)}{\frac{u}{8}}\right]^2$

$n_0 = 1.336$, the axial resolution is 24 μm in a conventional and 17 μm in confocal single-photon ophthalmoscope and 34 μm in a two-photon ophthalmoscope. Even though lateral and axial resolution when imaging point-like objects in a two-photon microscope are worse compared to other microscope types discussed here, the real advantage is due to the optical sectioning when imaging thick specimens, because the background is greatly reduced.

In general, all optical systems exhibit some optical imperfections. Optical materials such as glass elements can greatly reduce the system efficiency if their optical properties are not adequately taken into account. In addition, the optics of the eye is far from being perfect. The most deleterious imperfections for nonlinear ophthalmoscopy are monochromatic aberrations, chromatic aberrations and material dispersion. Understanding and correcting for these optical aberrations is essential when optimizing the imaging system. Monochromatic aberrations are imperfections that are present even for a single wavelength. These aberrations result from imperfections in surface shape of the optical elements and local refractive index changes. Monochromatic aberrations of lower orders can be corrected for with spherical and cylindrical lenses, whereas the real-time correction of higher order aberrations requires adaptive optics (AO). This technique makes it possible to routinely resolve single photoreceptors with scanning light ophthalmoscopes (Dubra *et al.*, 2011). Excellent reviews on AO for vision science have been published (Porter *et al.*, 2006; Roorda and Duncan, 2015).

If the spectral bandwidth of the imaging light is broad, the overall optical quality of the system is affected by the wavelength-dependent refractive indices of the optical elements. The refractive index of the eye is greater for shorter than for longer wavelengths. Transverse chromatic aberration causes a change in magnification with wavelength. When imaging close to the optical axis or in the temporal near-periphery, transverse chromatic aberration is generally small (Winter *et al.*, 2016). Longitudinal chromatic aberration causes light of different wavelengths to focus at different distances from the lens (Thibos *et al.*, 1992; Vinas *et al.*, 2015) and can be statically corrected with an achromatizing lens, emitting the opposite chromatic aberration of the eye (Fernández *et al.*, 2006). The simplest design is a symmetrical triplet compensating for the chromatic aberration of the eye to be imaged, when placed in a conjugate pupil plane. Proper alignment of the achromatizing lens with the pupil of the eye is important to avoid introducing additional transverse chromatic aberration.

Furthermore, the speed of light in the ocular media changes with wavelength, which results in light from a broadband source not arriving at the same time on the retina, and therefore in an increase in pulse duration. The broadened pulse duration can be estimated via $\tau_{out} = \tau_{in} \sqrt{1 + 7.68 \left(\frac{D \cdot L}{\tau_{in}^2} \right)^2}$, where L is the distance traversed within the optical media and D is the optical dispersion parameter. At 725 nm, the optical dispersion value of the vitreous humor is $32.2 \frac{\text{fs}^2}{\text{mm}}$, whereas that of the cornea-lens complex is $183 \frac{\text{fs}^2}{\text{mm}}$, for instance (Coello *et al.*, 2007).

Several approaches exist for dispersion correction. Second-order dispersion can be corrected by a prism pair, which is sufficient for pulses with a bandwidth of less than 30 nm. For lasers with larger bandwidths additional correction of higher-order dispersion may considerably increase TPEF efficiency. For this purpose, commercial 4 f pulse shapers that optimize dispersion pre-compensation via multiphoton intrapulse interference phase scan (MIIPS) (Lozovoy *et al.*, 2004; Pestov *et al.*, 2010) have been used with microscopes. MIIPS relies on a high-precision grating in combination with a spatial light modulator (SLM). The grating spectrally disperses the beam on the way to the SLM and recombines the spectral components on the way back. At the SLM, every pixel corresponds to a different spectral range and the phase of the pulse can be independently modulated for different wavelengths. In this way, the SLM has the capability to shape the temporal profile of the pulse. Traditionally, the SHG signal after transmission through a thin nonlinear crystal is used for optimization of two-photon microscopes. In the case of a two-photon ophthalmoscope, only second-order dispersion has been corrected using the TPEF signal from the retina as feedback (Hunter *et al.*, 2011).

Effects of Femtosecond Lasers on the Retina

A disadvantage of fluorescence imaging, and especially TPEF, is that the *in vivo* retina must be exposed to much higher light levels than are used in conventional reflectance imaging. Roughly speaking, *in vivo* single photon imaging generally requires exposures that are ~ 1 order of magnitude and TPEF requires ~ 4 orders of magnitude more light than reflectance imaging. The need to address safety in TPEFO is all the more pressing given the indication that diseased retina might be more susceptible to light damage than healthy retina, which is based on a study in dogs suffering a rhodopsin mutation as a model for retinitis pigmentosa (Cideciyan *et al.*, 2005). Efficient two-photon imaging currently requires the use of sub-100 fs pulsed lasers, but due to a lack of data, safety standards for these light exposures are not well established (ANSI Z136.1-2014). The use of a pulsed light source for non-linear retinal imaging generates peak powers that have the potential to cause thermal, mechanical, and photochemical damage (Boulton *et al.*, 2001; Rockwell *et al.*, 2010) or some combination of these mechanisms as well as transient effects.

Thermal Damage

Excess heating of the tissue ($> 20^\circ\text{C}$) leads to immediate thermal damage, seen as local coagulation and an inflammation response. Thermal lesions usually occur with exposure durations on the time scale of μs up to 10 s with a $\text{time}^{2/3}$ dependence of the damage threshold upon exposure duration for visible and near infrared laser exposures (Lund and Edsall, 1999). Cell death may be attributed to protein denaturation (Mellerio, 1994). In the retina, the action spectrum for minimal thermal damage is

consistent with the absorption spectrum of melanin (Lund *et al.*, 2008). The time for heat dissipation from a melanin granule in the retina is treated as 5 μ s (ANSI Z136.1-2014). The ultrashort femtosecond lasers used for TPE have a pulse repetition frequency faster than that cooling time and are often treated as continuous-wave (CW) lasers at the average power for the purposes of safety calculations in addition to considering the safety of an individual pulse corrected by the multiple pulse correction factor. Specific safety standard calculations are outside the scope of this review.

Mechanical Damage

Ultrashort pulse lasers emit peak powers that have the potential to cause mechanical damage. Mechanical (or acoustic) damage is due to compression or tension within the tissue (Youssef *et al.*, 2011) after energy deposition that occurs more rapidly than dissipation is possible. On the one hand, the nonlinear dependence of the refractive index on irradiance can cause self-focusing of the laser beam. In the extreme case, the beam diameter is decreased below the diffraction limit. On the other hand, high peak powers can cause ionization and thus plasma formation. Plasma has absorptive properties different from those of ordinary gases. The critical power for self-focusing and plasma formation can be calculated and compared to ensure they are above the estimated peak power for an ocular exposure at a given wavelength.

Self-focusing

When a short pulse propagates through a nonlinear medium, the Kerr effect leads to a phase delay which is largest on the beam axis (where the optical density is highest) and smaller outside the axis. This is similar to the action of a lens. Self-focusing occurs if the laser peak power approaches the critical power (Boyd *et al.*, 2009; Marburger, 1975) defined by:

$$P_{cr} = \frac{0.148 \cdot \lambda^2}{n_0 \cdot n_2}$$

where the linear and nonlinear refractive indices for vitreous humor are $n_0 = 1.336$ and $n_2 = 43.9 \cdot 10^{-21} \frac{m^2}{W}$ (Rockwell *et al.*, 1993), respectively.

Plasma Formation

Laser-induced breakdown (LIB) is the partial or complete ionization of a solid, liquid or gas through absorption of laser energy. The ionization results in a gas of charged particles, a plasma, which absorbs optical radiation much more strongly than ordinary matter. The plasma can thus be rapidly heated by the laser beam to very high temperatures, producing plasma expansion, an audible acoustic signature and a visible plasma emission. There are two mechanisms which can lead to LIB: direct ionization of the medium by multiphoton absorption or cascade ionization where free electron(s) have to be present at the beginning of the pulse. In the femtosecond regime only “pure” multiphoton ionization is fast enough to allow breakdown to occur over the duration of the pulse. For laser-induced breakdown with subsequent bubble formation, a critical electron density of 10^{24} electrons cm^{-3} is needed, whereas for laser-induced breakdown without subsequent bubble formation, a critical electron density of 10^{22} electrons cm^{-3} is sufficient. Low-density plasmas may also be a mechanism for femtosecond pulse tissue damage (Vogel *et al.*, 2002a,b). The critical electron density associated with significant optical absorption in the plasma is 10^{18} electrons per cm^3 .

The irradiance threshold for plasma formation in the femtosecond laser pulse regime in vitreous humor can be calculated (Schwarz *et al.*, 2016) following the example of Cain *et al.* (2005). Calculations are based on the first order model of Kennedy (Kennedy, 1995; Kennedy *et al.*, 1995b), with special attention to Kennedy (1995) sections IV D and V F. For the ultrashort pulse regime, this model relies on the theory of multiphoton ionization in condensed media (Keldysh, 1965). The irradiance threshold for multiphoton breakdown as derived by Kennedy is:

$$I_{cr} = \frac{\left(\frac{\rho_{cr}}{A \cdot 0.5 \cdot \tau_p} \right)^{1/K}}{B}$$

with ρ_{cr} being the critical free electron density explained below, $K = \langle 1 + \frac{\Delta}{\hbar \cdot \omega} \rangle = 4$ the number of photons required to ionize the medium when $\Delta = 6.5$ eV is the ionization energy of the medium and $\omega = \frac{2 \cdot \pi \cdot c}{\lambda}$ the optical frequency where $c = 3 \cdot 10^8 \frac{m}{s}$ is the vacuum speed of light, λ the wavelength and the parameters

$$A = \left(\frac{2}{9 \cdot \pi} \right) \cdot \omega \cdot \left(\frac{m' \cdot \omega}{\hbar} \right)^{\frac{3}{2}} \cdot e^{2K} \cdot \Phi(z) \cdot \left(\frac{1}{16} \right)^K$$

and

$$B = \frac{q^2}{m' \cdot \Delta \cdot \omega^2 \cdot c \cdot \epsilon_0 \cdot n_0}$$

where ω , K and Δ are the same as above, $\epsilon_0 = 8.85 \cdot 10^{-12} \frac{C}{Vm}$ is the permittivity of free space, $n_0 = 1.336$ the index of refraction of the medium at frequency ω , $m' = 4.55 \cdot 10^{-31}$ kg the exciton reduced mass, $\hbar = 6.58 \cdot 10^{-16}$ eVs the reduced Planck constant, $q = 1.6 \cdot 10^{-19}$ C the electron charge, and $\Phi(z) = e^{-z^2} \cdot \sum_{n=0}^{\infty} \frac{z^{2n+1}}{n!(2n+1)}$ represents Dawson's Integral with $z = \sqrt{2 \cdot K - \frac{2 \cdot \Delta}{\hbar \cdot \omega}}$.

Photochemical Damage

Photochemical damage occurs when the energy in a photon of light is strong enough to break chemical bonds in the irradiated molecules. The bond breakage can result in conformational changes to a molecule or in the formation of free radicals and reactive oxygen species. These molecular changes can eventually result in cell damage or death. Photochemical damage is usually observed with visible light exposures longer than a second. However, recent results suggest photochemical damage to the RPE is also possible using near infrared light (Zhang *et al.*, 2016). The particular molecules involved in photochemical damage are expected to vary with exposure wavelength.

As a consequence of the nonlinear optical process underlying two-photon excitation, light in the UV range of wavelengths that is usually blocked by the ocular media (Boettner and Wolter, 1962) can be generated at the retina. This is observed in the sensitivity to and color appearance of near-infrared pulsed lasers as compared to CW sources of the same wavelength (Palczewska *et al.*, 2014b). It is not known what impact the increased proportion of UV and visible light in combination with IR light might have on retinal structure and function. Recent evidence suggests that threshold damage as a result of sub-100 fs light at 730 nm 5 times above the ANSI standard (ANSI Z136.1-2014) corresponds to a loss of S-cones (Schwarz *et al.*, 2017), possibly via a photochemical mechanism.

Infrared Autofluorescence Reduction

Exposure to infrared illumination required for TPEFO causes a long-lasting reduction in infrared autofluorescence (IRAF) (Masella *et al.*, 2014b). Fundus IRAF is thought to originate mainly from the choroid and RPE with a slightly higher relative contribution of the choroid in older and darkly pigmented subjects. Candidate fluorophores are oxidized melanin and components closely related to melanin. IRAF reduction can occur with pulsed and CW infrared light exposures (Schwarz *et al.*, 2016) and appears to be consistent with a photochemical mechanism. In non-human primate, partial recovery was seen at 1 month, with full recovery within 21 months. This long-lasting effect of infrared illumination in both humans and monkeys occurs at exposure levels four to five times below current safety limits. Possible explanations are therefore the bleaching of melanin or changes in fluorescence efficiency of oxidized melanin secondary to changes in the environment. To date, there is no evidence of IRAF reduction causing a clinically significant impact on retinal health or visual function.

Outlook

In vivo multiphoton fluorescence ophthalmoscopy is a growing field for retinal imaging of intrinsic and extrinsic fluorophores because of its ability to provide insight into both retinal structure and function. The ability to image fluorescence from both NAD(P)H and FAD opens the possibility for reduction–oxidation (redox) measurements (Chance and Thorell, 1959; Skala *et al.*, 2007), an indication as to the state of cellular respiration. Whether a cell is favoring aerobic or anaerobic metabolism can be an indication of its health. Further insight can be gained by tracking of fluorescent properties such as emission spectra and fluorescence lifetime. The composition of fluorophores contributing to the emission signal may be identified by their spectral contribution. Fluorescence lifetime is a measure of the average delay between fluorescence excitation and the time at which photons are emitted (Venetta, 1959). The lifetime varies with the conformational state of the fluorophore and its microenvironment, which may provide a means to distinguish healthy from unhealthy cells. For example, NADH exists in both free and protein-bound forms with identical emission spectra, but different fluorescence lifetimes (0.3 ns and 2.36 ns, respectively) (Skala *et al.*, 2007). Altered lifetimes of NADH and FAD have been demonstrated in precancerous cells, likely related to the increased reliance on glycolysis in cancer cells (Skala *et al.*, 2007). Using non-cellular scale single-photon fluorescence lifetime imaging ophthalmoscopy (Schweitzer *et al.*, 2004), differences from control in ocular fluorescence lifetime have been reported for AMD (Schweitzer *et al.*, 2009), Stargardt disease (Dysli *et al.*, 2016), Alzheimer's disease (Jentsch *et al.*, 2015) and diabetes (Schweitzer *et al.*, 2011). However, measurements of fluorescence lifetime using TPEF ophthalmoscopy of the non-human primate photoreceptor mosaic have only recently been reported (Feeks *et al.*, 2017). Furthermore, fluorescence lifetime of extrinsic fluorescent markers can provide insight into particular cellular properties such as pH or the ratio of cytosolic NADH: NAD⁺ (Mongeon *et al.*, 2016; Yellen and Mongeon, 2015).

TPEF ophthalmoscopy has the potential to be an effective clinical measure of photoreceptor and RPE health and provide early detection of outer retinal dysfunction. This requires the safe translation of this imaging modality for use in humans. Schwarz *et al.* (2016) have demonstrated in macaque that TPEF measurements of photoreceptor function are feasible at light levels within safety standards. Using a variety of clinical and high resolution imaging methods, such as fundus photography, reflectance and fluorescence cSLO, OCT, fluorescein angiography, and AO imaging of photoreceptors and RPE, IRAF reduction was the only significant effect. No other structural or functional changes were detected for any of the exposures, though of course we cannot exclude the possibility that changes could be detected with more sensitive tests or longer follow-up. No effect of repeated exposures on TPEF time course could be detected, suggesting that visual cycle function is maintained. Photoreceptors and RPE appeared normal in adaptive optics images. This safety study suggests that TPEF ophthalmoscopy will soon be feasible in people.

Confocal and Multiphoton Imaging of Cornea

Introduction

Most of our daily activities depend on a proper vision, and any loss in the visual acuity will strongly influence our quality of life. Preserving vision throughout an individual's lifetime is of a major concern in ophthalmology. The reliable diagnoses in ophthalmology are determined by detecting and monitoring the infinitesimal changes in tissue structures. The ophthalmologists mostly rely on slit-lamp biomicroscopy that was developed over a century ago in the 1890s. Subjective slit-lamp biomicroscopy remains as the backbone of clinical examination; however, objective tools and technologies are needed in order to provide a comprehensive understanding of structural alterations at a cellular level. Corneal disease is one of the leading causes of blindness worldwide, and a prompt and accurate diagnosis of corneal diseases is a milestone for successful treatment and followup.

Since the invention of the first ophthalmoscope by Hermann von Helmholtz in 1851, the quest for quantitative in vivo imaging of ocular surfaces for diagnostic and monitoring purposes was initiated. Recently, a number of imaging technologies were developed for research and clinical purposes. Boosted by the newest developments in microscopy, confocal microscopy has been widely employed in clinics and research for corneal diagnosis. Confocal microscopy has emerged as a powerful technique to study the corneal structure (Fig. 1) with high spatial and contrast images compared to conventional microscopy.

With the introduction of ultrafast pulsed laser sources, multiphoton microscopy practically became feasible and experienced a tremendous success in biological microscopy. Multiphoton microscopy allows three-dimensional (3D) tissue imaging over time, and it is an important asset in investigational imaging. Intrinsic tissue fluorescence, called autofluorescence, which is initiated by collagen, elastin, NAD(P)H etc., can be imaged by multiphoton microscopy and provides structural and functional information of the cornea. In this article, we will discuss the principles and the potential use and limitations of confocal and multiphoton microscopy for corneal imaging.

Principles of Confocal and Multiphoton Microscopy

Confocal Microscopy

The principle of confocal microscopy was patented in 1957 by Marvin Minsky, in order to overcome the limitations of conventional wide-field microscopy. In a conventional wide-field microscope, the entire specimen (i.e., cornea) will be illuminated evenly by a light source, and the specimens in the optical path are all excited at the same time. The resulting fluorescence (i.e., emitted light) from the specimen will be detected by the photodetector or camera including a largely unfocused background part. In contrast, confocal microscopy uses a point illumination source with a pinhole in front of the detector to eliminate the out of

focus light or glare. The optical resolution of confocal microscopy images is better than conventional wide-field microscopy, since the fluorescence is produced very close to the focal plane.

Multiphoton Microscopy

Multiphoton microscopy includes two-photon excited fluorescence (TPEF), second harmonic generation (SHG) and third harmonic generation (THG) imaging (Fig. 2). In 1931, the theoretical basis of two-photon excitation was established by Maria Göppert-Mayer, and then the photophysical effect of two-photon excitation was experimentally verified by Kaiser and Garret in 1963. Two-photon excitation is a fluorescence process in which a fluorophore (a molecule that fluoresces) is excited by simultaneous absorption of two photons. The familiar single-photon (i.e., confocal) fluorescence process involves exciting a fluorophore from the electronic ground state to an excited state by a single photon. This single-photon process typically requires photons in the ultraviolet or blue/green spectral range. However, the same excitation process can be generated by the simultaneous absorption of two less energetic photons (typically in the infrared spectral range) under sufficiently intense laser illumination. This nonlinear process occurs if the sum of energies of the two photons is greater than the energy gap between the molecule's ground and excited states. Since this process depends on the simultaneous absorption of two infrared photons, the probability of two-photon absorption by a fluorescent molecule is a quadratic function of the excitation radiance. Under sufficient intense excitation, three-photon and higher photon excitation are also possible. This process is similar to two-photon excitation wherein three photons or higher number of photons must interact with the fluorophore simultaneously to produce the fluorescence.

Almost all multiphoton microscopy is based on ultrashort pulsed lasers, because the multiphoton efficiency of an n -photon process depends on the peak power P according to P^n relation. The use of pulsed lasers enables efficient fluorophore excitation at a fast scanning rate. Moreover, focusing a pulsed laser into a specimen can generate a harmonic upconversion as well. Although the nonlinear optical effect known as SHG has been recognized in early days of laser physics, the use of SHG and its three-photon variant third (THG) is fairly new in research. Harmonic generation is a nonlinear process in which photons with the same frequency interact with a nonlinear material and generate a new photon with twice the energy. SHG is useful for investigating the ordered structural protein assemblies such as collagen fibers in the cornea.

Confocal Laser Scanning Microscopy

Confocal laser scanning microscopy (CLSM) has been widely implemented in clinics for diagnostic purposes. It is based on a conventional optical microscope, instead of a lamp a laser is used as a light source. The laser is focused on the cornea through the objective lens to a single spot in the focal plane. The laser beam is scanned in a raster pattern using the scanning mirrors in x - y direction and an entire image of the cornea at a certain focal plane will be reconstructed. The emitted light generated from the cornea at the focal plane will be collected by the same objective lens and the collected signals will be recorded using a photo-multiplier tube (PMT). This scanning principle does not improve the spatial resolution over conventional optical microscopy, because the excitation is produced throughout the entire beam path of the laser in the cornea, i.e., above and below the focal plane. However, the spatial resolution can be improved by placing a pinhole in front of the detector to eliminate the out of focus light. This leads to an excellent spatial resolution and enables serial optical sections from thick specimens (Fig. 3(a)).

Fig. 2 Jablonski diagram of single-photon excitation, two-photon excitation (2PE), second harmonic generation (SHG), and third harmonic generation (THG). (<http://www.azooptics.com/Article.aspx?ArticleID=1175>)

Fig. 3 The principle of confocal and two-photon microscopy. (a) In confocal microscopy, the emitted fluorescent light from the focal plane will pass through the pinhole and the out of focus light will be blocked by the pinhole and (b) in multiphoton microscopy, the two-photon excitation generates fluorescence only at the focal plane, so a pinhole is not required since no background fluorescence is produced. Reproduced from Allocca, G., Kusumbe, A.P., Ramasamy, S.K., Wang, N., 2016. Confocal/two-photon microscopy in studying colonisation of cancer cells in bone using xenograft mouse models. *BoneKey Reports* 5. doi:10.1038/bonekey.2016.84.

Two-Photon Laser Scanning Microscopy

The invention of two-photon fluorescence light microscopy by Denk, Webb, and coworkers revolutionized the *in vivo* 3D cellular imaging. By focusing an ultrashort pulsed laser through the objective lens sufficient excitation intensity can be generated on the focal plane (**Fig. 3(b)**). When the laser beam is focused on the specimen, the photons become crowded and the probability of two photons interacting simultaneously will be increased.

The significant advantage of two-photon excitation over single-photon (confocal) excitation is the narrow localization. In confocal microscopy, although the fluorescence is excited throughout the illuminated volume of the specimen, the signal originating from the focal plane will pass through the pinhole. In two-photon excitation, the fluorescence will be generated only at the focal plane, and no background fluorescence will be produced. Therefore, a pinhole is not required for two-photon microscopy. Due to the localized excitation of two-photon excitation, the 3D resolution of the images can be achieved identically to confocal microscopy. Since there is no absorption in out of focus specimen area, the excitation light can penetrate much deeper through the specimen to the focal plane. This results in greater penetration compared to confocal microscopy. Also, two-photon microscopy minimizes photobleaching and photodamage.

Confocal and Multiphoton Microscopy of Cornea

Three types of confocal microscopes are available for corneal imaging:

- Tandem scanning microscopy.
- Slit scanning microscopy.
- Laser scanning microscopy.

Tandem scanning microscopy sheds the light of high intensity through a pinhole and generates a two-dimensional (2D) image. However, tandem scanning microscopy for confocal imaging is not produced anymore. In contrast to tandem scanning, slit scanning microscopy has been employed in clinics with reduced scanning and examination time with high contrast imaging. Slit scanning has the ability to scan many points in parallel to the axis of the slit. Laser scanning microscopy is the latest addition to corneal imaging, where the laser beam is scanned over the back of the microscope objective through scanning mirrors. The Heidelberg Retina Tomograph (HRT) in combination with the Rostock Cornea Module (RCM) is a commercially available

Fig. 4 (a) Heidelberg Engineering Heidelberg retinal tomograph-rostock cornea module (HRT-RCM) confocal microscopy and (b) schematic diagram of the optical set up of the HRT-RCM. Heidelberg Engineering Brochure.

confocal microscope that has been widely used in clinics for corneal imaging. The HRT-RCM uses a class I laser and this laser poses no risk of ocular injury.

Heidelberg Retinal Tomograph-RCM

The Heidelberg Retinal Tomograph-RCM (HRT-RCM) (**Fig. 4(a)**) was developed by Heidelberg Engineering GmbH in cooperation with Rostock Eye clinic for in vivo investigation of the cornea. A 670-nm laser is used as light source and the laser is focused on the cornea with a high numerical aperture objective lens ($63\times/0.95$ NA or $60\times/0.90$ NA; interchangeable). The laser is raster scanned by the scanning mirrors and is focused on the cornea by the objective lens. The emitted fluorescent light from the cornea is captured using a detector. The confocal pinhole is used in front of the detector to eliminate the out of focus light (**Fig. 4(b)**). The confocal imaging of the cornea can be acquired with the field of view $250\ \mu\text{m} \times 250\ \mu\text{m}$, $400\ \mu\text{m} \times 400\ \mu\text{m}$, and $500\ \mu\text{m} \times 500\ \mu\text{m}$ with a $63\times$ objective lens. A viscous sterile gel is interposed between the objective lens and cornea to eliminate the optical interface between two different refractive indices. The depth of the focus can be adjusted manually relative to the cornea in a plane parallel to the corneal surface, to scan the cornea from epithelium to endothelium.

Confocal Imaging of Normal Cornea

The HRT-RCM provides excellent resolution with sufficient contrast at different layers of the cornea, and distinct corneal layers from epithelium to endothelium can be visualized. The corneal epithelium is composed of five to six layers (**Fig. 5(a)–(d)**), as superficial cells, intermediate cells, and basal cells. The superficial cells are flat polygonal cells with well-defined border, prominent nuclei and uniform density of cytoplasm. It is about $40\text{--}50\ \mu\text{m}$ in diameter and approximately $5\ \mu\text{m}$ thick. The intermediate cells also known as wing cells are similar to superficial cells, but the nuclei are not evident. It is typically about $30\text{--}45\ \mu\text{m}$ in size and characterized by the cell borders. Basal cells are approximately $10\text{--}15\ \mu\text{m}$ and smaller in size. The basal cells appear denser than the superficial and wing cells.

The subbasal nerve plexus (**Fig. 5(e)**) is characterized by the presence of hyper-reflective fibers of $4\text{--}8\ \text{mm}$ length, and connected with anastomoses and organized in a vortex pattern in the lower nasal quadrant of the paracentral cornea. The visualization of corneal nerve plexus was not possible until the introduction of confocal microscopy. The nerve fibers appear bright and well contrasted against a dark background.

Corneal stroma accounts for 90% of total corneal thickness and the keratocytes density is much higher in anterior stroma than in posterior stroma. The keratocyte counts are $1000\ \text{cells}/\text{mm}^2$ in the anterior stroma and $700\ \text{cells}/\text{mm}^2$ in the posterior stroma. The confocal image of the stroma exhibits multiple irregular oval, round or bean shaped bright structures representing keratocytes (**Fig. 5(f)** and **(g)**). The collagen fibers cannot be visualized by confocal microscopy in normal cornea.

Corneal endothelium is composed of a single layer of cells that are $4\text{--}6\ \mu\text{m}$ thick and approximately $20\ \mu\text{m}$ in diameter. The endothelial cells progressively decline with age, and the normal endothelial cell count amounts to $3000\ \text{cells}/\text{mm}^2$ in a healthy cornea. The endothelial cells appear as bright hexagonal and polygonal cells with unrecognizable nuclei (**Fig. 5(h)**).

Confocal Microscopy in Corneal Pathologies

Confocal microscopy has been an effective tool in clinical diagnosis, and it is widely used to assess corneal infections, corneal dystrophies, pre and postsurgical assessment of laser-assisted in situ keratomileusis (LASIK), photorefractive keratectomy (PRK), keratoconus and infectious keratitis. Also, it is used to monitor the cornea after injuries, and for differential diagnosis of

conjunctival tumors and conjunctivitis. As an example for clinical confocal imaging of the cornea, the Langerhans cell distribution and postsurgical assessment of LASIK using the HRT-RCM is shown in Figs. 6 and 7.

Langerhans Cells

Langerhans cells can be evaluated using confocal microscopy with emphasis on cell morphology and cell distribution. In confocal microscopy, the Langerhans cells are visualized typically as bright corpuscular particles with dendritic morphology. These cells are distributed in low numbers at the center of the cornea and higher densities at the periphery of the cornea. Confocal microscopy helps in differentiating the Langerhans cells bodies that lack dendrites, Langerhans cells with small dendritic process form a local network, and Langerhans cells forming a meshwork via long interdigitating dendrites (Fig. 6(a)–(c)). The average density of Langerhans cells in normal subjects is 34 ± 3 cells/mm² (range 0–64 cells/mm²) in the center of the cornea, and 98 ± 8 cells/mm² (range 0–208 cells/mm²) in the periphery. Langerhans cells contribute to the immune and inflammatory responses, and determine the cell-mediated immunity.

Postsurgical Assessment of LASIK

LASIK is an excimer laser-based refractive surgical procedure that is currently being successfully used by surgeons to correct refractive errors (myopia, hyperopia etc.). After LASIK surgery, the cornea is typically evaluated by slit-lamp biomicroscopy and computerized corneal topography. The confocal microscopy evaluation of LASIK pre- and postsurgery adds new aspects in corneal diagnosis. The distribution of the corneal nerves and degeneration of the nerve structures can be visualized by confocal microscopy, and thus a direct comparison between innervation and sensitivity or symptom severity of the dry eye can be provided (Fig. 7).

Two-Photon Laser Scanning Microscopy

Two-photon laser scanning microscopy based on the HRT was developed to investigate the cornea (Fig. 8). A compact femto-second laser was employed in the system as the light source and an additional detection path for the two-photon mode was implemented. Both the confocal and two-photon images can be captured using the same instrument. An electronic switch facilitates the switching between the two imaging modes, while both detection modes are synchronized with the scanning unit. The laser beam is deflected in x - and y -direction via two scanning mirrors (scan unit, Fig. 8(b)) to trace out a square raster of $300 \times 300 \mu\text{m}^2$, $200 \times 200 \mu\text{m}^2$, or $150 \times 150 \mu\text{m}^2$ at a frame rate up to 16 Hz. The laser is focused on the cornea with a high numerical aperture objective lens ($40 \times /0.80$ NA or $16 \times /0.80$ NA; interchangeable). The wide field of view can be achieved by using the $16 \times$ objective lens with less distinct cell morphology. Like confocal microscopy (HRT-RCM) the focus can be adjusted manually and different layers of the cornea can be visualized. A viscous sterile gel has to be placed between the objective lens and the cornea to eliminate the optical interface between two different indices.

Two-Photon Imaging of Normal Cornea

The TPEF imaging of cornea has been extensively employed in preclinical studies, but has not been implemented in clinics yet. Although confocal microscopy has been used in clinical diagnosis, the collagen fiber orientation in the stroma cannot be visualized, and it provides only morphological information rather than the tissue's functional state. With two-photon imaging

Rapid identification of microorganisms using the two-photon ophthalmoscope. *Investigative Ophthalmology and Visual Science* 53 (14), 6175; Qu, Y., Thomas, K.E., Schuster, A.K., *et al.*, 2011. Identification of microorganisms utilizing the two-photon ophthalmoscope. *Investigative Ophthalmology and Visual Science* 52 (14), 5823.

both the tissue structures and the metabolic state can be well addressed. Two-photon microscopy provides excellent resolution and high contrast images of the cornea similar to confocal microscopy. High resolution two-photon images of the corneal epithelium and the collagen fibers from the human corneal buttons are shown in [Fig. 9](#). The collagen fibers in the stroma can be well established with TPEF and SHG imaging.

Two-Photon Imaging of Limbal Stem Cells

The limbal stem cells are located in the basal layer of the corneal limbus, and the proliferation of the limbal cells maintains the cornea by replacing the lost cells by tears. Limbal stem cells also prevent the conjunctival epithelial cells from migrating onto the surface of the cornea. The limbal stem cells have never been visualized with confocal microscopy and with the use of two-photon microscopy the limbal stem cells have been identified in mice. The limbal stem cells are smaller in size and it is shown by two-photon microscopy ([Fig. 10](#)). The two-photon imaging of limbal stem cells would help in the diagnosis of limbal stem cell deficiency and also differentiate and explore the nature of the limbal stem cells in a precise way.

Two-Photon Imaging of Infectious Keratitis

Confocal microscopy plays a significant role in detecting the microorganisms causing corneal infections. It is difficult to identify the microorganisms like *Acanthamoeba* on the ocular surfaces since the appearance can impersonate as herpetic or bacterial keratitis. In most cases, the *Acanthamoeba* keratitis is diagnosed either by tissue culture or corneal biopsy, and histological analysis.

Fig. 10 Two-photon imaging of mice limbal stem cells. Reproduced from Qu, Y., Thomas, K.E., Vola, M.E., *et al.*, 2012. Rapid identification of microorganisms using the two-photon ophthalmoscope. *Investigative Ophthalmology and Visual Science* 53 (14), 6175; Qu, Y., Thomas, K.E., Schuster, A.K., *et al.*, 2011. Identification of microorganisms utilizing the two-photon ophthalmoscope. *Investigative Ophthalmology and Visual Science* 52 (14), 5823.

Fig. 11 Two-photon imaging of *Acanthamoeba* keratitis. Reproduced from Qu, Y., Thomas, K.E., Vola, M.E., *et al.*, 2012. Rapid identification of microorganisms using the two-photon ophthalmoscope. *Investigative Ophthalmology and Visual Science* 53 (14), 6175; Qu, Y., Thomas, K.E., Schuster, A.K., *et al.*, 2011. Identification of microorganisms utilizing the two-photon ophthalmoscope. *Investigative Ophthalmology and Visual Science* 52 (14), 5823.

Although confocal microscopy lacks sufficient resolution in detecting the *Acanthamoeba* keratitis, it is used for diagnostic purposes since confocal microscopy is the only available diagnostic tool for patients. In confocal microscopy, the *Acanthamoeba* is visualized as round or ovoid highly reflective structures and the same is depicted by the two-photon microscopy (Fig. 11).

Second Harmonic Imaging of Cornea

Collagen is the major component of connective tissues including cornea, and due to its transparency to visual and near infrared light the human eye is ideal for laser-based diagnostic and imaging applications. Among different multiphoton implementations, SHG imaging is particularly suitable to investigate non-centrosymmetric structures like collagen fibrils (Figs. 12 and 13). The basic structure of the collagen fibril is a triple helix composed of three proteins chains, which gives collagen the intrinsic ability of SHG

Fig. 12 SHG imaging of corneal collagen fibrils in (a) forward and (b) backward directions from porcine cornea. The fibrillar structures resolved in (a) correspond to collagen bundles which are composed of regularly packed collagen fibrils. Scale=10 μ m. Reproduced from Han, M., Giese, G., Bille, J., 2005. Second harmonic generation imaging of collagen fibrils in cornea and sclera. *Optics Express* 13, 5791–5797.

Fig. 13 SHG imaging and two-photon imaging of human cornea from (a) Bowman's membrane and (b) corneal stroma. The collagen fibers were visualized using the SHG imaging and the keratocytes (arrows) were visualized with the two-photon imaging. Reproduced from Han, M., Giese, G., Bille, J., 2005. Second harmonic generation imaging of collagen fibrils in cornea and sclera. *Optics Express* 13, 5791–5797.

imaging. Similar to TPEF, SHG is produced in only a small focal volume, permitting high resolution 3D optical sectioning of thick tissues. In contrast to TPEF, SHG from collagen is an intrinsic and a coherent process. Intrinsic imaging avoids the complications of slicing and labeling, and samples can be investigated under physiological conditions. Coherent constructive or destructive interference of SHG provides extra hints to the ultrastructure of collagen fibrils and their organizations.

The collagen fibrils of the porcine cornea using SHG imaging are shown in [Fig. 12](#). Most collagen fibrils run parallel to the cornea surface and share similar orientations with their neighbors. One of the unique features of SHG is that the geometry of the SHG emission field reflects the size and shape of the collagen fibrils. The SHG radiation pattern is mainly determined by the phase matching condition and the objects with the axial size on the order of the second harmonic wavelength exhibit forward directed SHG, while objects with an axial size less than $\lambda/10$ (approx. 40 nm) are estimated to produce nearly equal backward and forward SHG signals.

In [Fig. 12\(b\)](#), the backward SHG from cornea was extremely weak and there was no correlation between the structures revealed by forward and backward SHG imaging. The predominant forward SHG implies that the corneal collagen fibrils are not randomly distributed. It's worth mentioning that the fibrillar structures revealed in [Fig. 12\(b\)](#) actually correspond to collagen bundles composed of many corneal collagen fibrils. In cornea, the collagen fibrils ($n=1.47$) and the extrafibrillar matrix ($n=1.35$) have different refractive indices, thus the collagen fibrils have to be treated as individual scatters. Since the dimension of the collagen bundle (approximately 0.5 μ m) is close to the second harmonic wavelength (400 nm), the phase correlation of SHG from neighboring collagen fibrils should be taken into account. The forward predominant SHG radiation from cornea indicates the regular arrangement of the collagen fibrils, at least in the domain of the collagen bundles.

In [Fig. 13](#), SHG and two-photon imaging of human cornea from Bowman's membrane ([Fig. 13\(a\)](#)) and corneal stroma ([Fig. 13\(b\)](#)) is depicted. The collagen fibers were visualized using the SHG imaging and the keratocytes (arrows) were imaged with TPEF imaging.

Fig. 14 Two-photon microscopy of enucleated rabbit eyes 2 weeks after standard corneal CXL, upper row: two-photon imaging at 710 nm excitation light and lower row: second harmonic generation. (a) Two-photon imaging of the central zone of control cornea; (b) the peripheral zone of the treated cornea shows keratocytes in a dense network; (c) at the tangential zone, there is a sharp transition between the treated area and the untreated area, as shown by diminished keratocytes and a strong autofluorescence signal toward the central zone; (d) in the central zone, there are no keratocytes and the autofluorescence signal is uniform and strong; (e) and (f) second harmonic generation of stromal collagen in the control zone and the peripheral zone of the treated cornea shows a wavelike pattern; (g) at the transition zone toward the treated area, the wavelike pattern changes to a uniform signal; (h) in the central zone, a uniform SHG signal is visible. Reproduced from Steven, P., Hovakimyan, M., Guthoff, R.F., Hüttmann, G., Stachs, O., 2010. Imaging corneal crosslinking by autofluorescence 2-photon microscopy, second harmonic generation, and fluorescence lifetime measurements. *Journal of Cataract Refractive Surgery* 36 (12), 2150–2159.

Two-Photon Imaging of Corneal Cross-linking

Keratoconus is a progressive, noninflammatory and bilateral ectatic corneal disease characterized by corneal thinning and weakening. The thinning is most apparent at the apex of the cornea, and the steep conical protrusion leads to high myopia with irregular astigmatism. The visual loss occurs primarily from irregular astigmatism and myopia, and secondarily from the corneal scarring. Computerized corneal topography has become a gold standard for the early identification of keratoconus and recently confocal microscopy has also been used to assess the keratoconus cornea. Corneal cross-linking (CXL) is an invasive treatment procedure for keratoconus in order to stop or delay the process. The CXL procedure increases the mechanical and biomechanical stability of the cornea by application of ultraviolet-A light of 370 nm and riboflavin (vitamin B2). The assessment of cornea after cross-linking is limited because the treatment effect cannot be visualized by slit-lamp biomicroscopy. Confocal microscopy can detect the side effects like stromal edema and rarefaction, the reappearance of stromal keratocytes over time. However, the effect of crosslinks between the collagen fibers after CXL cannot be visualized by confocal microscopy. Two-photon imaging with SHG is effective in measuring the crosslinks between collagen fibers as shown in [Fig. 14](#).

Laser Safety Considerations of Two-Photon Microscopy

The safe use of lasers has been a primary consideration since lasers are widely used for treatments and in research laboratories. The American National Standards Institute (ANSI) has specific standards for eye safety that take into account many of the important experimental variables such as laser power delivered at the cornea, viewing time, beam diameter or full-field viewing, the exposure area on the retina, and the wavelength. Near infrared radiation (NIR) relative to visible wavelength is considered to be less

phototoxic and has deeper penetration in thick biological tissues, which is one of the key reasons for its widespread use in imaging devices. Compared to retinal imaging, the safety standards for illuminating the cornea and anterior structures of the eye are tolerant. The laser safety limits for corneal imaging can be calculated by the maximum permissible exposures (MPE) according to the ANSI standards as follows:

$$\text{Recommended MP corneal irradiance} = 25 \times t - 0.75 \text{ (W/cm}^2\text{)} \text{ for } t < 10\text{s}$$

$$\text{Recommended MP corneal irradiance} = 4.0 \text{ (W/cm}^2\text{)} \text{ for } t > 10\text{s}$$

For example, if the irradiated area is described by $1536 \mu\text{m} \times 1536 \mu\text{m} = 0.0236 \text{ cm}^2$, the MPE should be 94.4 mW for longer exposure time ($t > 10\text{s}$) and should be 515 mW for shorter exposure time.

Future Directions

Before implementing multiphoton microscopy for in vivo imaging of the human cornea, the shortcomings of these nonlinear microscopy techniques have to be addressed. For TPEF imaging, the drawback of depositing the energy into the tissue has to be evaluated to prevent photodamage. Although SHG and THG are absorption-free and can be used without photobleaching effects, harmonic imaging has another disadvantage that currently obstructs its use in ophthalmic practice. The harmonic signals are emitted predominantly in forward direction, whereas in backward direction the harmonic signals are weak. This limits SHG imaging for in vivo applications, and the backscattered signal might be enhanced using an absorbing dye. Also, new optical techniques such as wavefront aberration optimization and adaptive optics may be a key for future in vivo applications. Until these restrictions of multiphoton microscopy are eliminated, confocal microscopy remains exclusive in the assessment of cellular morphology in living human cornea.

Definitions and Conventions

Refractive Error, Refractive Correction, and Their Physical Units

The purpose of the eye's optical system is to cast an image of the external world onto the photoreceptor layer of rods and cones in the retina. If the system were perfect it would focus all rays of light from a point source into a single image point on the retina. Real eyes, however, suffer from aberrations, which are optical imperfections that degrade the quality of the retinal image and hamper vision. Since aberrations are flaws in the refraction of light, one might presume that the terms aberrations and refractive errors are synonymous. However, in the field of ophthalmic and visual optics, the term refractive error is restricted to two specific types of aberrations: defocus and astigmatism. Historically, these are the only two aberrations that could be measured routinely in a clinical environment and then corrected easily with spectacles or contact lenses. Although the existence of other ocular aberrations (e.g., coma, spherical aberration, etc.) has been known since the time of Newton, those aberrations could not easily be measured or corrected clinically. Since these "higher-order" aberrations fell outside the domain of conventional clinical practice, they were excluded from the traditional definition of refractive error. Depending on context, astigmatism may also be excluded leaving just defocus as the only aberration implied by the term refractive error.

The sign convention for specifying refractive errors of eyes can appear confusing. Although scientists may be inclined to describe the refractive errors of the eye, per se, clinicians prefer to specify the lens needed to correct the eye's refractive errors. As illustrated in Fig. 1, the ideal condition of emmetropia exists when distant objects produce well-focused retinal images.

Fig. 1 Schematic optical diagrams of the eye. Upper panel shows an emmetropic eye focusing rays from a distant point source onto the retinal photoreceptors in the fovea. Lower panel shows a myopic eye focusing rays from a point source at finite distance onto the retinal photoreceptors. Middle panel is a Gaussian paraxial model for both eyes showing cardinal points (f, f' – focal points; P, P' – principal points; N, N' – nodal points), the entrance and exit pupils (E, E') and the corneal apex (A).

However, a short-sighted (i.e., myopic) eye has too much refractive power to clearly focus the retinal image of a distant object, and therefore requires a correcting spectacle or contact lens of negative power. Thus, the sign of the defocus component of refractive error for myopic eyes is negative by standard clinical conventions. Conversely, a hyperopic eye has too little power to focus on distant objects and therefore requires a positive correcting lens, so hyperopic refractive error is positive.

Refractive errors and viewing distance of objects are both specified in units of inverse meters, more commonly referred to as diopters (D). Diopters is the preferred unit in ophthalmic and visual optics because practical problems are more easily solved when the Gaussian conjugate equation of paraxial optics

$$n'/k' = n/k + (n' - n)/r \quad (1)$$

where k is the object distance, k' is the image distance, n is the refractive index of object space, n' is the refractive index of image space, and r is the radius of curvature of the refracting surface, is rewritten as

$$K' = K + F \quad (2)$$

where K is the object vergence, K' is the image vergence, and F is the refracting power of the surface attributed to the Gaussian principal planes. All three quantities in this linear equation have physical units of diopters. The situation here is analogous to electrical circuits involving parallel resistors, for which solutions are most easily obtained by introducing the term conductance when referring to the inverse of resistance. That maneuver requires a corresponding change of physical units of resistance (ohms) to inverse units of conductance (mhos). In the present optical analogy, inverse distance from object or image points to their respective principal points is called vergence, which has units of diopters. Thus, the Gaussian conjugate Eq. (2) reads "the vergence K' of light leaving a refracting surface (or thin lens) is equal to the incident vergence of light K plus the refracting power F of the lens". If the lens is astigmatic, this same equation applies to refraction in any meridian but the refracting power F varies sinusoidally with meridian angle. A simple mnemonic for distinguishing the closely related terms power and vergence is: "lenses have the power to change the vergence of light".

Given the terminology introduced above, the defocus component of refractive error may be defined three equivalent ways that are mutually consistent but have different interpretations. They may be understood by considering Fig. 1, which illustrates a simple case of myopia caused by axial elongation of the eye. Thus, the myopic optical system in this example has the same paraxial cardinal points as the illustrated emmetropic eye, but axial elongation causes the retinal conjugate surface to move from infinity to a finite distance from the eye. The myopic eye's far point, which is the point in object space that is optically conjugate to the retinal fovea, is located at some finite distance k from the first principal point P . So the first interpretation of refractive error occurs in object space: it is the vergence of the eye's far point,

$$\text{Refractive error} = K = n/k \quad (3)$$

The second interpretation is in image space: it is the focusing error for a distant object point. Since $K=0$ for objects at infinity, the focusing error is computed from Eq. (2) as the difference between the required power K' (sometimes called the dioptric length of the eye) and the eye's available power F ,

$$\text{Refractive error} = K = K' - F \quad (4)$$

The third interpretation conceives of refractive error as a lens prescription: it is the power of the correcting lens needed to focus a distant target on the retina. Again $K=0$, so the required correcting lens has to make up the difference between the eye's dioptric length and its power, as indicated in Eq. (4). In principle, the correcting lens should be placed in the eye's first principal plane but in practice it is placed on the cornea (i.e., a contact lens, which requires only a small adjustment in power), or in the spectacle plane (which requires a larger adjustment in lens power to compensate for the significant separation of the lens from the eye's first principal point).

Specification of Sphero-Cylindrical Lenses and Refractive Errors

Several conventions are in common use for specifying the sphero-cylindrical lens needed to fully correct an eye's refractive errors. Differences between these conventions arise from alternative ways of envisioning how a prescribed sphero-cylindrical lens is constructed from component lenses. Two of these conventions presuppose that the correcting lens is the combination of a spherical lens of power S juxtaposed with a cylindrical lens of power C oriented with the axis of the cylinder at some angle α . The difference between these two conventions is the sign of C . Optometrists typically prefer to think of C as a negative number, whereas ophthalmologists typically prefer to think of C as a positive number. Simple transposition formulae allow conversion from one convention to another. A third convention preferred by many researchers replaces S with M , the so-called mean spherical-equivalent power. If one imagines correcting an eye with sphero-cylindrical refractive error using only a spherical lens of power M , the eye would remain astigmatic by some amount J . The value of J refers to the power of a so-called Jackson crossed-cylinder, which is constructed from two conventional cylinder lenses of equal but opposite powers oriented with their axes mutually perpendicular.

All three of the conventions described above may be said to be in polar form since the astigmatic component of the correction is given in terms of a magnitude (lens power) and an angle (the orientation of the lens axis). For computational purposes, conversion from polar form to rectangular form is usually advantageous. This is easily accomplished for the cross-cylinder

convention using the following transposition formulae:

$$\begin{aligned} M &= S + C/2 \\ J_0 &= -\frac{C}{2} \cos 2\alpha \\ J_{45} &= -\frac{C}{2} \sin 2\alpha \end{aligned} \quad (5)$$

The three-dimensional vector $[M, J_0, J_{45}]$ is known in the ophthalmic optics literature as a power vector and the length of a power vector is called blur strength. Blur strength quantifies the overall blurring effect of sphero-cylindrical refractive error on image quality according to geometrical optics. The components of a power vector may be converted to second-order Zernike aberration coefficients using the following formulae:

$$\begin{aligned} M &= \frac{-c_2^0 4\sqrt{3}}{r^2} \\ J_0 &= \frac{-c_2^2 2\sqrt{6}}{r^2} \\ J_{45} &= \frac{-c_2^{-2} 2\sqrt{6}}{r^2} \end{aligned} \quad (6)$$

where c_n^m is the n th order Zernike coefficient of meridional frequency m and r is the pupil radius. If Zernike coefficients are specified in microns (10^{-6} m) and pupil radius is specified in millimeters (10^{-3} m) then the computed values of M , J_0 and J_{45} will have units of diopters (m^{-1}).

Specification of Higher-Order Aberrations of Eyes

The accepted convention for reporting Zernike aberration coefficients in the ophthalmic optics field is given in ANSI standard Z80.28. (ANSI, 2010) The normalization scheme used in this standard allows an interpretation of individual Zernike coefficients as the RMS wavefront error of the corresponding aberration mode. Accordingly, we may infer from Eq. (6) that defocus (M) and astigmatism (J_0, J_{45}) in diopters are proportional to the ratio of RMS wavefront error to pupil area.

Zernike polynomials Z_n^m are indexed according to their radial order n and their meridional frequency m . Historically, the attention of clinical practitioners has been directed at the lower Zernike orders 1–2 but increasing attention to the higher orders ($n > 2$) has occurred in recent years due to the technological development of wavefront aberrometers (see Section Aberrometry and Wavefront Sensing). The mathematical formula describing individual Zernike basis functions, or modes, is given by the equation

$$Z_n^m = N_n^m R_n^{|m|}(\rho) M(m\theta) \quad (7)$$

which is separable into a function of pupil-plane coordinates ρ (the normalized radial coordinate) and θ (meridian angle, measured counterclockwise from the horizontal when viewing the patient). The radial term for the Zernike polynomial function with indices n and m is given by the equation

$$R_n^{|m|}(\rho) = \sum_{s=0}^{0.5(n-|m|)} \frac{(-1)^s (n-s)!}{s! (0.5(n+|m|)-s)! (0.5(n-|m|)-s)!} \rho^{n-2s} \quad (8)$$

where s is an integer summation index incremented by one unit. The meridional (or azimuthal) term for a Zernike polynomial function with index m is given by the equations

$$\begin{aligned} M(m\theta) &= \cos(m\theta) \quad \text{if } m \geq 0 \\ M(m\theta) &= \sin(|m|\theta) \quad \text{if } m < 0 \end{aligned} \quad (9)$$

The normalization term N in Eq. (7) makes every Zernike mode have unit variance over the unit circle and is defined by the equation

$$N_n^m = \sqrt{(2 - \delta_{0,m})(n+1)} \quad \text{where } \delta_{0,m} = 1 \text{ if } m = 0, \quad \delta_{0,m} = 0 \text{ if } m \neq 0 \quad (10)$$

Zernike aberration coefficients provide the weighting factors needed to reconstruct a wavefront aberration for an individual eye with a weighted sum of orthonormal basis functions. The circle polynomials of Zernike were selected over the traditional Seidel series for the ANSI standard because they are a complete set that can be used to represent any continuous, smooth function over a circular domain. Moreover, individual basis functions in the set correspond to common aberrations found in optical systems (e.g., defocus, coma, spherical aberration). One disadvantage of Zernike basis functions is that their spatial derivatives are not orthogonal, which hampers the accurate calculation of coefficients from wavefront slope measurements. This disadvantage is overcome by fitting slope data with Zernike radial slope polynomials (Nam *et al.*, 2009).

Another disadvantage stems from the fact that Zernike basis functions of a given order are balanced with basis functions of lower orders to achieve orthogonality and minimize RMS variation. For example, the basis function for Zernike spherical aberration is constructed by subtracting an amount of defocus (which varies as ρ^2) from Seidel spherical aberration (which varies as ρ^4). Thus the total amount of defocus (in the ρ^2 sense) is distributed across multiple Zernike modes, a fact that can hamper interpretation and complicates the calculation of power vector description of refractive errors when higher-order aberrations are present. These problems are reduced by an alternative set of basis functions (Stephenson, 2009) that combine the benefits of Zernike polynomials (completeness) and Seidel polynomials (un-balanced).

Methods for Determining Refractive Error and Refractive State

Refraction is a clinical process for determining the refractive error of an eye. Refractions can be performed objectively with a clinical autorefractor, an instrument that determines spherical and astigmatic focusing errors of the eye, or with an aberrometer, an instrument that also measures higher-order aberrations. Traditionally, refractive errors are measured subjectively by clinicians using psychophysical methods to determine the best combination of spherical and cylindrical correcting lens for optimizing vision and therefore, by implication, optimizing focusing of the retinal image. Clinicians generally regard the subjective refraction as definitive since it includes the patient's judgment of optical focus based on their own visual perception using their own retina and brain. However, other considerations (e.g., matching image size in the two eyes) may lead the clinician to prescribe correcting lenses that are somewhat suboptimal optically in order to achieve overall objectives of visual comfort and performance. Consequently, the prescribed lens is often different from that indicated by the refraction procedure.

Locating the Eye's Far Point With Optical Measurements

The far point of an eye is that point in object space which is optically conjugate to the entrance apertures of the foveal photoreceptors when accommodation is relaxed. Since refractive error is equal to the vergence of the far point according to Eq. (3), locating an eye's far point is a straightforward means of determining refractive error. Unfortunately, an unambiguous far point exists only for an ideal eye which is free of all optical aberrations except defocus. Real eyes invariably suffer from other aberrations besides defocus, and therefore an operational definition of the far point is required. For example, an astigmatic eye may be described as having two far points, one for line objects oriented parallel to the axis of astigmatism and another for the orthogonal orientation. The point midway between these two extremes is a widely accepted approximation for the far point of an astigmatic eye since this is where the far point would be located if the astigmatism were corrected by a lens. This approximation assumes higher-order aberrations are negligible, in which case refractive errors may be computed directly from second-order Zernike coefficients using Eqs. (5) and (6).

One reasonable approximation for the far point of an eye with higher-order aberrations is that location in object space where an object must be located in order to maximize the quality of its retinal image. Unfortunately, this approximation does not locate the far point uniquely for several reasons. Firstly, image quality depends on the characteristics of the visual stimulus (e.g., luminance, size, spatial frequency spectrum, wavelength spectrum) and therefore may change as the stimulus changes. Secondly, there are many ways to define and measure image quality (Thibos *et al.*, 2004), none of which are universally endorsed by the clinical or vision science communities. Thirdly, the psychophysical judgment of optimum focus by an observer depends on factors other than optical image quality, such as neural sampling of the retinal image, cortical neural processing, and perceptual weighting given to the various features of optical blur (e.g., contrast attenuation, loss of sharpness, and doubling or ghosting of the image). Moreover, the selection of an objective method for locating the nominal far point of an eye is likely to depend on the intended application.

Definition of the Eye's Refractive State

The human eye is an active optical system that responds to changes in viewing distance by changing its refractive power, a process called accommodation. At any given state of accommodation, each point on the retinal surface is optically conjugate (at least approximately) to some location in visual space. The locus of all such points is called the retinal conjugate surface. Refractive state is defined as the vergence of the retinal conjugate surface, which in general will vary across the visual field. Thus, refractive state is essentially the same concept as refractive error defined above, but extended to apply to the accommodating eye. Although it would seem reasonable to use the general term "refractive state" for an eye in any state of accommodation, the historical precedent is to use the term "refractive error" for the special case of relaxed accommodation (i.e., minimum power). Clearly, the same difficulty in establishing a universally accepted method for specifying refractive error described above applies equally to specifying refractive state.

Methods for Estimating Refractive State From Zernike Aberration Coefficients

Wavefront aberrometers make comprehensive measurements of an eye's aberrations reported in the form of Zernike aberration coefficients, C_n^m . From these measurements one may compute the eye's wavefront aberration function $W(\rho, \theta)$ as a weighted sum of

Fig. 2 A reference coordinate system for specifying wavefront errors. A right-hand (x, y, z) coordinate reference frame is constructed such that the z -axis is the chief ray and the (x, y) plane is perpendicular to the z -axis at the center of the exit pupil.

Zernike polynomials,

$$W(\rho, \theta) = \sum_{n,m} c_n^m Z_n^m \quad (11)$$

A given aberration function refers to a specific visual direction, which is typically the foveal line of sight defined by the path of the chief ray in object space joining the point of regard (i.e., the fixation point) with the center of the eye's entrance pupil. More generally, the chief ray for any point in visual space defines a line-of-sight along which an aberration function may be specified.

Wavefront aberration functions, or maps, have a variety of physical, mathematical, and practical interpretations and uses. Physically, the map describes the optical distance from an object point to the corresponding retinal image point through different parts of the pupil, relative to the optical distance along a path through the center of the pupil (i.e., along the chief ray). An equivalent interpretation, illustrated in Fig. 2, is the sag (relative to an ideal plane-wave) in the z -direction of a wavefront reflected from the eye produced by a point source on the retina. These differential errors in optical path length cause phase errors in light arriving at the image point, which in turn degrades image quality. Mathematically, the aberration map $W(\rho, \theta)$ is the phase portion of the generalized pupil function $P(\rho, \theta)$ defined in optical theory as

$$P(\rho, \theta) = A(\rho, \theta) \exp(-ikW(\rho, \theta)) \quad (12)$$

where $A(\rho, \theta)$ is the corresponding amplitude function and $k=2\pi/\lambda$. The generalized pupil function is a fundamental description of an optical system that enables calculation of the optical point spread function (PSF) and optical transfer function (OTF) (Goodman, 2005), both of which are functional measures of optical quality. Scalar metrics of image quality computed from the PSF or OTF are useful in practical optimization problems, such as determining refractive state or prescribing lenses to correct the eye's aberrations.

Aberrometry and Wavefront Sensing

Wavefront sensors, the core technology used in ocular aberrometers, are both new and old. In the clinical literature, the first applications of aberrometry to refractive surgery (Applegate and Howland, 1997) and to ocular disease (Thibos and Hong, 1999) appeared near the end of the 20th century years. However, the fundamental principle by which modern aberrometers measure ocular wave-front aberrations of eye was discovered 400 years ago by the celebrated Jesuit philosopher-astronomer, Christopher Scheiner (Scheiner, 1619), a contemporary of Galileo and Kepler. All three astronomers conceived of the eye as an optical instrument that forms retinal images in the same way that a telescope forms images. However, it was Scheiner who first demonstrated how to measure the refractive error of the human eye using a simple device that is known today as Scheiner's disk. Although Scheiner used his invention to measure and study only spherical refractive error (i.e., defocus, which is the simplest and most prevalent of all ocular aberrations), the basic idea was generalized by Thomas Young at the beginning of the 19th century to measure astigmatism in his own eye (Young, 1801), and eventually by Liang *et al.* at the end of the 20th century to measure higher-order aberrations (Liang *et al.*, 1994). Thus, Scheiner's disk is the prototype of the modern Shack-Hartman wavefront sensor for measuring ocular aberrations.

Determining Optical Path Lengths From Ray Deflections

The challenge of using a Shack-Hartmann sensor with a living eye is that the eye is a closed system, so it can be measured only by reflecting light off the patient's retina as illustrated in Fig. 3. Thus, for measurement purposes, object space is inside the eye and image space is the external world. To make measurements, a narrow laser beam is introduced into the eye using a beam-splitter to produce a source of reflected light, a so-called retinal beacon. Light reflected out of the eye passes through an array of small,

Fig. 3 Principle of operation of the Scheiner–Hartmann–Shack wavefront aberrometer. A laser beam injected into the eye produces a retinal beacon that reflects light out of the eye for measurement. Angular deviation of an isolated test ray relative to the direction of the reference ray is a measurement of local wavefront slope. In a practical instrument, multiple apertures defined by a micro-lenslet array produce simultaneous measurements at many points in the eye's pupil.

Fig. 4 Geometry for defining wavefront vergence. A pinhole aperture located distance r from the z -axis isolates a ray perpendicular to the wavefront and intersecting the z -axis at some distance Z from the aperture plane. Skew rays that do not intersect the chief ray are projected into the plane of the diagram to determine the radial component of vergence.

pinhole apertures (i.e., Scheiner's disk or a Hartmann screen) to isolated rays exiting through specific locations in the eye's pupil. The ray's direction of propagation relative to the chief ray is specified by (α, β) , the angles of deviation from a secondary reference ray (dashed line) parallel to the chief ray and passing through the aperture. In a modern device, the array of pinholes is replaced by an array of micro-lenslets that subdivides the beam of light reflected out of the eye from the retinal beacon. Each lenslet forms a spot image that deviates horizontally and vertically from the optical axis of the lenslet by an amount that is directly proportional to the angular deviations (α, β) . Since rays are, by definition, normal to the exiting wavefront, the sensor is essentially a mechanism for measuring wavefront slope, from which wavefront shape is recovered by integration.

Converting Ray Aberrations to Wavefront Aberrations

As described in Section Determining Optical Path Lengths From Ray Deflections, the principle of operation of the Shack–Hartman wavefront sensor used in ocular aberrometers is to measure the deviation of individual rays of light passing through various locations in the eye's pupil. From the geometry of Fig. 4 we see that, for small angles of deviation of the ray from the reference direction, angle τ and wavefront slope are approximately equal,

$$\text{wavefront slope} = \tan(\tau) \cong \tau = \text{deviation angle} \quad (13)$$

In general, the aberrated ray does not lie in the meridional plane defined by the optical axis of the system and a point on the wavefront located at the foot of the ray. However, if we project the ray onto the meridional plane of Fig. 4, then another useful relationship can be deduced from the geometry:

$$\frac{\text{wavefront slope}}{\text{location in pupil}} = \frac{\partial W(\rho, \theta) / \partial \rho}{\rho} = \frac{\tan(\tau)}{r} = \frac{1}{d} = \text{wavefront vergence} \quad (14)$$

This equation says that, for any meridian θ , the radial component of wavefront vergence (in diopters) is equal to the ratio of radial wavefront slope (in radians) to pupil location (in meters). So, although wavefront vergence is a vector quantity with

Fig. 5 Geometry for expressing the relationship between wavefront aberrations and the size of blurred images. The diagram depicts a cross-section of a reflected wavefront of light emerging from the eye produced by a point source on the retinal fovea. The plane of the diagram is perpendicular to the eye's entrance pupil and contains the foveal line of sight (i.e., the z-axis). An isolated ray passing through the pupil plane at distance r from the pupil center intersects the image screen at distance b from the z-axis and thus contributes one point to the blurred image. (For simplicity, we assume the ray is in the plane of the diagram but in general this is not necessarily true.) The angular size (in radians, subtended at the pupil center) of this blurred point is approximately equal to the focusing error E (in diopters) of the aberrated ray (which depends on the axial location of the image screen) and radial distance r (in meters).

orthogonal components proportional to (α, β) , the radial component is a scalar quantity that may be used to recover wavefront phase by integration (Nam *et al.*, 2009).

A similar geometrical analysis reveals the relationship between wavefront aberrations and the size of blurred images. Although we are ultimately interested in blurring of the retinal image, aberration measurements are performed on the reflected wavefront emerging from the eye as illustrated in Fig. 5. Consider an image screen that is placed some small distance Δ from the focused plane where an isolated ray intersects the chief ray (i.e., the z-axis). This focusing error causes the image point contributed by the illustrated ray to be displaced by amount b from the image point O contributed by the chief ray. In other branches of optics, this linear displacement in the image plane is of primary concern. However, in vision science we are typically interested more in the angle β subtended by b at the pupil center. If we assume the pupil is near the eye's nodal point then the angles of blur subtended in image and object space are the same. The extent of this angular blur is easily computed if we express ray aberrations as a vergence error in diopters. That is, let the vergence of the image screen be $1/(d + \Delta)$ and the vergence of the ray in this example be $1/d$, so the vergence error E is

$$E = \frac{1}{d + \Delta} - \frac{1}{d} = -\frac{\Delta}{d^2 + d\Delta} \cong -\frac{\Delta}{d^2} \quad \text{for } \Delta \ll d \quad (15)$$

The negative sign in this result means a negative correcting lens would be required to focus this aberrant ray. A negative sign also means the ray crosses the optical axis before striking the image surface.

From the geometry of similar triangles in Fig. 5, $\Delta/d = b/r$ and for small values of defocus, $\beta \cong b/d$. Substituting these two relationships into Eq. (15) reveals that the angular subtense β of the blurred image point (in rad) produced by the aberrated ray is the product of focusing error E (in diopters) and radial position r of the ray in the pupil plane (in meters),

$$E = -\frac{b}{rd}, \quad -Er = \frac{b}{d} \cong \beta \quad (16)$$

The minus sign in Eq. (16) indicates that the ray intersected the chief ray before arriving on the opposite side of the image screen in this example. Although the derivation described the deviated ray as a focusing error for simplicity, Eq. (16) applies even when higher-order aberrations are present if E is computed from wavefront vergence as defined by Eq. (14).

The three fundamental concepts of wavefront phase, wavefront slope, and wavefront curvature can each be used to assess optical quality of the eye and determine the optimum sphero-cylindrical correcting lens as described in Section Optimizing Retinal Image Quality by Correcting Refractive Errors. These properties of a wavefront are linked together by geometry and calculus in a manner directly analogous to distance, velocity, and acceleration. Slope is the spatial derivative of wavefront phase and curvature is the spatial derivative of slope. Conversely, slope is the integral of curvature and phase is the integral of slope. Thus, measurements of wavefront slope provided by a wavefront sensor may be mathematically integrated to retrieve the shape of the aberrated wavefront. Just as distance, velocity, and acceleration each have different physical units, wavefront phase, slope, and curvature have different units. Wavefront phase is measured in microns, which is perhaps more easily interpreted if normalized by the wavelength of light to yield waves of phase shift. Wavefront slope is specified in micrometer per millimeter, which is the same as milliradians (1 mrad = 3.438 arcmin) and wavefront curvature is specified in micrometer per square millimeter which is the same as inverse meters or diopters.

An important practical application of Eq. (14) is to derive a formula for paraxial refractive error that takes into account the fact that 2nd order Zernike modes are included in higher-order modes for the purpose of building an orthogonal set of basis functions with minimum variance. Thus to determine paraxial refractive errors, it is necessary to apply Eq. (14) to the Zernike expansion given by Eq. (11) and evaluate the result at the pupil center. Since all terms in ρ^n with $n > 2$ have zero slope when $\rho = 0$, they make no contribution to paraxial wavefront vergence according to Eq. (14). For a 6th order Zernike expansion, the resulting formula for paraxial refractive error reduces to

$$\begin{aligned} M &= \frac{-c_2^0 4\sqrt{3} + c_4^0 12\sqrt{5} - c_6^0 24\sqrt{7}}{r^2} \\ J_0 &= \frac{-c_2^2 2\sqrt{6} + c_4^2 6\sqrt{10} - c_6^2 12\sqrt{14}}{r^2} \\ J_{45} &= \frac{-c_2^{-2} 2\sqrt{6} + c_4^{-2} 6\sqrt{10} - c_6^{-2} 12\sqrt{14}}{r^2} \end{aligned} \quad (17)$$

Optimizing Retinal Image Quality by Correcting Refractive Errors

The ultimate decision of whether a retinal image is optimally focused by a sphero-cylindrical correcting lens is complicated by the presence of higher-order aberrations and by how the question is framed. If the decision is an esthetic judgment, the observer's subjective criterion for making the decision may be unknown or difficult to articulate. If the decision is based on performance of an objective task, then optimum focus may depend on the nature of the task (e.g., reading printed text versus detecting a target) or on stimulus parameters (e.g., size, velocity, intensity, etc.). Experiments on human observers have shown that, for the task of reading small letters, refractive corrections based on Eq. (6) tend to leave the eye slightly myopic whereas corrections based on Eq. (17) tend to leave the eye slightly hyperopic (Martin *et al.*, 2011). The optimum correction lies between these limits, suggesting that optimization of some metric of retinal image is a better way to compute refractive error from wavefront aberration measurements. Numerous metrics have been evaluated for this purpose, several of which provide unbiased measures of optimum focus. One widely used unbiased metric called the visual Strehl ratio is analogous to the common Strehl ratio but is determined for a neutrally weighted optical PSF obtained by convolving the optical PSF with a neural weighting function that represents the spatial filtering properties of the visual system.

Introduction

For centuries humans have been inventing technologies to correct the eye's optical aberrations. As our understanding of the eye's optical defects has evolved, so too has the complexity of correction methods. But despite technological advances, from the medieval looking-stone to the modern-day femtosecond laser, aberration-free vision remains out of reach for most of the population.

Two primary approaches to correcting the eye's refractive error are wide-spread:

1. Introducing corrective lenses in front of the eye (e.g., spectacles or contact lenses).
2. Altering the eye's optical properties by modifying the cornea (e.g., refractive surgery) or replacing the crystalline lens with an intraocular lens.

In this article, we will review both approaches to correcting the eye's optical aberrations to improve visual performance. Finally, we consider promising future approaches to vision correction.

Background

Spectacles

The inventor of spectacles is unknown, however, it is thought that spectacles were invented in the late 1200s (Dreyfus, 1988). The earliest known depiction of spectacles in a painted work of art is the portrait of Cardinal Hugo of Providence, painted by Tommaso de Modena in 1352 (Fig. 1).

Spectacle technology has advanced in terms of lightweight optical materials and anti-reflection coatings, but their main function of correcting the eye's lower order aberrations (sphere and cylinder) has remained relatively unchanged.

Fig. 2 illustrates a myopic (i.e., near-sighted) eye before and after correction with a spectacle lens. In the case of myopia, the eye has excess refractive power (sphere), resulting in a focus in front of the retina (Fig. 2(a)) for light coming from infinity (i.e., a collimated beam). Therefore, the required corrective lens has negative defocus, which pushes the focus posteriorly towards the retina (Fig. 2(b)).

Despite the efficacy and convenience of spectacles, their limitations for certain optical corrections are significant. For example, as the eye's directional gaze changes, a different area of the spectacle is used. This is akin to a decentration, or misalignment of the correction-lens' wavefront from the eye's wavefront. This is not an issue for conventional lenses that only correct lower order aberrations, however it does prevent efficacious higher-order aberration correction in spectacles.

Contact lenses

While the initial ideas behind contact lenses can be traced back to the 16th century to Leonardo da Vinci, it was not until 1888 that a German ophthalmologist, Adolf Fick, successfully fit the first contact lens. Fick used glass blowing to create lenses which rested on the sclera of the eye and neutralized the refractive power of the cornea by filling the space between with dextrose. The solution, given its similarity in refractive index to the cornea, would minimize the power arising from the corneal front surface, otherwise exposed to air. Indeed, the same refractive index matching approach to alter the corneal power was proposed earlier by Leonardo da Vinci, and later used by Thomas Young to confirm the presence of astigmatism in the cornea (Fig. 3).

Since their inception, contact lenses have taken different forms varying in their size, material properties, oxygen permeability and optical characteristics. Their growth is marked by two key inventions. First, the development of polymethyl methacrylate (PMMA) made lenses lighter and smaller than those made from glass, leading to contacts which could be worn on the cornea as opposed to earlier glass sclerals. These plastic polymers were later refined to allow for better oxygen permeability and led to a class of lenses which are now more commonly called rigid gas permeable (RGP) contact lenses. The second revolutionary advance came with the development of soft hydrogel materials (Wichterle and Lim, 1960) which substantially increased the wear time of contacts by improving oxygen permeability and led to the conventional "soft" contact lenses. While the permeability characteristics of such hydrogels were advanced following their invention, a major breakthrough came about from the development of silicone hydrogels in the 1990s that allowed for extremely high oxygen permeability leading to extended wear times and wearing comfort. Note however that all the aforementioned types and materials (except for glass) of contacts are still in use today for varying degree of abnormalities in the cornea and the ocular surface. In addition to optical correction discussed below, some applications of contact lenses pertain to non-refractive cases also. Scleral lenses ranging in diameter from 13 to 24

Fig. 1 Earliest depiction of spectacles in art: Cardinal Hugo of Providence. Painted by Tommaso de Modena, 1352.

Fig. 2 Schematic of an (a) un-corrected and (b) corrected myopic eye with a negative diopter spectacle lens.

mm rest on the sclera of the eye and create a reservoir tear layer between the cornea and the lens. By virtue of being placed on the sclera and not the sensitive corneal tissue, these lenses are often used to provide relief in patients with corneal disease or following injury- for instance in extreme cases of dry eye, corneal ectasia, post-LASIK or corneal transplant complications, Stevens-Johnson syndrome and Sjogren's syndrome. A similar protective role for the cornea is met by bandage soft contact lenses as well.

Contact lenses provide a unique vehicle for delivering optical corrections to the eye – both for conventional refraction (sphere and cylinder) and for those corneas affected by higher order aberrations beyond sphero-cylindrical errors. The advantage of contacts in providing optical correction arises mainly because the lenses sit in close axial proximity to the eye's optical and physical pupil leading to two key desirable features. First, when the eyeball moves, the contacts move in unison, thereby continuously providing the requisite optical correction despite large changes in gaze. Second, the accessible field of view remains large and consistent across a variety of viewing conditions. Conversely, spectacles, by virtue of being stationary, do not align the eye's optical axis when the gaze changes. Furthermore, by being displaced axially from the eye's pupil, the isoplanatic patch (the field of view over which the aberrations remain relatively constant) shrinks and leads to a smaller effective field of view when using spectacles.

Fig. 3 Thomas Young's illustration of neutralizing the cornea by refractive index matching by applying a lens with water reservoir. Reproduced figure from 1801 publication.

These two factors are less critical for conventional sphero-cylindrical corrections however pose a significant challenge for compensating large magnitudes of asymmetric optical aberrations.

The overall principle of a contact lens in providing refractive error correction is similar to that of spectacles, albeit with a few key differences. Similar to a spectacle prescription, a positive/negative powered lens is used to correct for hyperopia/myopia, while unequal spherical powers across the horizontal and vertical meridians are used to correct for cylinder. However, the magnitude of refraction needs to accommodate for the different axial locations of the spectacle and contact lens corrections. In a clinical setting, prescriptions are sought using trial lenses placed at the spectacle plane. To convert the spectacle prescription to contact lens power at the cornea, the following equation is used, where K : refraction at the corneal/contact lens plane, F : refraction at the spectacle plane, d : vertex distance or the distance between the spectacle and the corneal plane (typically 12–13 mm).

$$K = \frac{F}{1 - dF}$$

In addition to the optical considerations, contacts are designed to accommodate for the physiological demand of supporting metabolism in the cornea via replenishing the supply of the tear film. The physical characteristics (curvature, diameter, edge profile, thickness) are thus optimized for the lens to move with every blink and realign with the visual axis afterwards. The alignment is less critical for pure spherical error correction compared to cylindrical and higher order aberration. This is because spherically asymmetric errors are not corrected optimally when the optical axes of the eye and the corrective optics are not co-aligned. Common strategies to align the lens include prism-ballast or double slab-off wherein different thickness profiles across the surface of the lens help in its optimum interaction with the eyelids and stabilizing it post-blink (Holden, 1975).

The efforts to compensate for higher order aberrations using ophthalmic lenses received a major boost mainly due to the advent of wavefront sensing techniques (Liang *et al.*, 1994). Using these advanced techniques, the corneal abnormality of keratoconus (KC) and its optical consequences have been evaluated (Pantanelli *et al.*, 2007; Maeda *et al.*, 2002). Given the large magnitude of higher order aberrations found in KC, it was immediately appreciated that these patients stand to benefit greatly from an optical correction aimed at minimizing these aberrations.

Soft contact lenses with wavefront-guided surface profiles have been shown to have potential in correcting HOA and improving vision in KC (López-Gil *et al.*, 2003; Sabesan *et al.*, 2007; Marsack *et al.*, 2008). In such a scheme of correction in two eyes with KC shown by López-Gil *et al.*, the lens was designed according to the aberration profile of the eye, but the reduction in higher order aberration and improvement in vision were relatively small (López-Gil *et al.*, 2003). One possible explanation for the small average reduction in higher order aberration could be the failure to account for the decentration and rotation of the contact lens on the eye. Static and dynamic contact lens movements critically affect correction performance of HOA, as the lens is not aligned to the center of the visual axis, especially in eyes with abnormal corneal surface profiles (Navarro *et al.*, 2000; Guirao *et al.*, 2001). Sabesan *et al.* demonstrated a scheme of correction in KC using soft contact lenses where the lens was designed by accounting for both the eye's aberration profile and the static lens decentration and rotation on eye (Sablesan *et al.*, 2007). Using these wavefront-guided customized soft contact lenses, an improvement in optical quality by a factor of 3 in HOA with respect to the conventional lens on average in 3 KC patients was demonstrated. The improved optics resulted in an average improvement of 2.1 lines in visual acuity over the conventional correction of defocus and astigmatism alone. However, the residual higher order wavefront error was still nearly double of what is observed in normal eyes. This residual error was explained to a reasonable extent by the manufacturing error and lens movement. To reduce the variability of lens position by conferring mechanical stability between blinks, Chen *et al.* (2007) employed back surface customized soft contact lenses whose posterior surface profiles were sculpted to match

Fig. 4 Different contact lens strategies to overcome corneal higher order aberrations in highly aberrated eyes, such as keratoconus.

the anterior corneal surface in KC. On-eye performance of the back surface customized soft contact lens demonstrated that the lens stability was improved by a factor of 2 for horizontal and vertical decentration, and a factor of 5 in rotational orientation over conventional lens. However, significant residual HOA induced by internal optics, especially posterior corneal surface still degraded retinal image quality. Additional customization of the front surface of the lens thus has the potential to further correct these residual aberrations.

Clinically, RGPs and scleral lenses are considered the standard of correction in KC. These lenses achieve correction by masking corneal irregularities with the tear lens between the posterior lens surface and the anterior corneal surface, in the same manner as the first attempts of fitting contacts. RGP corneal contact lenses are 8.5–10.5 mm in diameter and cover only 75–80% of the cornea. Mini-scleral, corneo-scleral and scleral lenses which range in diameter from 13–24 mm, depending on type or fit, may rest partly on the cornea. A scleral lens prosthetic device (SLPD) with diameters ranging from 17.5–24 mm is designed and fit to vault the cornea entirely. A noteworthy difference between RGP corneal lens and SLPD is the dynamic movement of these corrective devices on the eye. A well-fitted corneal RGP lens slides with each blink to allow for tear exchange necessary for physiological tolerance at the corneal surfaces where contact is made. Optical correction in an RGP corneal lens is thus inherently unstable. A carefully fitted SLPD is expected to exhibit minimal movement because the bearing haptic aligns with a large area of conjunctiva overlying the sclera. Suction is avoided by precise alignment with the sclera or by creation of channels on the posterior surface (Rosenthal, 2009, 2010). The clinical benefits of an SLPD in terms of improvement in visual acuity and visual function across a wide range of diagnoses including KC have been established (Stason *et al.*, 2010). By virtue of their larger diameter and broader bearing zone, these devices have been employed in the treatment of various other forms of corneal ectasia, corneal irregularity following transplant, ulcers, dry eye syndrome, ocular surface disease and others (Pullum *et al.*, 2005; Segal *et al.*, 2003). Reduction of HOA has been reported in normal and KC eyes with corneal RGP lens (Hong and Himebaugh, 2001; Dorronsoro *et al.*, 2003; Marsack *et al.*, 2007; Negishi *et al.*, 2007) and SLPD (Gumus *et al.*, 2011). However, since these lenses minimize only anterior corneal aberrations, significant posterior corneal aberrations remain uncompensated (Chen and Yoon, 2008). In addition, aberrations such as coma and astigmatism are induced due to RGP corneal lens rotation and decentration, further degrading retinal image quality. The positional stability between blinks due to the large surface coverage in SLPD makes it an ideal platform for wavefront-guided correction of HOA in KC. Sabesan *et al.* demonstrated significant reduction in root-mean-square of HOA and improvement in vision in 11 advanced KC eyes wearing wavefront-guided SLPD (Sabesan *et al.*, 2007). HOA were effectively corrected by the customized SLPD with wavefront-guided optics and RMS was reduced 3.1 times on average to $0.37 \pm 0.19 \mu\text{m}$ for a 6 mm pupil, comparable to normal levels. This correction resulted in significant improvement of 1.9 lines in mean visual acuity ($P < 0.05$). Contrast sensitivity was also significantly improved by a factor of 2.4, 1.8 and 1.4 on average for 4, 8 and 12 cycles/degree, respectively ($P < 0.05$ for all frequencies). Interestingly, although the residual aberration was comparable to that of normal eyes, the average visual acuity in logMAR with the customized SLPD was 0.21, substantially worse than normal acuity. This implicates the role of chronic exposure to poor retinal image quality that may restrict the visual benefit achievable immediately after wavefront-guided customized treatment in these eyes (Fig. 4).

Visual Benefit of Correcting Higher Order Aberrations

The amount of benefit to be gained from correcting the eye's higher order aberrations depends on subjects' native wavefront profiles and pupil size. However, the visual benefit has been shown to be significant for various visual tasks (e.g., visual acuity, contrast sensitivity), especially in low light levels where pupils are large or in ocular pathologies such as KC. Higher order aberration correction in the human eye has been demonstrated with several methods, such as soft contact lenses (Chen *et al.*, 2007; Sabesan *et al.*, 2007), scleral lenses (Sabesan *et al.*, 2013; Marsack *et al.*, 2014), phase plates (Yoon *et al.*, 2004; Allen and Raasch, 2005) and adaptive optics (Yoon and Williams, 2002; Legras and Rouger, 2008; Rossi *et al.*, 2007; Sabesan *et al.*, 2007, 2012). However, the degree of visual benefit can vary widely depending on the individual subjects.

In a seminal population study ($n=109$ eyes) by Williams *et al.* (2000), it was found that contrast sensitivity was expected to improve by a factor between 1 (no improvement) and 8 times (16 cyc/deg, 5.7 mm pupil) after higher order aberration correction. The variability in visual benefit indicates that some subjects are more suited for higher order aberration correction than others. Patients with large amounts of higher order aberrations or abnormal eyes (e.g., KC, high spherical aberration post-laser refractive surgery) would clearly stand to benefit from higher order aberration correction. However, aside from the magnitude of aberrations, other factors such as subjects' native pupil size should also be considered. As pointed out by Williams *et al.*, visual benefit is minimal in bright light conditions (i.e., when the pupil is small) or in the presence of focusing error, which is commonplace due to accommodative lag (Williams *et al.*, 2000).

Furthermore, the vast majority of studies on the impact of higher order aberration correction have been monocular. Using a binocular adaptive optics vision simulator, Sabesan *et al.* (2012) showed that binocular summation decreased when subjects' native higher order aberrations were corrected. Therefore, monocular estimates of visual benefit tend to overestimate in the case of binocular correction.

While individual higher order aberrations vary randomly from patient to patient, the exception is primary spherical aberration (Porter *et al.*, 2001; Thibos *et al.*, 2002), the correction of which has been shown to lead to significant improvements in both visual acuity and contrast sensitivity (Sabesan *et al.*, 2012; Piers *et al.*, 2004, 2007; Schwarz *et al.*, 2014). The primary source of the eye's spherical aberration is the cornea (Artal *et al.*, 2002), and thus intraocular lenses have been a natural platform for its correction (Holladay *et al.*, 2002; Muñoz *et al.*, 2006). However, it is important to note that depth of focus suffers with the correction of spherical aberration (Piers *et al.*, 2004). This is particularly important in regard to intraocular lenses, as cataract surgery leaves patients unable to accommodate.

Chromatic Aberration

Longitudinal chromatic aberration of the human eye is approximately 2 diopters across the visible spectrum (Thibos *et al.*, 1992; Atchison and Smith, 2005). Due to the dispersion of ocular media (i.e., positive Abbe number), the longer wavelengths are relatively hyperopic compared to shorter wavelengths. Because this is caused by the inherent material properties of the eye's anatomy, chromatic aberration is more consistent across the population relative to the monochromatic aberrations (e.g., sphere, cylinder and higher order aberrations). With advances in diffractive intraocular lens technology, there has been a renewed interest in correcting ocular chromatic aberration (Schwarz *et al.*, 2014; López-Gil and Montés-Micó, 2007; Artal *et al.*, 2010). However, as discussed by López-Gil and Bradley, the clinical benefit of correcting spherical and chromatic aberrations may be modest (López-Gil and Bradley, 2012), especially under photopic conditions. In addition, misaligned intraocular lenses providing spherical and chromatic aberration correction lead to unwanted aberrations, such as transverse chromatic aberration, coma and astigmatism (López-Gil and Montés-Micó, 2007; Cheng *et al.*, 2010).

Presbyopia

Past the age of approximately 40 years, even emmetropic eyes require vision aids. As the eye ages, it loses its ability to accommodate (i.e., change focus from far to near objects) due to lifelong crystalline lens growth and loss of elasticity. The age-related loss of accommodation is known as *presbyopia*. As first measured by Donders in 1864 (Donders and Moore, 1864) and later by Duane in 1912 (Duane, 1912), the eye's amplitude of accommodation suffers a steady decline, starting in childhood until a plateau is reached at approximately 50 years (Fig. 5).

Evidence of visual aids can be traced to magnifying lenses known as "reading stones" developed in the 9th century, CE. The English friar Roger Bacon wrote in 1250 CE of such devices to correct for his presbyopia:

"It may be observed that old people hold objects they wish to examine further from the eye. ...If anyone examines letters or other minute objects through the medium of crystal or glass or other transparent substance, if it be shaped like the lesser segment of a sphere, with the convex side being towards the eye, and the eye being in the air, he will see the letters far better, and they will seem larger to him. ...For this reason, such an instrument is useful to old persons..." (James, 1928).

Until the 18th century invention of Benjamin Franklin's bifocal spectacles, little progress was made for correcting presbyopia. However, the last several decades have experienced a tremendous increase in research and development devoted to presbyopia correction. As a result, there are currently a wide variety of strategies available, which are outlined in Table 1.

The field of presbyopia correction can be segmented into two categories: (1) the restoration of the eye's ability to accommodate, i.e., change focal length and (2) increase the eye's depth of focus.

Restoring Accommodation

The majority of accommodation restoration techniques have focused on using eye's lens as the engine for dynamic optical power change. For example, pharmacological agents (Renna *et al.*, 2016; Crawford *et al.*, 2014) and femtosecond laser induced micro-incisions (Holzer *et al.*, 2009; Ripken *et al.*, 2008) are currently in development for restoring elasticity to the presbyopic crystalline lens.

Fig. 5 Amplitude of accommodation as a function of age. Average and upper and lower limits are indicated by black line and grey area, respectively. Figure adapted from Duane, A., 1912. Normal values of the accommodation at all ages. *Journal of the American Medical Association* 59 (12), 1010–1013.

Table 1 Methods for correcting presbyopia

	<i>Method</i> <i>Spectacles</i>	<i>Description</i> <i>Reading glasses</i> <i>Bifocals, trifocals, progressives</i>	<i>Mechanism</i> <i>Single vision</i> <i>Change of gaze</i>
Restoring Dynamic Accommodation (<i>pseudophakic accommodation</i>)	Intraocular Lenses	Accommodating IOL	Positional and shape changes induced by ciliary body
Extending Depth of Focus (<i>pseudoaccommodation</i>)	Contact Lenses	Bifocal, multifocal	Wavefront aberrations
	Corneal Surgery	Tissue removal: LASIK, PRK	Wavefront aberrations
		Implantable refractive corneal inlay	Wavefront aberrations
		Implantable small-aperture inlay	Pinhole effect
	Intraocular Lenses	Multifocal IOL	Wavefront aberrations and/or diffraction
	Monovision	Dominant eye corrected for distance, non-dominant eye corrected for near	Binocular combination of two eyes' retinal images

Otherwise, novel accommodating intraocular lens (IOL) designs have been proposed to restore accommodation (Pepose *et al.*, 2017). Such lenses are designed to change surface curvature or shift axially within the eye during accommodative effort. One such curvature-change design is the Powervision (Belmont, CA) FluidVision IOL, which is comprised of a hollow lens and liquid-filled reservoir haptics. When the eye is in its relaxed state, the liquid resides within the haptics and the lens rests in a relatively flat shape, defining the geometry for viewing distant objects. As the eye exerts accommodative effort, the ciliary muscle contracts, decreasing the equatorial diameter of the capsular bag. This forces the fluid from the haptic reservoir into the central lens cavity, increasing its curvature and optical power, thereby providing near vision (Sheppard *et al.*, 2010).

Alternatively, accommodating IOLs may function on axial displacement, such as the Crystalens (Bausch and Lomb, Rochester, NY). The Crystalens is a single-optic IOL mounted on hinged haptics, allowing the lens to vault anteriorly during accommodative effort, as illustrated in Fig. 6. However, in a theoretical analysis by Hunter *et al.*, it was shown that a 1 mm axial shift of a 20D IOL induces a 1.2D optical change. Therefore, single-optic accommodating IOLs must travel an excessive distance through the anterior chamber to provide a meaningful optical change for presbyopia correction.

Several investigators (Koepl *et al.*, 2005; Marcos *et al.*, 2014; Zheleznyak, 2014) have assessed accommodative IOL movement by measuring changes in anterior chamber depth during accommodative effort. They have found that on average, the single-optic accommodating IOL (Crystalens, Bausch + Lomb) undergoes a posterior shift during accommodative effort by approximately 0.15 mm. Similarly, studies measuring changes in wavefront aberrations during accommodative effort show inconsistent changes in defocus, and in some cases, an incorrect change in the eye's power (Zheleznyak, 2014; Pérez-Merino *et al.*, 2014).

To overcome this limitation, dual-optic IOL designs have been proposed (e.g., Synchrony IOL, Abbott Medical Optics, Santa Clara, CA). In comparison to single-optic designs, the dual-optic accommodating IOL achieves approximately 2.2D increase in power with a 1 mm shift of the anterior lens (McLeod *et al.*, 2007). However, the expected benefit of the dual-optic design over the

Fig. 6 (a) Single-optic accommodating intraocular lens (Crystalens, Bausch + Lomb, Rochester, NY). Illustration of the intended axial movement of a single-optic accommodating IOL in the (b) unaccommodated and (c) accommodated states of the pseudophakic eye.

single-optic accommodating IOL has not been reflected clinically (Alió *et al.*, 2012) and may be due to capsular bag fibrosis limiting IOL movement (Koepl *et al.*, 2005).

Extending the Eye's Depth of Focus

In the absence of true accommodation restoration, extending the eye's depth of focus has been a common path taken by clinicians to alleviate the symptoms of presbyopia. This can be achieved by reducing pupil size or introducing multifocality to the wavefront aberrations via aspheric refractive surfaces, diffractive optical elements, or both.

The Pinhole Effect

Reducing the pupil size of the eye is the easiest way to lessen the impact of presbyopic blur. For example, eyelid squinting is a common means of truncating the pupil, albeit only vertically, to improve acuity in the presence of refractive error (Sheedy *et al.*, 2003). Pupil size also effects aberration-free image quality at OD of defocus. The cutoff frequency of the modulation transfer function (MTF) is linearly dependent upon the pupil size, as shown below.

$$f_{\text{cutoff}} = \frac{d}{\lambda}$$

Where f_{cutoff} , r and λ represent cutoff frequency (in cycles/radian), pupil diameter and wavelength, respectively. Therefore, as pupil size decreases, so does the cutoff frequency of the MTF and the spatial bandwidth of the image, thereby degrading distance image quality. Therefore, decreasing pupil size for extended depth of focus is a trade-off with distance optical quality. This concept is illustrated below in Fig. 7.

Extended depth of focus via small pupils has been implemented with pinhole corneal inlay (KAMRA, AcuFocus, Irvine, CA). The inlay is implanted within the corneal stroma and has a 1.6 mm inner diameter. Although significant improvements in near vision have been demonstrated (Yilmaz *et al.*, 2011), it may only be implanted monocularly (typically the non-dominant eye), due to the reduction in retinal illuminance.

Multifocal Wavefront Aberrations

In contrast with the pinhole effect, manipulating the wavefront aberrations is a means of extending depth of focus without reducing retinal image brightness. However, wavefront multifocality is also accompanied by the trade-off with distance optical quality. As shown in Fig. 8(a), monofocal wavefronts result in all rays across the pupil converging to a single point, or a single focus. An example of a refractive bifocal with a central add power for near vision is illustrated in Fig. 8(b). In this case, when the blue ray bundle is in focus on the retina, the red ray bundle is out of focus. Thus, the out of focus (red) ray bundle degrades retinal image quality and is commonly referred to as halo or glare. An example of a continuous distribution of refractive powers across the pupil is spherical aberration (Fig. 8(c)). Although spherical aberration is known to increase depth of focus, efforts of mitigating negative side-effects (e.g., degraded distance vision) have included incorporating higher order spherical aberrations (Yi *et al.*, 2011; Benard *et al.*, 2011) and pupil amplitude apodization (Zheleznyak *et al.*, 2014).

A novel concept in multifocal wavefront design segmenting the wavefront angularly into zones of refractive power, also known as a light-sword wavefront (Petelczyc *et al.*, 2009, 2011; de Gracia *et al.*, 2013; Mira-Agudelo *et al.*, 2016). A benefit of this technique is that the relative energy allocated to far and near vision is unaffected by pupil size. Recent theoretical (Petelczyc *et al.*, 2011; de Gracia *et al.*, 2013) and psychophysical (Mira-Agudelo *et al.*, 2016) studies have shown that angular multifocal designs have promise in offering superior through-focus image quality over traditional radial designs (e.g., Fig. 8(b)).

Fig. 7 (a) Schematic eye with ray bundle from a distant object for large and small pupils. Through-focus blur circles are shown for comparison. (b) Through-focus point spread functions with 6, 4 and 2 mm pupil diameters. (c) Through-focus normalized retinal image quality in monochromatic light (550 nm) of an aberration-free eye with various pupil sizes.

In addition to refractive multifocal wavefronts, diffractive multifocals also offer a means of increasing the eye's depth of focus. Typically implemented in intraocular lenses, diffractive multifocals consist of a radially symmetric diffractive structure which separates the light into several orders of diffraction. The phase height (in multiples of the design wavelength, λ) determines the diffraction efficiency, or the amount of energy allocated to far or near image quality. Three diffractive multifocals with various phase heights exhibiting (a) an emphasis on far vision, (b) equal energy to both far and near vision or (c) an emphasis on near vision are shown in Fig. 9. Diffraction efficiency may also be modified by means of apodizing the phase height as a function of pupil radius, as in the case of the ReSTOR (Alcon) apodized multifocal intraocular lens (Davison and Simpson, 2006). Recent advances in diffractive multifocal design have also resulted in trifocal intraocular lenses aimed at improving vision for intermediate object distances (Gatinel *et al.*, 2011).

Fig. 8 Wavefront aberration maps and ray diagrams of (a) monofocal, (b) refractive bifocal and (c) spherical aberration wavefronts.

Fig. 9 Diffractive multifocal wavefronts and their associated through-focus image quality are shown for designs with (a) an emphasis on far vision, (b) equal energy to both far and near vision or (c) and emphasis on near vision.

Through-focus image quality (in-vitro) of a monofocal and various multifocal IOLs is shown in [Fig. 10](#). In this case, retinal image quality is defined as the fidelity of a resolution target, which has been shown to correlate well with clinically measured visual acuity in pseudophakic patients ([Plaza-Puche et al., 2015](#)). Optical bench metrology of IOLs is critical to understanding their optical performance. Alternatively, while Shack–Hartmann wavefront sensing measure the wavefront, it does not typically quantify

Fig. 10 Through-focus retinal image quality of a monofocal and various diffractive multifocal IOLs. Adapted from Zheleznyak, L., Kim, M.J., MacRae, S., Yoon, G., 2012. Impact of corneal aberrations on through-focus image quality of presbyopia-correcting intraocular lenses using an adaptive optics bench system. *Journal of Cataract & Refractive Surgery* 38 (10), 1724–1733.

Fig. 11 (a) Through-focus monocular image quality for the dominant and non-dominant eyes in traditional monovision. The magnitude of anisometropia is defined as the dioptric difference in peak monocular image quality. (b) Through-focus interocular difference in monocular image quality.

scatter and its measurement may be confounded by diffractive multifocal designs. By observing a point-spread function or resolution target through a pseudophakic model eye, the eye's optics may be more fully understood. An important side note: optical bench tests are not conclusive in their representation of a patient's perception. A combination of optical and neural factors, such as the Stiles–Crawford effect (Applegate and Lakshminarayanan, 1993), retinal sampling (Hirsch and Curcio, 1989) and cortical processing inform a patient's perception of the visual world.

Binocular Approaches to Presbyopia Correction

Monovision is a paradigm of presbyopia correction which capitalizes on the binocularity of the visual system. In traditional monovision, the dominant eye is corrected for distance vision, whereas the fellow non-dominant eye is corrected for near vision by introducing positive defocus. To illustrate the impact of anisometropia on optical quality of the two eyes, through-focus monocular image quality in the presence of 1.5 diopters (D) of anisometropia is shown in Fig. 11(a). Typical amounts of anisometropia induced clinically in traditional monovision vary from 1D to 2D (Evans, 2007; Jain *et al.*, 1996; Johannsdottir and Stelmach, 2001).

Traditional monovision requires patients to suppress the image from the blurred eye and to rely solely on the eye with superior image quality for high acuity tasks. While this technique does improve presbyopic visual performance at near object distances, binocular visual functions such as binocular summation (Pardhan and Gilchrist, 1990; Legras *et al.*, 2001) and stereopsis (Lovasik and Szymkiw, 1985) are sacrificed. As shown in Fig. 11(b), anisometropia leads to a large difference in interocular image quality. In this example, the largest interocular difference occurred at distance (0D) and intermediate (1.5D) object distances.

To overcome the limitations of traditional monovision, it has been proposed to ease the large difference in interocular image quality by increasing each eye's depth of focus. This technique, also known as modified monovision, may be implemented with spherical aberration (Vandermeer *et al.*, 2015; Zheleznyak *et al.*, 2013, 2015), multifocal intraocular lenses (Ravikumar *et al.*, 2016) or by constricting the eye's entrance pupil diameter, as with a small-aperture corneal inlay (Fernández *et al.*, 2013).

Fig. 12 Illustrations of PRK, LASIK and SMILE laser refractive surgeries. The red segment in each figure indicates the ablation zone.

Refractive Surgery

In 1948, Jose I. Barraquer Moner introduced a surgical procedure to correct the eye's refractive error by sculpting the cornea's topography, a procedure he named *keratomileusis*. Almost 70 years later, laser vision correction is among the most widely performed elective surgical procedures worldwide (Reinstein *et al.*, 2012).

The premise behind refractive surgery is the reshaping of the cornea's topography to control the eye's wavefront aberrations. This can be achieved in a variety of ways, although currently there are three primary techniques: PRK, LASIK and SMILE (illustrated in Fig. 12).

In *photorefractive keratectomy*, or PRK, the cornea's epithelial layer is removed, exposing the underlying stroma. An excimer laser (193 nm wavelength) is subsequently used to ablate undesired tissue, resulting in a new thickness profile of stroma (Seiler *et al.*, 2000). The epithelial layer regrows on the newly sculpted stromal bed within a week of the procedure (Caldwell and Reilly, 2008; Lee *et al.*, 2005).

Alternatively, in *laser-assisted in situ keratomileusis*, or LASIK, the epithelial layer is not removed. Instead, to expose the stromal bed for laser sculpting, a flap is created in the cornea with a microkeratome blade, or more recently, with a femtosecond laser (~ 1040 nm wavelength). The flap is cut such that a section of tissue remains, serving as a hinge for the folding of the flap to expose the underlying stroma. After excimer laser ablation is complete on the stroma (similar to PRK), the flap is folded back into place.

The desire for less-invasive refractive surgery has ushered in a relatively new procedure known as *small incision lenticule extraction*, or SMILE, which avoids both epithelial removal or creating a flap. This is achieved via femtosecond laser used to remove a section of tissue (i.e., the *lenticule*) from within the cornea's stroma through a small incision outside the optical zone.

Due to the invasive nature of these procedures, which inherently sever collagen fibrils in the stromal bed, there may be unintended consequences, such as dry eye (due to nerve damage) and ectasia (due to biomechanical instability) (Randleman *et al.*, 2008).

A common patient complaint after refractive surgery is poor visual quality, especially under low light conditions (e.g., starburst, halos and glare during night driving) (Villa *et al.*, 2007; Hammond *et al.*, 2004). The root of most of these visual symptoms is the unintended induction of higher order aberrations that accompanies the correction of myopia and hyperopia with refractive surgery due to the cornea's biological response and ablation efficiency (Yoon *et al.*, 2005). For example, several studies have shown a significant correlation between the diopters of correction (i.e., myopia or hyperopia) and induction of spherical aberration (Yoon *et al.*, 2005; Marcos *et al.*, 2001), subsequently degrading contrast and visual quality. Decentration of the ablation zone has also been shown to induce unwanted optical aberrations (Mrochen *et al.*, 2001).

The Future of Vision Correction

To address the limitations of ablative refractive surgery, several less invasive procedures are under development, such as corneal collagen crosslinking and femtosecond laser induced refractive index correction.

Corneal collagen crosslinking is a technique in which ultra-violet radiation, when paired with doping agents such as riboflavin, cross-links the corneal collagen, thereby increasing the mechanical strength of the corneal tissue (Snibson, 2010). A challenge of this technique however is accurate doping of the cornea. Because the epithelial cell layer acts as a barrier, the most common application (e.g., the *Dresden protocol*) requires epithelial cell debridement (similar to PRK). While this procedure is invasive, the subsequent radiation is non-ablative and tissue-sparing. Corneal crosslinking is typically used for mechanically stabilizing the progression of keratoconus or ectasia, and research and development are underway to transition this method to refractive error (Kanellopoulos and Asimellis, 2014) and presbyopia (Kanellopoulos and Asimellis, 2015) correction by way of targeted ultra-violet radiation.

Another recent advance in non-invasive vision correction includes the use of femtosecond lasers to alter the refractive index of corneal stroma (Savage *et al.*, 2014; Ding *et al.*, 2008; Xu *et al.*, 2011; Wozniak *et al.*, 2017). This procedure does not require any epithelial cell layer debridement and is non-ablative and tissue-sparing. In this technique, a pulsed laser is focused into the cornea, triggering a multiphoton absorption process which results in a highly localized refractive index change, limited to a voxel of several micrometers. Due to the multiphoton nature of this process, the laser focus is scanned throughout the optical zone of the

treatment. The short pulse duration (~ 100 femtoseconds) and high repetition rate of laser pulses (MHz regime) allows for relatively little energy required to alter the cornea's refractive index, as compared to femtosecond lasers specifically designed for cutting tissue (e.g., flap cutting). By varying laser parameters such as pulse energy and scan speed, the magnitude of refractive index change is highly controlled during scanning. This approach has also been demonstrated in intraocular lens material (Sahler *et al.*, 2016), and contact lens material (Gandara-Montano *et al.*, 2015). In addition, visual performance has been demonstrated with phase plates modified by the laser induced refractive index correction technique (Zheleznyak *et al.*, 2017).

Summary

Methods of vision correction have come a long way, from medieval looking-stones to advances in modern technology, such as surgical implants and laser refractive surgery. Whether it is sphero/cylindrical error, or the more subtle higher order and chromatic aberrations, all eyes suffer from some degree of optical aberrations. Thus, the need for a robust, non-invasive means of providing clear vision persists. While many methods for correction exist, they are each limited in their efficacy for reasons detailed above. Therefore, advances in technology and our fundamental understanding of vision are critical to ushering in the future of vision correction.

The human eye is a complex transparent optical system that receives light in the electromagnetic spectrum. The key structures of the eye include the pupil, iris, lens, cornea, conjunctiva, sclera, conjunctiva, fovea, choroid, optic nerve, optic disc, ciliary body, macula and retina, the latter of which contain photoreceptors responsible for light perception and vision including color differentiation and the perception of depth. The eye can be divided into three layers: the outermost fibrous layer comprised of the cornea and sclera; the middle layer, which consists of the choroid, ciliary body, pigmented epithelium and the iris; and, the retina which represents the innermost layer. A transparent, watery fluid, called aqueous humour occupies the anterior and posterior chambers, i.e., between the cornea and the iris and between the iris and the lens, respectively, while vitreous humour, with a more jelly like consistency, fills the posterior cavity behind the lens. The ciliary body connects the iris to the choroid and is responsible for focusing the crystalline lens and secreting aqueous humour. The lens is attached to ciliary body by the Zonule of Zinn.

In order for the eye to operate correctly, each structure of the eye must function correctly. Given the complexity of the eye it is perhaps not surprising that it may be affected by numerous and systemic disorders, ranging from conjunctivitis and dry eye syndrome to age-related disease including macular degeneration and cataracts. Additionally, refractive disorders including hyperopia, myopia, astigmatism and presbyopia are thought to affect more than two billion of the world population; the World Health Authority estimates that 153 million people worldwide have uncorrected refractive errors, excluding presbyopia ([World Health Organization, 2009](#)).

Light and Laser Therapy

Lasers and light technologies have become important diagnostic and therapeutic tools in ophthalmology. They can be used for imaging the eye and can also be used to treat eye conditions, including glaucoma and retinal disease as well as refractive conditions involving the cornea and lens.

Laser and light treatments used in ophthalmology have photochemical, photothermal and photomechanical mechanisms. The Interactions of light with biological tissues depend on its wavelength, pulse duration and irradiance ([Fig. 1](#)). However, all are caused primarily by the interaction of photons with the molecules and the molecular compounds of the tissue.

Reducing the illumination time (micro- to millisecond range) and increasing the intensities the tissue temperature can be increased and thermal processes might occur. As temperature rises, the cellular and tissue structural proteins undergo denaturation and conformational changes a process defined as thermal coagulation. Increasing the temperature up to 100°C or more, may cause

Laser-tissue-interaction processes

Fig. 1 The interaction between laser and biological tissue.

vaporization of the liquid within the tissue. Further reduction of the illumination time might finally lead to an explosive tissue removal (photoablation).

Photochemical Interaction

The primary interaction mechanism between tissue and laser light are mainly depending on the wavelength, irradiation time (pulse duration) and the intensity or energy dose. For long irradiation times (seconds to minutes) and low intensities one can observe mainly photochemical processes. Photochemical interactions are the basis for cross linking of corneal collagen (CXL).

Therapeutic photochemical interactions are typically performed at low irradiances ($<1 \text{ W/cm}^2$) for long durations, i.e., tens of seconds, to avoid tissue heating. During photochemical interactions, a photon of a specific wavelength is absorbed by a photosensitizer which transforms the molecule (e.g., porphyrin, riboflavin) into the excited singlet state. The molecule decays back to the ground state, or it can be converted into the excited triplet state which in turn is able to transfer energy to a triplet ground state of oxygen. This energy transfer results in highly toxic singlet oxygen. This toxic singlet oxygen in turn produces irreversible oxidation of the cell structures in the areas to which the photosensitizer has been concentrated (Palanker, 2014).

As noted earlier, CXL is an example of a photochemical reaction. It involves four important factors: energy dose of the applied ultraviolet (UV) light, concentration or formulation of riboflavin, oxygen concentration within the tissue, timing of riboflavin diffusion, oxygen diffusion, and light exposure. Riboflavin acts as a photosensitizer that is activated by the absorbed UV light to create reactive oxygen species (ROS) which help to produce bonds between molecules in the stroma, thus increasing the biomechanical strength of the cornea.

The Dresden Protocol uses a 0.1%–0.15% aqueous solution of riboflavin-5-phosphate (vitamin B2) that provides a high absorption and, therefore, good shielding-effect at a wavelength of 360–370 nm. The typically used radiant exposure (energy dose) of 5.4 J/cm^2 allows for biomechanical stiffening of the cornea following treatment.

CXL is an established treatment for keratoconus and post-LASIK ectasia with numerous clinical studies showing that it helps to slow disease progression, regularize the cornea and improve visual acuity in patients with these disorders. Other indications include pellucid marginal degeneration, iatrogenic keratectasia after refractive laser surgery and corneal melting that does not respond to conventional therapy. More recently, CXL has also been investigated as a treatment for refractive errors including myopia, hyperopia and astigmatism (Kanellopoulos, 2014) and for infectious keratitis.

It is known that upon photochemical activation, oxygen species are released from each of the carboxylic groups present in riboflavin, leading to the generation of a light activated riboflavin and single reactive oxygens in solution ($\text{O}_2^{\cdot-}$). As there are two by-products of the photochemical activation, there are two mechanisms available to interact with the collagen structure. In the direct mechanism (Type I), the light activated riboflavin interacts directly with the collagen molecule by hydrogen abstraction of amines to stabilize its own carbon double bonds therefore enabling intermolecular covalent crosslinks to form in the collagen. In the indirect mechanism (Type II), single reactive oxygens form hydrogen peroxide (H_2O_2) and free radicals (e.g., superoxide anion $\text{O}_2^{\cdot-}$) which in turn oxidize the collagen molecule and therefore enable the formation of indirect covalent crosslinks. Most cross-linking occurs through Type I photochemical reactions (Lichtman and Conchello, 2005; Rich *et al.*, 2014; Balasubramanian *et al.*, 1990).

It seems to be of relevance that when an anaerobic solution of riboflavin is exposed to blue or ultraviolet light in the presence of an electron donor, the yellow color of the solution is reduced in intensity. The spectrum of the resulting solution is identical to that of chemically reduced riboflavin and aeration of the solution results in a complete return of the color such that the spectrum of the original and aerated solutions. The photoreaction of riboflavin in the presence of an electron donor would appear to be a photoreduction. In aqueous media, photoreduction in the presence of an electron donor is considered to be more efficient than photobleaching (Carr, 1960; Smith, 1963; Cairns, 1970).

As a result of Type I and Type II reactions, are two reaction mechanisms competing for oxygen in the cornea: excited riboflavin and reduced-state riboflavin. Consequently oxygen is rapidly consumed in the cornea. Unfortunately, reduced-state riboflavin is not reactive and does not act as a photosensitizer. Only new oxygen molecules that diffuse into cornea from atmosphere can lead to further crosslinking activities. The depletion of oxygen during CXL suggests a combined Type I and Type II mechanism after several minutes as oxygen begins to replenish itself. Of note, Herekar (2007) reported on the depletion of oxygen during corneal cross linking and found a significant reduction of oxygen available for Type II reactions within the first 3–5 min at an intensity of 3 mW/cm^2 . At an intensity of 16 mW/cm^2 , the depletion occurred in less than 1 min. Thus, during CXL, both anaerobic and aerobic conditions are created in the cornea. Anaerobic conditions occur where reduced state riboflavin is formed and all oxygen is consumed. Aerobic conditions occur when oxygen from the air diffuses into the cornea. It is reasonable to conclude then that it is the oxygen diffusion time might be primary driver for the depth and effectiveness of CXL. Specifically, reducing the diffusion time will create a thinner aerobic layer, producing a CXL effect only at anterior part of cornea. Higher diffusion of oxygen will cause deeper CXL effects and higher efficacy (Fig. 2).

Photothermal Interactions

Photothermal interactions are the basis for treatments such as panretinal photocoagulation (PRP). Simply speaking, when tissue absorbs laser energy, a photothermal interaction occurs. Tissue temperature changes both during and after the laser irradiation are crucial. Depending on the temperature change and duration of exposure, different effects may occur, i.e., necrosis, coagulation and

Fig. 2 The photochemical relationship between oxygen, riboflavin and UVA light.

vaporization. Daniel Palanker Department of Ophthalmology and Hansen Experimental Physics Laboratory, Stanford University, Stanford, CA, notes that heat diffusion during the laser pulse becomes significant when the pulse duration exceeds the time it takes for heat to spread over the distance equal to the laser penetration depth in tissue. For pulses shorter than the characteristic diffusion time across the light absorption zone, the heat cannot escape from the energy deposition zone during the pulse; this results in the most efficient heating (Palanker, 2014).

Panretinal photocoagulation was first evaluated in the 1970s using both xenon arc laser and argon laser treatments on patients with proliferative diabetic retinopathy (PDR). The study found that while both laser types were similarly effective, the argon laser was associated with fewer adverse effects.

Panretinal photocoagulation for the treatment of PDR typically uses visible light to create a thermal burn in the retinal tissue. When the retinal pigment epithelium (RPE) which overlays the choroid, just below the retina) absorbs laser light, localized coagulation necrosis occurs, i.e., the laser coagulates the RPE and adjacent photoreceptors, but the retina remains intact. As a result, PRP reduces the area of ischemic tissue, which in turn reduces total vascular endothelial growth factor (VEGF) production in the eye. This in turn helps to reduce neovascularization (American Academy of Ophthalmology).

Ischemic diseases, namely diabetic retinopathy, retinal vein occlusions and sickle cell retinopathy, are the main therapeutic targets for PRP. Indications for focal photocoagulation treatments include retinal breaks, ocular tumors, extrafoveal choroidal neovascular membrane, and microaneurysms.

The overall goal of panretinal photocoagulation is to reduce the oxygen consumption of the outer retina and re-establish a balance between the oxygen supply and demand. PRP typically employs or PRP, typically yellow, green, or red laser light to create micro burns. Specifically, absorbed laser energy is converted into thermal energy, raising the tissue temperature to 20°C–30°C. Tissue burns denature tissue proteins leading to local cell death and coagulative necrosis. An average PRP treatment administers 1200–1500 burns across an area 0.5 mm diameter. This number of burns/area may help to reduce the number of photoreceptors and oxygen consumption of the outer retina by around 20%.

There are several PRP protocols including long duration and short duration protocols. A short duration protocol uses pattern scanning that delivers a pattern of multiple burns in roughly the same time it takes for a conventional laser to deliver one burn. Consequently, the pulse duration is approximately 10–30 ms per spot and the number of spots administered is approximately 3000–5000. As the name suggests, the long duration protocol is more time consuming because the burns are delivered individually. The pulse duration is usually 100 ms with a large spot size (200–500 μ). A power of 200–250 mW is typically applied (American Academy of Ophthalmology).

Photomechanical Interactions

Photomechanical interactions (photodisruption) form the basis for precise tissue cutting, useful in refractive and cataract surgery. Photodisruption occurs when absorption of the laser intensity results in an optical break down due to the high electric field strength beyond the binding energy of molecules. The created electron plasma requires more space leading to fast expansion of the plasma. Expanding and collapsing cavitation bubbles can rupture nearby tissue or eject tissue fragments from the exposed surface. To avoid heat diffusing away from the laser absorption site, energy should be delivered within the thermal confinement time accounting for the use of relatively short pulse durations, i.e., in femto- to picosecond range (Palanker, 2014).

The Small Incision Lenticule Extraction (SMILE) procedure, which is a minimally invasive procedure, designed to correct higher degrees of myopia is an example of photomechanical laser application. Specifically, a femtosecond laser is used to create a 3 mm corneal micro-tunnel through which the lenticule is extracted. SMILE received FDA approval in 2016.

SMILE is indicated for myopia (-1.0 D to -8 D) – and may be particularly useful for myopic patients with dry eye because there is less disruption of corneal surface, and in turn, the tear film, as compared with LASIK. Patients should also have ≤ -0.50 D cylinder and MRSE -8.25 D in the affected eye. SMILE is unsuitable for patients with astigmatism.

The SMILE procedure employs a femtosecond laser. During the procedure, the individually calibrated curved glass of the femtosecond laser is placed against the cornea. Formation of a meniscus tear film allows the patient to see the fixation target because the vergence of the fixation beam is focused according to the patient's refraction. The patient looks at the fixation target and corneal suction ports are activated to fixate the eye. The lower interface of the intrastromal lenticule is created first, followed by the upper interface of the lenticule (which is known as a cap). The laser is then used to create a 2–3 mm tunnel incision that links the cap interface to the corneal surface (Reinstein *et al.*, 2014).

An applanation-free femtosecond laser has also been proposed by Pajic and colleagues and is designed to circumvent the problems associated with weak and strong applanation, respectively. In the case of weak applanation on one hand, an adaption piece of almost the same curvature as the cornea is brought onto the eye. In the case of strong applanation on the other hand, a painful applanation is generated by pressing the eye down with a glass plate. In an applanation-free procedure, physiological saline with a refractive index ($n=1.338$) close to that of the cornea (regularly $n=1.376$) is brought on top of the eye into the suction ring. This liquid ensures a very good refractive index matching and thus minimizes the wave front distortion of the fs-laser pulses upon entrance into cornea. The thickness of the liquid can be varied from a few hundred μm to 1 mm. In this way, an applanation-free processing of the cornea becomes possible (Pajic and Hafezi, 2011).

Laser and Light Interaction and Ocular Target Tissue

Cornea

Laser and light technology play an important role in the treatment of corneal conditions, such as keratoconus. Keratoconus is a bilateral disorder characterized by steepening and thinning of the central cornea, which leads to loss of visual acuity. In early stages keratoconus is treated with contact lenses; however, traditionally, when patients become contact lens-intolerant, keratoplasty, or corneal transplant surgery is performed. Advances in lasers and light, decreased the need for keratoplasty. For example, CXL helps to increase the biomechanical strength of the cornea, with the goal of avoiding corneal transplant.

The procedure utilizes a 0.1%–0.15% aqueous solution of riboflavin-5-phosphate (vitamin B2) and UVA light at a wavelength of 360–370 nm (intensity 3 mW/cm²), usually for 30 min. This is known as the Dresden Protocol. The typically used radiant exposure (energy dose) of 5.4 J/cm² allows for biomechanical stiffening of the cornea following treatment. Newer accelerated protocols with shorter treatment times are currently under development.

Findings from a meta-analysis of randomized controlled trials that assessed the effect of CXL in slowing progression of keratoconus show that CXL significantly decreased mean keratometry, maximum keratometry and minimum keratometry. There were also significant improvements in best spectacle-corrected visual acuity (BCVA). Manifest cylinder error decreased significantly in patients undergoing CXL procedure compared with control patients in sensitivity analysis. Thus, CXL appears to be an effective option in stabilizing the cornea in keratoconus (Li *et al.*, 2015; Cummings *et al.*, 2016; Choi *et al.*, 2017). Some authors found that the accelerated CXL protocol with higher UV intensity and reduced irradiation time showed a smaller topographic flattening effect when compared to the standard Dresden protocol. Sadoughi *et al.* (2016) also compared the Dresden protocol with accelerated CXL (9 mW/cm² for 10 min) in patients with progressive keratoconus. Like Cummings *et al.*'s study, they found that accelerated CXL had similar refractive, visual, keratometric, and aberrometric results and significant less adverse effects on the corneal thickness and endothelial cells as compared with the conventional method after 12 months follow-up.

There is a large body of published studies describing outcomes in the treatment of keratoconus. Collagen corneal cross-linking was first pre-clinically evaluated as a conservative treatment for keratectasia in 1998 by Spoerl *et al.* (1998). Enucleated porcine eyes were treated with UV-light ($\lambda=254$ nm), 0.5% riboflavin, 0.5% riboflavin and UV-light (365 nm) blue light (436 nm) and sunlight, and the chemical agents, glutaraldehyde (1% and 0.1%, 10 min) and Karnovsky's solution (0.1%, 10 min), and were then compared with untreated corneas. They found that compared to untreated corneas treatment with riboflavin and UV-irradiation as well as weak glutaraldehyde or Karnovsky's solutions significantly increased corneal stiffness (Spoerl *et al.*, 1998). This early in vitro study paved the way for Wollensak *et al.*'s prospective, nonrandomized clinical pilot study in 23 eyes with moderate or advanced progressive keratoconus. Data from this study showed that treatment with riboflavin and ultraviolet-A (UVA) irradiation (370 nm, 3 mW/cm² for 30 min) halted the progression of keratoconus in all eyes and caused disease regression in 16 eyes (70%) (Wollensak *et al.*, 2003).

The initial clinical results have been confirmed and reproduced during the past 15 years in multiple clinical studies and have lead to regulatory approvals around the world including FDA approval of the Dresden protocol in 2016. Overall, it appears that CXL's main benefit is in halting, or at least slowing, disease progression. However, it may also help to improve visual acuity. A systemic literature review and meta-analysis of ocular functional and structural parameters of patients with keratoconus undergoing cross-linking procedures found an improvement in visual acuity of 1–2 Snellen lines 3 months or more after undergoing CXL; changes were more pronounced in uncorrected visual acuity. Some topography parameters were found to be improved (0.6–1 diopters) 12–24 months after CXL (Meiri *et al.*, 2016). According to a study by Greenstein and Hersh, outcomes following CXL may be predicted by preoperative patient characteristics. Results of the study, which comprised 104 eyes (66 keratoconus;

38 corneal ectasia), showed that patients with worse preoperative CDVA and higher K values, (particularly with a CDVA of 20/40 or worse or a maximum K of 55.0 D or more), were most likely to have improvement after CXL. However, the authors noted that no preoperative characteristics were predictive of CXL failure (Greenstein and Hersh, 2013).

Lens

Lasers play a key role in modern-day cataract surgery. For many cataract surgeons, femtosecond lasers have replaced hand-held tools for creating the corneal incision and anterior capsulotomy as well as lens and cataract fragmentation. It is also possible to correct astigmatism through corresponding arcuate incisions. It has been suggested that use of femtosecond laser may help to improve safety and precision and reduce postoperative complications versus traditional cataract surgery. A study by Abell and colleagues of outcomes and safety in more than 4000 cases at a single center, however, showed that the two cataract surgery techniques appear to be equally safe. The authors reported that the safety of femtosecond-assisted cataract surgery (FLACS) in terms of posterior capsule complications was equal to that of phacoemulsification, and that anterior capsule tears was a concern in both groups (Abell *et al.*, 2015). A meta analysis of 14,567 eyes that also compared FLACS to manual cataract surgery similarly found that there were no statistically-significant differences between groups in terms of patient-important visual and refractive outcomes and overall complications (Popovic *et al.*, 2016).

Lasers are often also use post-cataract surgery. The neodymium: yttrium-aluminum-garnet (Nd: YAG) laser is used to perform postoperative opacification, and has largely replaced surgical cutting or polishing of the posterior capsule in the management of opacification. The Nd: YAG laser is a solid-state laser with a wavelength of 1064 nm and has a photomechanical effect (Steinert, 2013).

Vitreoretinal

Light is also employed in the treatment of vitreoretinal disorders. Retinal laser photocoagulation is used to treat retinal tears (laser retinopexy) in order to inhibit progression to a retinal detachment. For this indication, green light is the wavelength typically because it is well absorbed by melanin and hemoglobin but is poorly absorbed by xanthophylls thus limiting the potential of macular damage. Red wavelengths are also used and are particularly helpful in patients with media opacity such as cataracts. However, since red light has a longer wavelength than green light, there may be more unpredictable and more heterogeneous absorption by the choroid; this in turn may increase pain and may also lead to focal damage to Bruch's membrane (Silva and Blumenkranz, 2013).

Panretinal photocoagulation is used to treat diabetic retinopathy; it may also be used to retinal ischemia and retinal neo-vascularization of avascular areas. A number of lasers have been used in panretinal photocoagulation including ruby lasers (694-nm wavelength), argon lasers which can use the blue (488-nm wavelength) and green (514-nm wavelength) light emission, and dye lasers. In the 1990s diode lasers (810-nm wavelength) and micropulsed diode lasers, and later, transpupillary thermotherapy (TTT) using a near-infrared (810-nm wavelength) laser were introduced. Newer developments include pattern scan laser photocoagulator with a 532-nm laser and 532-nm pattern-type eye-tracking lasers (Kozak and Luttrull, 2015).

There are a number of landmark studies describing PRP outcomes in diabetic retinopathy. These include the Diabetes Control and Complications Trial, the Diabetic Retinopathy Study, the Early Treatment Diabetic Retinopathy Study (ETDRS) and the Diabetic Retinopathy Vitrectomy Study Research Group trial (Royle *et al.*, 2015).

These studies highlighted a number of points. The randomized, controlled DRS trial, undertaken by the National Eye Institute in the 1970s, compared the efficacy of PRP (versus no treatment) in delaying the progression of PDR and preventing vision loss. The study included 1700 patients with non-proliferative PDR in both eyes or PDR in at least one eye. Patients received PRP treatment in one eye, and no treatment in the fellow eye. Patients were randomly assigned to receive either xenon arc treatment or argon treatment. Findings showed that PRP reduced the risk of severe visual loss by more than 50%. The vision loss rate was 16.3% in untreated eyes versus 6.4% in treated eyes over two years. The study also showed that argon laser was more effective than the xenon arc laser. Importantly, the DRS study also showed that at 2 years, 11% of treated eyes versus 26% of untreated eyes with high-risk retinopathy developed severe visual loss. At 4 years, 20% of treated eyes and 44% of untreated eyes developed severe visual loss (> 5/200). In patients with early proliferative retinopathy – 3% of treated eyes and 7% of untreated eyes developed severe visual loss at 2 years. At 4 years 7% of treated eyes and 21% of untreated eyes developed severe visual loss. The ETDRS group subsequently examined whether early PRP was more effective than delayed PRP treatment. The ETDRS study group concluded that scatter photocoagulation should not be offered in mild cases of PDR as the potential adverse effects and relative risks of treatment may outweigh minimal benefits gained by treatment at early stages. They advised that PRP treatment should commence when non-proliferative PDR becomes severe or progresses into PDR (American Academy of Ophthalmology; Royle *et al.*, 2015).

Lasers are also being increasingly used to reduce symptomatic vitreous floaters. Vitreous floaters are deposits of various size, shape, consistency, refractive index, and motility within the eye's vitreous humour, which is normally transparent. Previously, neodymium–yttrium-aluminum-garnet (Nd: YAG) were employed which was associated with mixed success. More recently, modified YAG lasers have been used. The Ultra Q Reflex™ system (Ellex Medical Lasers, Australia,) is a Q-switched Nd: YAG laser that vaporizes floaters at lower energy levels and with fewer shots than older laser systems. Unlike traditional Nd: YAG lasers, this modified laser is focused onto the front surface of the floater. The laser emits a short and small burst of energy that provides a

potent power density (10^9 J/cm²). This energy converts collagen and hyaluronic molecules found in a floater into a gas, which is then reabsorbed into the eye (*The Ultra Q Reflex*). Findings from a retrospective, observational study by Inder Paul Singh, MD (*Cummings et al., 2016*) of 168 eyes of 124 patients (mean age, 66 years (range, 42–89 years)) who underwent YAG vitreolysis (laser power range 2.0–5.5 mJ) demonstrated that 92% of patients were satisfied with the procedure. There was one case of intraocular pressure (IOP) spike, and two phakic lenses were damaged, one of which required cataract surgery. No retinal detachment or other retinal complications were seen and there was no anterior chamber or vitreous reactions (*Singh, 2014*).

Refractive

Lasers and light therapy has perhaps received the widest recognition in the treatment of refractive errors, in particular the use of excimer lasers.

Excimer laser (PRK and LASIK)

Excimer lasers are used in the treatment of myopia, hyperopia and astigmatism; operates in the ultraviolet spectral region. Laser-assisted in situ keratomileusis (LASIK) and PRK both employ this type of laser technology. While PRK uses an excimer to reshape the surface of the cornea, LASIK uses an excimer laser reshapes the cornea under a corneal flap at the stromal level.

Excimer lasers typically operate in the UV spectrum and use a gas mixture (known as the excimer gain medium) containing a noble gas such as argon, and a halogen, e.g., chlorine or fluorine. When a high voltage electric discharge is delivered into the laser cavity these gases combine to form a high energy excited gas state (excited dimer). When this high-energy compound subsequently dissociates, a photon of energy is released corresponding to the energy of the noble gas-halogen molecule. This light energy is amplified in the laser system resulting in the production of a high-energy discrete pulse of laser energy which disrupts chemical bonds of proteins, glycosaminoglycans, and nucleic acids in the cornea. Importantly, laser energy is absorbed by these compounds but with minimal damage to surrounding tissue because of a high energy density and short pulse duration (*Manche et al., 1998*).

The efficacy of LASIK and PRK is well established. However, a literature analysis that included randomized controlled trials comparing LASIK and PRK for the correction of any degree of myopia (1135 participants, 1923 eyes) concluded that LASIK gives a faster visual recovery and is a less painful technique than PRK. Nevertheless, the authors added that the two techniques appear to give similar outcomes 1 year after surgery (*Shortt et al., 2013*).

Photorefractive keratectomy (PRK) is a laser that utilizes excimer laser technology, and is typically used in the treatment of keratoconus. Current regimes for PRK utilize topography-guided ablation profiles designed to help reduce corneal surface irregularities with the goal of improving vision. In a retrospective follow-up study by *Tambe et al. (2015)*, 28 eyes of 23 patients (age 17–60) with grade 1–3 keratoconus received topography-guided PRK between 1998 and 2013. Of the 28 eyes, 18% underwent corneal transplantation at a median of 7 years (range 3–10) after PRK, four eyes were not available for follow-up, and in the remaining 19 eyes, corrected distance visual acuity (CDVA) was improved in 16 eyes (84.3%), reduced in 2 eyes (10.5%), and unchanged in 1 eye (5.2%). The mean spherical equivalent was reduced from -6.2 to -3.7 diopters (D) after 3 months and to -2.1 D at the late follow-up visit. Similarly, the mean cylinder was reduced from -4.2 to -3.0 D after 3 months and at the late follow-up. The authors suggested, therefore, that topography-guided PRK in keratoconus may help to reduce myopia and astigmatism and may offer a temporary or permanent alternative to keratoplasty in contact lens-intolerant keratoconus.

Femtosecond laser

Femtosecond laser technology is now also being employed in LASIK. Known as femtosecond laser-assisted LASIK (FS-LASIK), the femtosecond laser is used for flap creation while the excimer laser is used for stromal bed ablation. Thus the femtosecond laser allows the surgeon to create a thin-hinged corneal flap and a significant less deviation in flap thickness without using a micro-keratome. An analysis published in 2017 concluded that FS-LASIK yielded more predictable corneal flaps, lesser ocular aberrations, better uncorrected visual acuity, less variations in IOP and a reduced risk of developing dry eye. However, FS-LASIK may cause transient light sensitivity, diffuse lamellar keratitis, opaque bubble layer, corneal haze and rainbow glare (*Bashir et al., 2017*).

The SMILE procedure also uses femtosecond laser technology. SMILE evolved from Femtosecond Lenticule Extraction (FLEX) and has been shown to be safe and effective treatment for myopia (*Vestergaard et al., 2012; Wang et al., 2013; Kamiya et al., 2014*). The procedure involves cutting a small lenticule in the corneal stroma with a femtosecond laser. The lenticule is subsequently removed through a small incision.

There are number of published studies describing SMILE visual and refractive outcomes (*Vestergaard et al., 2012; Wang et al., 2013; Kamiya et al., 2014; Sekundo et al., 2014; Agca et al., 2014; Lin et al., 2014*). A systematic review and meta-analysis that compared (SMILE) with (FS-LASIK) for treating myopia concluded that both FS-LASIK and SMILE are safe, effective and predictable surgical options for treating myopia. However, they also found that dry eye symptoms and loss of corneal sensitivity may occur less frequently after SMILE than after FS-LASIK (*Shen et al., 2016*). Nevertheless, limitations of SMILE have been identified. A literature analysis published by Seiler *et al.* noted that the visual rehabilitation after SMILE takes significantly longer (weeks) compared to LASIK (days). They added that the refractive success rate of SMILE is still not as good as that of LASIK (88% vs. 95% within ± 0.5 D) (*Seiler et al., 2017*). The disadvantage of SMILE is that a rest refractive error it is said an enhancement is not possible with the FS laser. Thus for this procedure an excimer laser is needed.

Femtosecond lasers are also used in the treatment of keratoconus. The femtosecond laser is a near-infrared laser that works at a wavelength of 1053 nm. This laser is utilized to cut small precise channels in the cornea, for implantation of intrastromal corneal ring segments (ICRS). ICRS are thin curved pieces of plastic that are inserted into the cornea in order to provide biomechanical stability in keratoconus. Historically these channels were made with a handheld instrument, but this often resulted in the instrument inadvertently puncturing through the already thinned corneal stroma. The femtosecond laser is now used to cut precise channels prior to implantation of ICRS. The laser has an ultra-short-pulse duration (in the range of 10^{-15} s), allowing it to produce smaller shock waves which helps to minimize collateral damage (Kullman and Pineda, 2010; Mamalis, 2011). There are only a few studies comparing the effectiveness of femtosecond versus manual channel creation; however, published data suggest that femtosecond laser channel creation is safe with few complications. Coskunseven *et al.* (2011) conducted a retrospective chart review of 531 patients (850 eyes) who underwent ICRS using a femtosecond laser for channel creation. They noted that the overall complication rate was 5.7% (49 cases out of 850 eyes). The main complication was incomplete channel formation (2.7% cases).

Other

Lasers also play an important role in the treatment of glaucoma (Table 1) and include selective laser trabeculoplasty (SLT), argon laser trabeculoplasty (ALT) (both of which target the trabecular meshwork and are used in the treatment of open-angle glaucoma) and laser iridotomy, which targets the outer edge of the iris and is used to treat closed-angle glaucoma. Lasers are also used in cyclophotocoagulation (targeting the ciliary body) and for suture lysis.

Selective laser trabeculoplasty has largely replaced ALT, mainly due to its improved safety profile. The improved safety of SLT versus ALT is due to the former's very short pulse duration of three nanoseconds. This permits selective photothermolysis, i.e., the laser selectively targets cells of the trabecular meshwork. Unlike ALT, it does not cause coagulative damage to the trabecular meshwork and reduces collateral damage to surrounding tissues (Song, 2016).

Future Applications

There is a large variety of application developments and new technologies under development in ophthalmology. In this article we are highlighting some of the current developments that might affect the current standard of care for treating patients with vision disorders.

Photochemical– Corneal cross linking for refractive procedures

Encouragingly, CXL is also emerging as a treatment for pathologies other than corneal ectasia. As noted, CXL is being evaluated as a treatment for refractive errors. Known as photorefractive intrastromal corneal collagen cross-linking (PiXL™), the procedure uses riboflavin and a ultraviolet-A (UVA) 365 nm wavelength light source with programmable illumination pattern delivered by a proprietary device to cause differential corneal tissue “stiffening” to reshape the cornea. A key advantage of this approach is that, unlike tissue ablation/removal in current corneal refractive procedures, there is no removal of stromal tissue. Early study findings are encouraging.

Thus far, studies have focused on the use of PiXL as a treatment for low myopia. Feasibility study findings published in 2014 (Kanellopoulos, 2014) showed that application of 12 J/cm² applied transepithelially in a predetermined pattern led to an average improvement of 2.3 diopters (D) 1 week postoperative. Findings from a 6-month prospective study of 14 patients with myopia or myopic astigmatism undertaken by Matthias Elling, FEBO, showed statistically-significant improvement in UCVA at 1, 3 and 6 months postoperatively. A significant improvement in BCVA was also observed. Data also improvements in mean manifest sphere and manifest refractive spherical equivalent at all visits versus baseline (Elling *et al.*, 2017). Data presented at XXXIV Congress of the European Society of Cataract and Refractive Surgeons (ESCRS) from a 12-month study of 39 eyes, also undertaken by Matthias Elling showed significant improvements in UCVA and no loss of BCVA. In a 9-month study of eight patients, a mean myopia reduction of 0.75 D with no loss of BCVA was noted (Primary Care Optometry News, 2017).

Photochemical – Corneal cross linking for corneal infections

Collagen corneal cross-linking is also being investigated as a treatment of infectious keratitis. Known in this context as PACK-CXL (photo activated chromophore for infectious keratitis), the procedure may provide an alternative to standard antibiotic therapy in treating infectious corneal disorders (Tabibian *et al.*, 2015). The antimicrobial effect occurs due to the effect of UV light interacting with riboflavin. The resulting reactive oxygen species damage the pathogen cell walls; riboflavin may also interact with the nucleic acids of the pathogen, preventing replication.

Larger randomized prospective clinical trials are few for PACK-CXL thus far, but smaller case reports findings from small series prove promising. Makdoui and colleagues reported a series of 16 patients with culture proven bacterial ulcers who all improved after being treated with CXL alone. All eyes achieved epithelial healing and less inflammation, although two patients required antibiotic therapy to completely resolve their infection (Makdoui *et al.*, 2012). Said *et al.* (2014) compared PACK-CXL with standard anti-microbial therapy in 40 eyes of 40 patients with advanced infectious keratitis and coexisting corneal melting. Twenty-one patients underwent PACK-CXL and antimicrobial therapy while 19 patients received antimicrobial therapy only.

Table 1 Application of laser and light technologies according to tissue type/indication

<i>Intended use</i>	<i>Application</i>	<i>Tissue structure</i>	<i>Laser/light source</i>	<i>Wavelength</i>	<i>Interaction mechanism</i>
Treatment of corneal ectasia	Corneal cross linking	Cornea	UV-LED (continuous wave or pulsed)	365 nm	Photochemical
Corneal scars or other corneal disorders	Phototherapeutic keratectomy (PTK)	Cornea	ArF Excimer laser	193 nm	Photoablation
Treatment of refractive errors	Photorefractive keratectomy (PRK) and Laser assisted in-situ keratomileusis (LASIK)	Cornea	ArF Excimer laser	193 nm	Photoablation
	LASIK- Flaps and Small Incision Lenticule Extraction (SMILE)	Cornea	Femtosecond lasers (pulse duration 220–580 fs)	1043 nm	Photomechanical/ photodisruption
Treatment of glaucoma	Laser trabeculoplasty	Trabecular mesh work	2w-Nd: YAG Argon laser	532 nm 515 nm	Photothermal
	Laser iridotomy/laser peripheral iridoplasty	Iris	Nd:YAG (2w)	532 nm 1064 nm	Photothermal/ photomechanical
	Cyclophotocoagulation	Ciliary body	Argon Nd:YAG	515 nm 1064 nm	Photothermal
	Glaucoma laser suture lysis	Cutting a suture of trabecular ectomy scleral flap	Diode laser 2w-Nd:YAG Argon laser	810 nm 532 nm 515 nm	Photothermal
Treatment of cataract	Femtosecond laser-assisted cataract surgery (FLACS)	Cataractous lens fragmentation and incisions for cataract surgery	Neodymium: glass (pulse duration 300 – 500 fs)	1053 nm	Photomechanical/ photodisruption
	Posterior Capsulotomy	Turbid posterior lens capsule after intra-ocular lens implantation	Nd:YAG (Q-switched)	1064 nm	Photomechanical/ photodisruption
Treatment retinal or choroidal pathology	Retinal ischemic processes (e.g., diabetes, retinopathy of prematurity)	Retina	2w-Nd: YAG Argon laser	532 nm 515 nm	Photothermal
	Retinal tears	Retina	2w-Nd: YAG Argon laser	532 nm 515 nm	Photothermal
	Focal macular laser therapy for focal macular oedema	Retina	2w-Nd: YAG Argon laser	532 nm 515 nm	Photothermal
	Photodynamic therapy for choroidal neovascularization	Choroid	Diode laser	690 nm	Photochemical
	Transpupillary thermotherapy (TTT)	Malignant choroidal melanoma	Diode laser	810 nm	Photothermal
Treatment of vitreous disorders	Vitreous strand in the anterior chamber, posterior vitreous detachment and vitreous floaters	Vitreous	Nd: YAG (Q-switched)	1064 nm	Photomechanical
Treatment of lid and orbit	Blepharoplasty	Upper and lower eye lid	CO ₂ laser	10,600 nm	Photoablation

Although PACK-CXL did not shorten the time to corneal healing, the complication rate was 21% in the antimicrobial group, whereas there was no incidence of corneal perforation or recurrence of the infection in the PACK-CXL group.

Photothermal – Computer guided treatments

Studies of PRP in diabetic macular edema (DME) using conventional slit-lamp based laser application have shown low success rates in terms of either visual acuity gains or reductions in anti-VEGF use burden, likely due to inadequate accuracy and completeness associated with conventional laser therapy (ETDRS Study Group, 1985; Michael *et al.*, 2011; Mitchell *et al.*, 2011; Brown *et al.*, 2013). Consequently, technology has been developed to improve laser spot accuracy. Computer-guided technology for navigated laser photocoagulation offers significantly greater accuracy in laser spot application to areas of edema than traditional laser treatment. Study findings also show that navigated laser photocoagulation reduces the retreatment rate (as compared with conventional laser therapy) by almost half in patients with DME (Neubauer *et al.*, 2013). An additional development is sub-threshold diode micropulse laser. This was developed with the treatment of DME in mind, but it may also be effective in the treatment of PDR.

Photomechanical – The SMILE procedure

As noted earlier, SMILE is indicated for myopia with clinically-insignificant astigmatism. However, trials are underway to evaluate SMILE in myopic patients with astigmatism and hyperopic patients. Use of 345 nm UV femtosecond laser pulses, which may have applications in SMILE, but also flap creation and ultrathin Descemet-stripping endothelial keratoplasty has also been tested in vivo by Hammer and colleagues (Hammer *et al.*, 2015). The Laser energy levels required by a ultraviolet femtosecond laser to disrupt corneal tissue are tenfold lower than those required by an infrared laser offering significant safety advantages. Additionally, light of shorter wavelength can be focused more precisely and may therefore allow more precise photodisruption of the corneal stroma. Clinical studies are needed to determine the safety and efficacy of 345 nm UV femtosecond laser.

Conclusion

Laser and light therapy continues to play a key role in the management of many ophthalmic disorders. Ongoing developments suggest that improvements may be made to existing treatments, and may even provide new ways of treating problems, for example, guided crosslinking in the treatment of myopia. Although, a greater body of evidence is needed to ascertain whether these new technologies will have a clinically-significant impact, it appears likely that lasers and light therapies will have a growing role in ophthalmology.

Glossary

Acoustic radiation force Physical force exerted by acoustic waves.

Brillouin Scattering Inelastic light scattering phenomenon where incident light interacts with acoustic phonons within a material to produce scattered light with different color (wavelength or frequency).

Corneal Refractive Surgery Surgical reshaping of the cornea (generally using laser ablation or corneal lenticule extraction) to produce a refractive change to correct refractive errors.

Corneal Videokeratography Technique to measure anterior corneal surface topography, generally base on the projection of rings onto the cornea and analysis of the acquired image.

Cross-Linking Surgical treatment of keratoconus using a photosensitizer and a light irradiation to produce chemical bonds between collagen fiber and increase corneal stiffness.

Ectasia Posterior corneal bulging resulting from reduced corneal thinning in corneal refractive surgery or disease.

Elastography Imaging modality that maps the elastic properties of tissues.

Etalon Transparent slab with two reflecting surfaces used to separate light components of different colors based on multi-pass interference.

Glaucoma Ocular disease in which damage is produced in the optic nerve head (generally due to increased Intraocular Pressure), resulting in nerve fiber loss and peripheral vision loss.

Gonioscopy lens Specialized lens used in ophthalmology placed on the surface of the cornea for visualizing the anterior segment angle.

Interference (of light) Physical phenomenon where two light waves are superposed and form a resultant wave of larger or smaller amplitude depending on the relative delay of the two.

Intrastromal Corneal Ring Segments Surgical treatment of keratoconus consisting on sections of ring segments (with triangular or hexagonal section) implanted in the corneal periphery through a manual or femto-second laser channel in order to flatten the cornea and increase surface regularity.

Keratoconus Ocular disease produced in which corneal weakening leads to corneal bulging and degraded optical quality and vision.

Modulus (of elasticity) Parameter that quantifies the resistance of a sample to be deformed.

Myopia Ocular condition in which distant objects are focused in front of the retina resulting in a blurred image.

Optical Coherence Tomography Low coherence interferometric imaging technique allowing high resolution tomographic images of the eye. Common modalities (Fourier domain) include spectral and swept source operation principles.

Presbyopia Age-related loss of accommodation capacity with age, associated to increased stiffness in the crystalline lens.

Rayleigh surface waves Elastic waves propagating at the surface of a solid, comprising both longitudinal and transverse components, solutions of the elastic wave equation for a semi-infinite medium.

Scheimpflug Imaging Eye anterior segment imaging modality in which a slit is projected onto the eye and cross-section images of the eye from the anterior cornea to the posterior cornea (or to the posterior lens) are collected. The

camera axis is tilted 45° with respect to the optical axis in order to increase the depth of focus. Geometrical and optical distortion needs to be corrected for proper quantification.

Spectrometer Instrument capable of splitting incident light in its sub-components of different color (wavelength or frequency).

Introduction

The cornea and crystalline lens of the eye are optical elements that project images of the outside world onto the retina. Although primarily regarded as lenses and investigated in terms of their optical performance, understanding the mechanical properties of the ocular elements is also crucial. The mechanical structure of the cornea determines its shape, which in turn determines its optical quality. A compromise of the corneal mechanical structure will therefore highly impact vision of the patient (Dupps and Wilson, 2006). On the other hand, the crystalline lens in the young eye has the capability of changing its shape to focus near and far objects, so called accommodation. Increased in the crystalline lens stiffness results in the loss of accommodation capacity (Weeber *et al.*, 2007), a condition called presbyopia, affecting 100% of the population beyond the age of 45. The quest for a treatment restoring crystalline lens elasticity, or alternatively, accommodating intraocular lens with the mechanical capacity to respond to an accommodative stimulus would be the ultimate solutions for presbyopia. The mechanical properties of another ocular tissue, the sclera, have also been linked with the development of myopia, which results from the excessive elongation of the eyeball. It has been acknowledged that understanding the matrix and cellular factors contributing to a weakened sclera in myopes may aid in the development of a clinically appropriate treatment for myopia (McBrien and Jobling, 2009). Finally, because pressure is a mechanical phenomenon, and because of elevated intraocular pressure (IOP) is a risk factor for glaucoma, the role of ocular biomechanics in understanding the development and progression of glaucomatous optics neuropathy has long been recognized. On the one hand, standard measurements of IOP are largely affected by corneal biomechanics (Liu and Roberts, 2005). On the other hand, the mechanical effects of IOP on the optical nerve head, and the contribution of the tissue mechanical properties to the susceptibility of IOP insult are key to understand individual differences in the mechanical, ischemic and cellular events occurring in glaucoma (Sigal and Grimm, 2012).

While the implication of ocular tissue mechanics in presbyopia, myopia and glaucoma is clear, the cornea has been a primary focus of attention to the investigation and clinical measurement of biomechanics. Knowledge of the corneal biomechanical properties is key in the understanding of the progression of certain corneal diseases (such as keratoconus) or the corneal response to treatments. Certain corneal treatments such as surgeries involving incisions (cataract, incisional refractive surgery) (Denoyer *et al.*, 2013) or intrastromal corneal ring segment implantation to treat keratoconus rely specifically on the mechanical response of the cornea (Ortiz *et al.*, 2012; Pérez-Merino *et al.*, 2013, 2014). Emerging treatments of keratoconus, such as corneal collagen cross-linking, aim at increasing corneal stiffness, therefore changing the corneal mechanical response.

Despite the agreement on the clinical need to monitor the mechanical properties of the cornea, most knowledge of the inherent constituent properties of the cornea comes from tests in vitro (uniaxial extensimetry, two-dimension flap extensimetry, or corneal or whole eye inflation) (Andreassen *et al.*, 1980; Wollensak *et al.*, 2003; Kling *et al.*, 2010, 2012; Boyce *et al.*, 2007; Elsheikh *et al.*, 2007; Kling and Marcos, 2013a,b,c). The reports of the corneal Young modulus in the literature span almost two orders of magnitude. The differences across studies likely arise from the differences across methods, the relative complexity of the corneal structure, and the differences in the experimental conditions across studies (Andreassen *et al.*, 1980; Wollensak *et al.*, 2003; Kling *et al.*, 2010, 2012; Boyce *et al.*, 2007; Elsheikh *et al.*, 2007; Kling and Marcos, 2013a,b,c). Some methods attempt to reproduce the geometry and the integrity of the cornea of an intact eye (i.e., whole eye inflation), however it is likely that the effect of hydration and post-mortem time in experiments *ex vivo* are an important source of variability in the measurements (Kling and Marcos, 2013a,b,c). Besides, there is a clinical need for in vivo evaluation of corneal biomechanical parameters, at the patient level, for diagnostics and monitoring of disease and treatment. The availability of a method to quantify the corneal biomechanical properties of a patient in the clinic will allow to identify the risk of post-LASIK ectasia in a refractive surgery candidate (Ambrosio *et al.*, 2011). A clinical tool will also aid in the diagnosis of keratoconus, which at present is solely based on topographic and geometrical evaluation of the patient's cornea. State-of-the-art treatment techniques for keratoconus will also largely benefit for quantification of corneal biomechanics. The selection of the appropriate Intrastromal Ring Segment (ICRS) design in refractive or keratoconus treatment (Kling and Marcos, 2013a,b,c) can be guided by individual assessment of the corneal biomechanical response. On the other hand, quantitative biomechanical parameters will help to monitor the effect of collagen cross-linking (Bak-Nielsen *et al.*, 2013), a new treatment for keratoconus aiming at stiffening corneal tissue.

Requirements of in vivo measurements of corneal mechanics include non-invasiveness, rapid acquisition times, and the availability of data allowing direct reconstruction of the inherent mechanical properties of the cornea, in isolation from other factors. The use of optical imaging methods fulfills most of those requirements, and is ideal for in vivo assessment. Several approaches have been suggested to measure corneal biomechanical properties in vivo, either using optical, acoustic or magnetic imaging. These include: corneal videokeratography upon stepwise central indentation with a cantilever that measures corneal bending-resistance (Grabner *et al.*, 2005); ultrasonic and magnetic resonance techniques that use the shear wave propagation velocity to map corneal elasticity in vivo (Litwiller *et al.*, 2010); corneal optical coherence elastography producing a strain mapping based on speckle tracking (Muthupillai *et al.*, 1995; Ford *et al.*, 2006); air-puff corneal deformation imaging; phase-sensitive

Optical Coherence Tomography based on phase changes of successive corneal cross-sectional images (Chang *et al.*, 2002); and Brillouin microscopy providing a spatially resolved map of corneal Brillouin modulus, which is correlated to the local relative values of corneal elastic modulus, upon induction of quasi-static oscillations (GHz) in the tissue (Scarcelli *et al.*, 2007a,b). A drawback of several of these techniques is that they are slow (magnetic imaging), show a relatively low spatial resolution (ultrasonic/magnetic resonance imaging) or require contact of a probe with the patient's corneal surface and hence the use of anesthetics (physical applanation and ultrasound based techniques). The current article will address the three last based techniques, given the advantages of using light to capture mechanical information.

Besides, imaging techniques track corneal deformation, but quantification is needed to retrieve the inherent corneal bio-mechanical properties from the acquired images. Corneal tissue is a complex mechanical biomaterial, frequently described as a non-isotropic viscoelastic material. As in most soft-biological tissues, viscoelastic properties arise from the time-dependent nature of the biomechanical properties, are expected to be of major importance. For example, progressive deformation of the cornea (ectasia) occurring in keratoconus, and after some LASIK procedures, is a result of a viscoelastic phenomenon. Nevertheless, *ex vivo* techniques have primarily quantified the elastic properties (Young's modulus), which is in fact non-linear. Most *in vivo* techniques describe corneal deformation parameters, which are only partially dependent on the mechanical properties (other factors such as corneal thickness and IOP play a role in deformation). Besides, the corneal properties vary across corneal depth, which is directly addressed by the depth-resolved nature of Brillouin Microscopy.

The full power of light-based imaging techniques to quantify inherent mechanical properties is only achieved when those are combined with Finite Element Modeling (FEM). Assuming a certain material model and an accurate knowledge of the applied forces it is possible to retrieve the material variables through inverse optimization. Applied forces can be an air puff (which dynamically changes through a deformation event) or an acoustic stimulus. In Brillouin microscopy it is necessary to assume relationships between the Brillouin modulus and the modulus of elasticity and values for tissue density and index of refraction. Relationships between the shear modulus and the Brillouin modulus can also be validated with the aid of FEM analysis.

While these techniques have been primarily used to analyze the cornea, some of them are also suited to study mechanical properties of other tissues such as the crystalline lens (Brillouin microscopy) or the sclera (air puff deformation or OCT vibrography).

This article describes three optical imaging techniques to measure ocular biomechanics: (1) Air Puff Corneal Dynamic Imaging, using Scheimpflug imaging or Ocular Coherence Tomography (OCT); (2) Phase-sensitive OCT Elastography (3) Brillouin Microscopy; also known as OCT Vibrography. Special emphasis will be made on applications in corneal tissue. Inherent corneal properties in human and animal models obtained from FEM analysis and Inverse Optimization using input data from imaging techniques will be presented.

Air Puff Corneal Dynamic Imaging

High-speed corneal imaging in combination with an air puff combines the advantages of non-invasiveness and high-speed acquisition suitable for measurements *in vivo*. This concept, using Scheimpflug imaging has been recently commercialized by Oculus (Corvis ST system by Oculus). Air puff OCT has been demonstrated by groups at Copernicus University (Torun, Poland) and at the Institute of Optics CSIC (Madrid, Spain). This system is FDA approved as a tonometer, but provides also quantitative analysis of corneal deformation parameters (but not inherent material properties). Previous attempts (Ocular Response Analyzer by Reichert) to use air-puff applanation measurements to derive corneal mechanical properties were limited by the collection of relatively indirect data.

Direct imaging of the temporal and spatial corneal deformation profile during the air-puff event allows quantitative analysis and, through the use of Finite-Element modeling, retrieval of corneal elasticity moduli. In addition, the selected time for deformation (in the order of milliseconds) allows quantification of viscoelastic properties (relative viscoelasticity modulus and relaxation time constant) in a regime of interest for characterization of the corneal mechanical response to disease and treatments.

Air Puff Scheimpflug Imaging

The Corvis instrument by Oculus operates under the principle of Scheimpflug imaging. In Scheimpflug imaging a slit is projected onto the eye. A tilt of the imaging plane with respect to the optical axis of the instrument allows for a large depth-of-focus. While this generates geometrical distortions, these can be corrected by software. In the Corvis, the Ultra High Speed Scheimpflug camera takes over 4300 frames per second to monitor corneal response to a metered collimated air puff with fixed profile that has symmetrical configuration and fixed maximal internal pump pressure of 25 kPa. The Scheimpflug camera has blue light LED (455 nm) and covers 8.5 mm horizontally of a single slit. Recording measurement time is 30 ms, which allows for acquiring 140 digital frames. Each image has 576 measuring points.

Air Puff OCT Imaging

Direct OCT measurements of the human corneal dynamics during an air-puff induced deformation were first presented in 2011 (Alonso-Caneiro *et al.*, 2011). The authors reported a novel apparatus that combined swept source OCT (ssOCT) system

Fig. 1 Air-puff corneal deformation imaging (porcine eyes ex vivo). A. Spatial deformation from Scheimpflug-based imaging, Corvis ST by Oculus; B. Temporal deformation (A-scan of apex as a function of time) from air-puff ssOCT imaging (Nicolaus Copernicus University); C. Spatial deformation imaging (B-scan) from air-puff sOCT imaging (Instituto de Optica, CSIC). Merged undeformed cornea and maximally deformed cornea. Air-puff deformation event ≈ 20 ms in all cases. Images are from Alonso-Caneiro, D., Karnowski, K., Kaluzny, B.J., *et al.*, 2011. Assessment of corneal dynamics with high-speed swept source optical coherence tomography combined with an air puff system. *Optics Express* 19 (15), 14188–14199 and Dorronsoro, C., Pascual, D., Pérez-Merino, P., Kling, S., Marcos, S., 2012. Dynamic OCT measurement of corneal deformation by an air puff in normal and cross-linked corneas. *Biomedical Optics Express* 3 (3), 473–487.

(Karnowski *et al.*, 2011) with an air-puff chamber adapted from a commercial non-contact tonometer (**Fig. 1(A)**). A commercial prototype of swept source laser (AXSUN Technologies Inc., Billerica, MA) was used as a light source (50 kHz; 1300 nm; 110 nm optical bandwidth centered at 1300 nm, axial resolution of 9 μm in air; 0.9 mm imaging depth range; 102 dB; for 2.5 mW average optical power at the cornea). The module of an air-puff pressure chamber was extracted from a clinically approved tonometer (XPert NCT; Reichert Inc., Buffalo, NY) and was built into the imaging head of ssOCT system (**Fig. 1(B)**). A custom designed electrical circuit was used to power the air-puff chamber motor with high-voltage pulse. Additionally during the air-puff the induced corneal deformation reference pressure signal is obtained via pressure sensor originally built in the chamber.

Single A-scans are collected in time during the corneal deformation from the single/central point on the cornea where air stream is applied (M-scan). As a result the direct measurement of air induced deformation of the corneal surfaces and the anterior surface of the lens is presented. The corneal applanation/recovery time is approximately 20 ms.

The combination of an air-puff with a sOCT system was presented by Dorronsoro *et al.* (2012). In this configuration, a tilted mirror was used to couple a commercial non-contact tonometer (NT 2000, Nidek, Hiroishi, Japan) with a custom spectral domain OCT system (Alonso-Caneiro *et al.*, 2011). The tube of the tonometer providing the air puff passes through the center of the tilted mirror through a drilled hole. This configuration allows both instruments, the OCT system and the tonometer, point at the corneal apex in an almost normal orientation. This configuration allows dynamic imaging of corneal cross-sections during the air puff deformation event. The OCT imaging axis and the axis of air puff tube are perpendicularly oriented, and lying in a horizontal plane, with the tilted mirror located at the point of intersection between these two axes, at 45° (See **Fig. 1(C)**). In the vertical direction the mirror an additional tilt of 8° was imposed to avoid the horizontal scanning beam of the sOCT to overlay the mirror hole (tube tip) and therefore vignette the image. As in conventional non-contact corneal tonometry, the air puff impacts the cornea directly and produces a fast deformation event (< 30 ms). The distance from the non-contact tonometer tube tip to the corneal apex was set to 11-mm. This distance is the identical configuration to that used in the standard use for corneal applanation tonometry of the instrument. The air puff configuration was manually set, in order to obtain the same standard air puff spatio-temporal profile in all measurements. The full air pressure provided by the instrument was used in the experiments, and delivery timing was electronically triggered, in synchronization with the image acquisition by the OCT.

Corneal Deformation Parameters

This Corvis processing software allows dynamic inspection of the actual deformation process during deformation. Advanced algorithms for edge detection of the corneal contours are applied for every frame. The recording starts with the cornea at the natural convex shape. The air puff forces the cornea inwards (ingoing phase) through applanation (first or ingoing applanation) into a concavity phase until it achieves the highest concavity. There is an oscillation period before the outgoing or returning phase. The cornea undergoes a second applanation before achieving its natural shape when there is a possible oscillation. The Corvis ST commercial system identifies the timing and corresponding pressure of the air puff at the first and second applanations and at the moments of highest concavity in the spatial deformation images. Intraocular pressure (IOP) is calculated based on the timing of the first applanation event. This initial IOP measurement is dependent of corneal resistance. The deformation amplitude is determined as the highest displacement of the apex in the highest concavity moment image. Other measured parameters are: the radius of curvature at highest concavity; applanation lengths and corneal velocities during ingoing and outgoing phases (**Fig. 2**).

Quantitative parameters can also be extracted from the captured set of OCT images, using custom routines (Dorronsoro *et al.*, 2012). These routines involve corneal edge detection algorithms and numerical computations of temporal and spatial deformation parameters (deformation amplitude, speeds and durations of deformation) to extract the parameters, the stable non-deformed cornea immediately before the deformation event is compared with the deformed cornea during the air puff event. A subset of used descriptive parameters are graphically illustrated in **Fig. 3**: corneal thickness (1, red) at the corneal apex before and

Fig. 2 A. Air-puff spatio-temporal profile (from pressure measurements and hydrodynamics calculations); B. Cornea at maximum air-puff spatial deformation: Experimental and Fine-Element model in inverse optimization. C. Simulated corneal deformation with retrieved biomechanical parameters. Data are from Kling, S., Bekesi, N., Dorronsoro, C., *et al.*, 2014. Corneal viscoelastic properties from finite-element analysis of in vivo air-puff deformation. PLOS ONE 9 (8), e104904.

after the deformation, and during maximum deformation; *deformation amplitude* (4, red) at the corneal apex (representing the maximum deformation depth); *overall deformation period* (9); *increasing deformation period* (7); *decreasing deformation period* (8); *mean increasing and decreasing deformation speeds* (2 and 6, black); *peak increasing and decreasing deformation speeds* (3 and 5, orange) (maximum positive and negative slopes of the deformation curve, represented as orange lines).

The parameters above were obtained from high-speed A-scan measurements at the corneal apex, a measurement mode available in both described approaches. Additional information can be extracted from the dynamic B-scan measurements (along the horizontal meridian; Fig. 3), providing a direct view of the dynamic spatial deformation of the cornea. Analysis of the B-scans during the deformation event could theoretically provide similar results on the apex dynamics than the A-scan measurements. However, the temporal sampling in those measurements is lower resulting in a lower precision of the extracted temporal parameters. The B-scans were also used to obtain additional deformation parameters at maximum deformation: *diameter of the deformed zone* (10, green), *displaced corneal volume* at the moment of peak deformation (11, gray), *non-deformed corneal radius* (12) and *peak deformed corneal radius* (13).

Corneal Mechanical Properties From Air Puff Corneal Dynamic Imaging

Although the air puff corneal deformation can be characterized using several temporal and spatial deformation parameters deformation is affected not only by mechanical properties, but also by geometrical parameters (corneal thickness and, to a lesser extent, corneal curvature) as well as Intraocular Pressure (IOP) (Kling and Marcos, 2013a,b,c). Finite-Element-Models (FEM) have been recently been applied to reconstruct the inherent mechanical parameters of corneal tissue from Scheimpflug-based temporal and spatial deformation imaging, and on measurements of the temporal and spatial properties of the air-puff (Fig. 1) (Marcos *et al.*, 2014). To simulate the experimental conditions accordingly, the pressure characteristics provided by the air-puff system were determined. The temporal pressure profile was measured experimentally using a pressure sensor and then a computational fluid dynamics simulation was performed to determine the spatial pressure profile, and its change during the deformation event. The corneal tissue was modeled as a linear viscoelastic material, in 2-D. Inverse modeling, with a multi-step optimization procedure, was performed in order to find the biomechanical parameter set that best represented the different experimental conditions. Retrieved parameters include the modulus of elasticity, viscoelastic relative modulus and relaxation constant, and represent the suitable descriptive parameters to monitor corneal biomechanical properties and to predict the mechanical response to modeling.

The reconstruction of the inherent material properties from air-puff corneal deformation has been validated using phantom corneas of different hydrogel polymer materials and thicknesses and on porcine corneas, at a constant IOP of 15 mmHg (Bekesi *et al.*, 2016a,b). Uniaxial tensile tests were performed on the model cornea materials as well as on corneal strips, and the results were compared to stress-strain simulations assuming the reconstructed material parameters. The simulated stress-strain curves of the studied hydrogel corneal materials fitted well the experimental stress-strain curves from uniaxial extensimetry. Equivalent Young's moduli of the reconstructed material properties from air-puff were 0.31, 0.58 and 0.48 MPa for the three polymer materials respectively which differed <1% from those obtained from extensimetry. The simulations of the same material but

Obtained from extensimetry on corneal strips, and from air-puff corneal deformation imaging and inverse optimization. Green and Purple correspond to two different corneas. C. Obtained from air-puff corneal deformation imaging and inverse optimization in untreated rabbit corneas, rabbit corneas 1-month and 2-month following cross-linking treatment (RGX, Rose Bengal Cross Linking) in vivo, rabbit corneas following cross-linking ex vivo (measurements immediately after enucleation and treatment). Data are from Bekesi, N., Kochevar, I.E., Marcos, S., *et al.*, 2016a. Corneal biomechanical response following collagen cross-linking with rose bengal–green light and riboflavin–UVA. *Investigative Ophthalmology & Visual Science* 57, 992–1001; Bekesi, N., Dorronsoro, C., de la Hoz, A., Marcos, S., 2016b. Material properties from air puff corneal deformation by numerical simulations on model corneas. *PLOS ONE* 11 (10), e0165669 and Bekesi, N., *et al.*, 2017. Biomechanical changes after in vivo collagen cross-linking with rose bengal–green light and riboflavin–UVA. *Investigative Ophthalmology & Visual Science* 58, 1612–1620.

different thickness resulted in similar reconstructed material properties. The air-puff reconstructed average equivalent Young's modulus of the porcine corneas was 1.3 MPa, within 18% of that obtained from extensimetry.

Clinical and Experimental Applications of Air Puff Deformation Imaging: Cross-Linking

Corneal cross-linking (CXL) is an emerging treatment to halt the progression of ectatic disorders by crosslinking collagen fibrils and glycoproteins in the corneal stroma. Reconstruction of corneal mechanical parameters from air puff corneal deformation has been applied to the characterization of different modalities of CXL (Riboflavin UVA UVX and Rose Bengal Green light RGX) on rabbit eyes ex vivo and in vivo (under constant IOP) (Bekesi *et al.*, 2016b, 2017) as well as in a human eye in vivo (Kling *et al.*, 2014).

Corneal deformation amplitude decreased significantly after both CXL methods. The material parameters obtained from inverse modeling were consistent with corneal stiffening after both RGX and UVX. Within the treated corneal volume, the elasticity was found to decrease by a factor of 11 after RGX and by a factor of 6.25 after UVX following treatments ex vivo. Conversely, elasticity increased by factors of 3.4 (RGX) and 1.7 (UVX) 1 month and by factors of 10.7 (RGX) and 7.3 (UVX)

2 months after treatment in vivo. The equivalent modulus of elasticity of rabbits eye ranged from 1.43 MPa (untreated eyes) and 15 MPa (2-month post RGX, treated area). The estimated equivalent modulus of elasticity in a human eye was 0.45 MPa. Other estimates include viscoelastic properties, such as relative modulus and time relaxation constants. The viscoelastic effect was evidenced by the remaining deformation (between 18.7% and 24.1% of the overall deformation at different IOPs), which gradually decreased with time after the air-puff event. The viscoelasticity of the cross-linked porcine corneas ex vivo was described by a relative modulus of 0.7 and a relaxation time constant of 1.5 ms, and contributed with 46% to the maximal apex indentation.

Phase-Sensitive Optical Coherence Elastography

Principles and Implementations of Optical Coherence Elastography

The interferometric nature of OCT allows phase measurement for the detection of tissue deformation at micro- and nano-scales in amplitude and from static to ultrasound frequencies in the time scale. This capability has been harnessed for elastography, also known as optical coherence elastography (OCE), by employing appropriate mechanical stimuli. In the previous section, we have described an air-puff stimulus to induce macroscopic corneal deformation. Stimulus with reduced amplitudes can induce microscopic corneal deformation, which can be readily measured by phase-sensitive OCT. Compared to macroscopic air-puff, microscopic perturbation involves proportionally smaller strain changes in the tissue and less IOP changes. The smaller perturbations avoid the need of nonlinear mechanical analysis and minimize secondary effects, such as corneal tension and scleral expansion, induced by the IOP change. In this section, we describe a variety of elastography techniques based on phase measurement in OCT.

Early OCE studies used intensity-based measurement to track displacement of structures under an applied load. Intensity-based OCE has been applied for ophthalmic applications (Ford *et al.*, 2006, 2011, 2014; Torricelli *et al.*, 2014; Armstrong *et al.*, 2013), in which displacement vector is calculated from cross-correlation between initial and mechanically perturbed images. However, nowadays phase-sensitive detection has become a far more popular choice for OCE because it provides better displacement sensitivity compared to the intensity-based method.

In Fourier domain OCT, the phase of each image pixel is readily measured from the Fourier transform of the measured interferometric signal. The phase change $\Delta\phi$ can be directly related to the change in optical path length delay ΔL by a simple relationship: $\Delta\phi(z, t) = \frac{4\pi}{\lambda} \Delta L(z, t)$. Converting the optical delay to a true geometrical displacement requires knowledge of or assumptions about the refractive index distribution $n(z)$. It is also important to take into account the discontinuity of the refractive index at the corneal surface (Song *et al.*, 2013). The cornea is generally simplified as a two-layer structure consisting of a coupling medium of index n_0 (often the air) and a tissue layer of index n_1 . Then, the geometrical displacement is calculated from the phase profile within the tissue with respect to the phase at the corneal surface $\Delta\phi_0$ (Wang and Larin, 2014):

$$\Delta u_z(z, t) = \frac{\lambda}{4\pi n_1} \left(\Delta\phi(z, t) + \Delta\phi_0(t) \frac{n_1 - n_0}{n_0} \right)$$

The amplitude sensitivity, $\sigma_{\Delta L}$, of shot-noise-limited, phase-sensitive measurement is given by the signal-to-noise ratio (SNR) via $\sigma_{\Delta L} = \frac{\lambda}{4\pi} \frac{1}{\sqrt{\text{SNR}}}$. For example, for regions with SNR of 40 dB in OCT images, a displacement sensitivity better than a thousandth of the optical wavelength (i.e., sub-nanometer) is achieved.

Other noise sources, such as mechanical vibrations of optical components in an OCT system can increase the phase noise above the fundamental SNR limit. Some of the noise may be reduced by common-path interferometer designs (Choma *et al.*, 2005). Wavelength swept lasers in swept-source OCT tend to introduce additional noise to due phase jitter between wavelength sweep cycles and a data acquisition clock. A calibration mirror (Vakoc *et al.*, 2005) and real-time interferometric clock generation (Braaf *et al.*, 2011) have been developed to mitigate the swept laser-induced noise. Phase-sensitive detection can only measure the axial component of the displacement parallel to the axis of an OCT beam, and phase measurement may present phase-wrapping errors when the displacement amplitude is greater than the optical wavelength. Techniques to get around these problems have also been put forward.

Depending on the type of mechanical perturbations the applied stimuli induce on the cornea, we may sort elastography techniques in three categories: static, standing waves (i.e., vibrational resonance), and traveling (acoustic) waves, which are illustrated in Fig. 4. All approaches share common steps in operation. First, a mechanical force is applied to the tissue to induce deformation. Second, OCT is used to measure the deformation. And, finally a biomechanical model is applied to relate the observed deformation to tissue stiffness.

Static OCE was the first proposed approach for general OCE (Schmitt, 1998) and for ophthalmic applications (Ford *et al.*, 2006). It is based on the simple concept that softer areas deform more than stiffer areas. The well-known static mechanics is applied to derive tissue elasticity from measured strain for given external stress. Typically, the external stress is applied by compressing the tissue with a contact device, such as an objective lens or a transparent plate. Although this simple mechanical method is widely used for general measurements of ex vivo tissue samples, it is not as commonly used for applications to the eye because a noncontact approach is preferred for clinical diagnosis in patients. Nonetheless, several studies using ex vivo rabbit and human eyes showed the proof of concept by using a gonioscopy lens to compress the cornea (Ford *et al.*, 2011, 2014). Another

Fig. 4 OCT elastography techniques. Various mechanical loading methods have been employed to induce different types of perturbations ranging from static deformation and vibrational resonance to propagating acoustic waves.

variant of static OCE is to externally modulate IOP as a loading mechanism for cornea elastography. Proof-of-concept experiments were performed on ex vivo corneal explants (Ford *et al.*, 2006, 2016). Although this invasive technique is unlikely to be applicable in clinical settings, it could be useful for ex vivo measurements and animal studies.

Traveling wave OCE has been extensively used for ocular elastography. The basic principle of operation was adapted from shear wave elastography in ultrasound imaging. It uses a localized energy source to excite mechanical acoustic waves, which then propagate in the tissue. The wave parameters, such as the amplitude, velocity, and decay rate, are extracted from OCT measurements and related to the mechanical properties of the tissue. Various non-contact approaches are available to excite the traveling waves in the eye. As a direct analogue of ultrasound shear wave elastography, amplitude-modulated ultrasound was used to excite shear waves via acoustic radiation force (ARF), which are then detected by phase-sensitive OCT (Nguyen *et al.*, 2015). Intense pulsed laser light can excite acoustic waves via the photo-acoustic effect (Li *et al.*, 2012). However, both of these techniques require high ultrasound and optical energy to generate measurable acoustic amplitudes, raising safety concern to the eye. Some techniques to mitigate this issue have been proposed, such as numerical ultrasound pulse compression (Nguyen *et al.*, 2015) and surface reflection-induced ARF (Ambroziński *et al.*, 2016).

As described in the previous section, large-amplitude air puffs can induce millimeter-scale deformations in the cornea but such large deformations involve the non-linear response of collagen fibrils in the corneal stroma and thus add complexity to the mechanical analysis. Air puffs with a significantly lowered amplitude and shorter duration have been introduced to OCE as a way to excite traveling acoustic waves in the cornea (Wang *et al.*, 2013) and have extensively been investigated.

An advantage of traveling-wave OCE is that analytical relationships between Young's modulus and the acoustic wave velocity can be established. A few expressions have been derived, which are valid under different circumstances depending on the frequency and location of the excitation force. Vibrations generated at the surface of the cornea were often modeled as Rayleigh surface waves (Li *et al.*, 2012; Wang *et al.*, 2013), and Young's modulus E is obtained from the wave group velocity c_g using $E = \frac{2\rho(1+\nu)^3}{(0.87+1.12\nu)^2} c_g^2$. This formula is accurate only in a high-frequency limit in which the acoustic wavelength is much smaller than the corneal thickness. In more general cases, the impact of the thickness and curvature of the cornea, as well as the aqueous humor, have been investigated in detail (Han *et al.*, 2015b,c; Aglyamov *et al.*, 2015). A modified Rayleigh-Lamb wave model that accounts for the layered structure and viscosity of the cornea has been developed (Han *et al.*, 2015a, 2017).

Standing wave OCE is based on modal analysis, with the rationale that for a given structure geometry, a stiffer material will cause a higher resonance frequency. A frequency-domain method using sound wave stimulus has been proposed, in which the vibrational modes of the cornea or the whole eye globe are analyzed by sweeping the acoustic frequency. The eye has a fundamental resonance frequency of about 100 Hz (Akca *et al.*, 2015). As in the case of the air-puff methods, to extract elastic modulus numerical simulations would be necessary, which takes into account the entire eye globe as well as the cornea.

Applications of Optical Coherence Elastography in Ocular Tissues

Corneal biomechanics has been the major application area of OCE. This is in part because cornea is readily accessible for the induction of a mechanical stimulus but more due to the fact that the mechanical properties of the cornea are involved in number of pathological processes and are considered an important factor to consider in refractive surgeries and some vision treatments. The first demonstrations of cornea OCE were performed in the mid-2000s (Ford *et al.*, 2006; De La Torre-Ibarra *et al.*, 2006). But the interest for ophthalmic OCE increased considerably in the early 2010s with the progress of phase-sensitive OCE (Li *et al.*, 2012; Manapuram *et al.*, 2012; Ford *et al.*, 2011).

OCE can measure the biomechanical changes induced by CXL (Ford *et al.*, 2014; Singh *et al.*, 2016). In particular, OCE has been used to quantify the effects of standard epithelium-off CXL procedures for various transepithelial crosslinking reagents and femtosecond laser-assisted riboflavin-UVA CXL (Armstrong *et al.*, 2013). A follow-up study (Torricelli *et al.*, 2014) showed that benzalkonium chloride-ethylenediaminetetraacetic acid (BKC-EDTA) induced a larger stiffening effect than the standard epithelium-off riboflavin-UVA procedure. More recently, stiffness mapping of customized CXL treated corneas has been demonstrated (Singh *et al.*, 2017).

The age dependence of corneal stiffness was examined by using an oscillating tip as the source of mechanical waves on live mice (Manapuram *et al.*, 2012). The observed age-related increase in corneal stiffness with age was in agreement with previous measurements done by conventional mechanical measurements (Cartwright *et al.*, 2011; Elsheikh *et al.*, 2007). The relaxation rate after a mechanical stimulus was also shown to increase with age (Li *et al.*, 2014).

Besides the cornea, phase-sensitive OCE has been used to characterize the mechanical properties of the posterior sclera in ex vivo porcine eyes (Singh *et al.*, 2017) and measure the mechanical properties of crystalline lens in rabbit eyes (Wu *et al.*, 2015). Similarly, retinal OCE was performed on ex vivo porcine eyeballs (Song *et al.*, 2015).

Brillouin Microscopy

Brillouin Microscopy Technique

Brillouin microscopy takes advantage of a light scattering phenomenon first described by Brillouin (1922). When incident light hits a sample, it interacts with microscopic sound waves (acoustic phonons) within the material so that the scattered light has a slightly different frequency than the incidence light. Such acoustic phonons are inherently present in any material and are specific to the mechanical properties of the material. As such, the Brillouin frequency shift between incident and scattered light, can provide local mechanical information of the sample (Fig. 5). The Brillouin frequency shift is described by the equation:

$$(v)_B = \pm \frac{2n}{\lambda_p} \sqrt{\frac{M'}{\rho}} \cos\left(\frac{\theta}{2}\right) \quad (1)$$

In Eq. (1), n is the refractive index of the sampled material, M' is the real part of the longitudinal elastic modulus of the material, ρ is the density of the material and θ is the angle between incident and scattered optical radiation; importantly.

Because the light scattering is driven by acoustic waves, the changes in wavelength between incident and scattered light are in the 1–10 picometer wavelength range, or GHz frequency range. This is more than 1000 times smaller than changes observed with Raman scattering or fluorescence. Thus, to detect Brillouin signals, ordinary spectrometers cannot be used as they lack the spectral resolution to resolve Brillouin signal from input laser light and the spectral extinction to detect Brillouin scattered light in the presence of strong light with similar wavelength. A solution to this problem was first developed by JR Sandercock who developed a spectrometer using multiple-pass scanning Fabry–Perot (FP) interferometers (Sandercock, 1975). Sandercock's spectrometer has been used since the 1970s enabling noncontact mechanical analysis of materials in a variety of fields (Dil, 1982) including the first

Fig. 5 Brillouin Principle: When incident light hits a sample, it interacts with microscopic sound waves (acoustic phonons) within the material so that the scattered light has a slightly different frequency than the incidence light. Such acoustic phonons are inherently present in any material and are specific to the mechanical properties of the material.

characterization of ocular tissue (Vaughan and Randall, 1980). However, FP spectrometers are characterized by slow acquisition times (~ 10 min to hours per spectrum), therefore their applications to biomedical sciences is difficult.

In 2008, the introduction of virtually-imaged phased array (VIPA) etalons (Shirasaki, 1996) in lieu of FP interferometers greatly improved acquisition time (Scarcelli *et al.*, 2008). The VIPA etalon is similar to a FP etalon with few key differences: (1) the etalon is tilted and input light is diverging so that different incidence angle find different resonances; this enables to collect all the spectrum in one shot (Koski *et al.*, 2002); (2) the first surface of a VIPA is totally reflective and only allows light to enter the interferometer through a narrow anti-reflection-coated window; this prevents the formation of a reflected interference pattern which translates in about two-order of magnitude higher throughput. VIPA-based Brillouin spectrometers have been further improved in recent years thus enabling the transition from single-point Brillouin spectroscopy to an imaging modality through the combination with confocal microscopes (Scarcelli *et al.*, 2007a,b, 2008, 2011). This configuration has now been used for several years to measure tissue, cells and sub-cellular structures (Scarcelli *et al.*, 2015a; Scarcelli and Yun, 2012; Zhang *et al.* 2017a,b).

Brillouin modulus and relationship with standard mechanical properties

From a mechanical standpoint, Brillouin spectroscopy probes the response of a sample to a one-dimensional oscillatory strain of hypersonic ($\sim$ GHz) frequency. The measured frequency shift is related to the longitudinal modulus of material, as shown in Eq. (1). However, in Eq. (1) both index of refraction and density of material are not constant within a sample and from sample to sample therefore the extraction of Brillouin longitudinal modulus needs to be carefully examined. In biological material such as cells and tissues, density and refractive index are strongly correlated; for ocular tissues approximating density and index to constant values yields only a small percentage error. Therefore, local, three-dimensional, direct measurement of the longitudinal elastic modulus of material can be obtained by measuring the Brillouin spectrum. In crystalline materials, the longitudinal modulus (M') is related to traditional Young's modulus (E') in a straightforward manner through the Poisson's ratio (σ) via $M' = E'(1 - \sigma)/(1 + \sigma)(1 - 2\sigma)$. However, in biological material the fundamental relationship to Young's or shear moduli is not yet established because of the large difference in frequency of the test (quasi-static vs GHz) which is relevant due to the frequency-dependent moduli of most biomaterials (Mofrad and Kamm, 2006) and because of the near incompressibility of biological tissue due to the high water content.

For both cornea and lens tissue, an empirical correlation between Brillouin modulus and traditional Young's or shear modulus has been established experimentally. Such correlation has been found to be linear in log-log scale (Scarcelli *et al.*, 2011), which suggests a power-law relationship, consistent with what was previously found in tissue, polymers and cells (Deng *et al.*, 2006; Fabry *et al.*, 2001; Gittes and MacKintosh, 1998; Jonas *et al.*, 2008; Duck, 1990; Holm and Sinkus, 2010).

This offers the possibility of quantitatively measure cornea and lens mechanical properties after proper calibration. Specifically, for a given material we can write: $\log(M') = a \log(E') + b$, where the coefficients a and b are intrinsic properties of material that have a fundamental basis on atomic and molecular interactions. We can also write $\frac{\Delta M'}{M'} = a \frac{\Delta E'}{E'}$ where $\Delta M'$, $\Delta E'$ are respective derivatives or variations. This allows to estimate the sensitivity of the instrument to actual variations in Young's modulus. Current Brillouin instruments reach frequency sensitivity of ± 1 MHz/ $\sqrt{\text{Hz}}$, which corresponds to a relative error in longitudinal moduli, $\Delta M'/M' \approx \pm 0.3\%$ for an integration time of 0.1 s. Using for example $a=0.03$ measured with porcine corneal tissues, we determine that the Brillouin measurement can detect a difference in Young's modulus, $\Delta E'/E'$ of about 9% at an integration time of 0.1 s.

Applications of Brillouin Microscopy in the Cornea

Recent Brillouin measurements for the analysis of keratoconus, corneal collagen crosslinking and refractive surgery are promising (Fig. 6) (Scarcelli *et al.*, 2014, 2015b). For keratoconus, both ex vivo and in vivo human experiments were performed. For ex vivo

Fig. 6 Cornea Applications: (a) Representative Brillouin cross-section of a bovine cornea ex vivo reveals depth-dependence of Brillouin shift. Scale Bar 200 μm . (b) Representative depth profile of a bovine cornea ex vivo. A high correlation in depth is observed between regions of higher Brillouin shift and regions with higher content and more branching of corneal collagen.

analysis, normal tissue samples were obtained from donor corneas used in Descemet's stripping endothelial keratoplasty (DSEK); keratoconic tissue samples were obtained from deep anterior lamellar keratoplasty (DALK) procedure in advanced keratoconus patients. For the in vivo study, patients with advanced keratoconus were measured just before undergoing DALK surgery and compared to healthy volunteers. Ex vivo and in vivo analysis are consistent with each other: keratoconic corneas had overall lower Brillouin shift, thus lower elastic modulus. Thanks to Brillouin spatial resolution, we performed a spatially resolved analysis: the Brillouin shift of the normal corneas was observed to be relatively uniform across the central region of the cornea; while in keratoconus patients a strong spatial variation was measured with the cone showing the lowest Brillouin shift and indicating a large (up to ~70%) focal reduction in Young's modulus. Interestingly, away from the cone, the elastic modulus was very similar to normal cornea in both ex vivo and in vivo investigations.

For the analysis of corneal crosslinking, Brillouin has the potential to quantify the mechanical efficacy of various procedures. Because a universally recognized standard CXL protocol (Dresden) exists, we can use the log-log correlation to relate the changes of elastic modulus induced by CXL without calibration by comparing the unknown procedure to the standard Dresden protocol via the following equation:

$$\frac{\Delta M'_X}{\Delta M'_{Dresden}} = \frac{\Delta E'_X}{\Delta E'_{Dresden}}$$

Thus far, we have been able to use demonstrate Brillouin's ability to assess the efficacy of several cross-linking protocols while varying parameters of the CXL procedure (Reiss *et al.*, 2011). For example, corneal cross-linking currently requires an epithelium debridement prior to exposure to Riboflavin and UV-A. However, recent efforts have been given towards assessing the efficacy of the procedure without removing the epithelium (epi-On CXL) and, thereby, decreasing patient discomfort. The epi-on CXL procedure was estimated to induce about 33% of the stiffening done by the standard Dresden procedure. For comparison, the mechanical stiffening of the epi-on procedure was tested with gold-standard quasi-static rheology and was found to induce approximately 39% of the stiffening of epi-off CXL. Prior studies (Wollensak and Iomdina, 2009) found the mechanical efficacy of transepithelial CXL to be approximately 20% of standard CXL.

For the analysis of refractive surgery, we recently tested Brillouin's ability to assess corneal mechanical changes associated with LASIK surgery. LASIK surgery is expected to decrease the stiffness of the cornea due to the creation of a flap and the subsequent corneal ablation. To revert this potentially harmful effect, an accelerated CXL procedure has begun to be tested in combination with LASIK surgery. We used Brillouin microscopy to observe the properties of the cornea during the various stages of the LASIK/CXL combined procedure. After the LASIK flap was created, the cornea showed lower stiffness, especially in the anterior and central portions, where the flap was created. However, we observed no statistically significant difference after the flap-induced cornea was exposed to accelerated CXL. Therefore, using Brillouin microscopy, we were able to conclude the accelerated CXL procedure commonly paired with LASIK did not yield significant benefits towards increasing the compromised stiffness.

Applications of Brillouin Microscopy in the Crystalline Lens

The condition commonly known as presbyopia is related to the age-related loss of accommodation. Accommodation is the crucial biomechanical process of human vision that enables young persons to see near and distant objects by dynamically adjusting the focusing power of the eye. As age increases, the accommodation power drops. From a biomechanical point of view, this process is

Fig. 7 Lens Applications: Brillouin microscopy can detect the crystalline lens longitudinal modulus with high-spatial resolution in vivo. Here shown the mean sagittal longitudinal elastic modulus in 28-(black square) and 60-(purple dot) year-old human lenses ($n=3$). The red curves are power fits of the lens profiles.

due to the inability of the eye muscles to significantly change the shape of the crystalline lens. It has long been suspected that the loss of accommodation power is due to the diminished capacity of ciliary muscles to contract the lens with age. However, recent data indicate that ciliary muscles maintain ability to contract after the loss of accommodation (Ostrin and Glasser, 2007). Other potential candidate factors for presbyopia onset are age-dependent changes of the capsule and zonular fibers; but experiments have found too little changes to account for the decrease in accommodation power (Brian and Melinda, 2009; Fisher, 1969). Thus, the crystalline lens seems to be the main factor in the loss of accommodation; specifically age-related increased stiffness of the crystalline lens is suspected as the primary cause of presbyopia: as age progresses, the lens tissue stiffen which diminishes its ability to change shape (Glasser and Campbell, 1998, 1999).

Brillouin microscopy is a promising technique to characterize lens mechanical properties. In particular, the high 3D spatial resolution of Brillouin microscopy enables to characterize the spatial distribution of the longitudinal modulus within the crystalline lens (Fig. 7). In animal lenses, Brillouin microscopy revealed a dramatic age-dependent increase in the longitudinal modulus of the murine lens in vivo (Scarcelli *et al.*, 2011) and in porcine/bovine lenses ex vivo. In human lens, both the spatial distribution and the age dependence have been characterized (Besner *et al.*, 2016). In terms of spatial distribution, at all ages, the central portion of the lens was stiffer than the periphery, a result that was confirmed by ex vivo experiments using traditional standard shear rheometry. This result is consistent with some previous studies (Scarcelli *et al.*, 2011; Reiss *et al.*, 2011, 2012; Randall and Vaughan, 1982; Bailey *et al.*, 2010; Yoon *et al.*, 2013; Hollman *et al.*, 2007; Pau and Kranz, 1991) but not others (Fisher, 1971; Heys *et al.*, 2004; Weeber *et al.*, 2007; Wilde *et al.*, 2012). In terms of age dependence, Brillouin analysis did not find a statistically significant change of the peak longitudinal modulus with age, which confirmed previous Brillouin analysis performed ex vivo with FP interferometers (Bailey *et al.*, 2010). The most prominent age-related feature revealed by Brillouin was the increase of the stiff portion of the lens. Thus, Brillouin analysis does not support the previously reported “massive” increase of lens modulus as main factor to loss of accommodation (Fisher, 1971; Heys *et al.*, 2004; Weeber *et al.*, 2007; Wilde *et al.*, 2012). However, although more calibration mechanical studies are needed, with the given profiles and log-log correlation, the increase of the stiff portion of the lens would yield a 2-fold increase in the overall stiffness of the lens with age, which is consistent with previous ex vivo data (Glasser and Campbell, 1999; Augusteyn *et al.*, 2011).

Towards a Clinical Brillouin Microscopy System

A widely-available clinical Brillouin device that could measure biomechanical properties of the cornea and lens could find widespread application in both ophthalmic research and in the clinic. Currently available Brillouin microscopes have reached the performance levels to enable clinical testing and clinical studies to test the potential of Brillouin microscopy for keratoconus, crosslinking and presbyopia are currently on-going. For both cornea and lens applications, Brillouin microscopy has already shown biologically- and clinically-relevant information.

However, the success of Brillouin microscopy is highly dependent on its technology development. At the current mechanical sensitivities of in vivo instruments, Brillouin technology offers only ~10 discernable values for the stratification of patients of varying keratoconus stages. Also, current imaging sessions to collect a full Brillouin map of cornea or lens tissue may take 10–30 min. Finally, both the cost of the Brillouin microscope and the complexity of the setup represent an obstacle for widespread adoption in the clinic. Technological improvements are needed to address all of these issues. On this front, significant improvements have been shown already, although still at proof-of-principle stages: improved spectral selection at low loss has the potential to increase the throughput of Brillouin spectrometers (Fiore *et al.*, 2016; Shao *et al.*, 2016; Edrei *et al.*, 2017; Berghaus *et al.*, 2015a,b); novel multiplexed geometries could potentially speed-up the acquisition time by one to two order of magnitudes (Zhang *et al.*, 2016); standardized procedures for spectrometer alignment have been developed (Berghaus *et al.*, 2015a,b); the sensitivity of clinical instruments is currently limited by drifts due to temperature changes or laser instabilities, which could be removed with frequency locking or absolute frequency standards. Finally, improved speed and sensitivity could come from using higher laser power as all the experiments reported so far have used smaller illumination levels than the ones used in other clinical ophthalmic instruments. As a result, there is reason for optimism that Brillouin technology could be adopted in the clinic, focused engineering efforts aimed at making Brillouin microscopy faster, more sensitive, portable and easy to operate by non-experts will be crucial for the widespread use of the technology.

C-scan En-face image extracted from an OCT volume scan

Introduction

Optical coherence tomography (OCT) provides cross-sectional images of tissue with high axial resolution. Thereby the sample is probed using light in the infrared range. Image acquisition is performed noninvasively and nondestructively. The axial resolution of OCT lies in the micrometer range and is decoupled from the transverse resolution. This overcomes limitations associated with the numerical aperture of the objective and allows imaging with high axial resolution despite a moderate transverse resolution. Thus layered structures, such as human skin or the human retina, are well suited to be investigated with OCT. The penetration depth in tissue depends on the corresponding scattering properties and typically lies in the order of 1–2 mm. Structures that lie deeper within tissue can be visualized either because of overlying transparent tissue (as is the case in the human eye) or because of endoscopic probes that can be moved inside the body. OCT can be regarded as bridge between microscopic imaging technologies such as confocal microscopy (with limited depth penetration) to macroscopic imaging technologies such as ultrasound or computer tomography.

OCT is a highly sensitive technique and can achieve sensitivities ranging up to 110 dB or more. This allows detection of light even from weak backscattering samples. Image acquisition in OCT is done through recording of depth profiles (A-scans). Several laterally displaced A-scans form a cross-sectional image or B-scan. In a volume scan of the sample several laterally displaced B-scans are recorded. Another advantage of OCT is the high imaging speed. A-scan rates of several megahertz have been reported. Thus highly sampled volumes or several volumes per second can be recorded.

The highest impact of OCT certainly lies in the field of ophthalmology. No other imaging modality is capable to provide three-dimensional (3D) information of retinal tissue. Diagnosis and treatment control of retinal diseases are strongly depending on OCT images and the impact to the field can be compared with the invention of the direct ophthalmoscope more than 200 years ago. Many instruments are commercially available and OCT imaging has found a wide range of applications. Apart from ophthalmology OCT imaging can be found in dermatology, cardiovascular research, pulmonology, and many more. In addition to the biomedical field OCT has been applied to material sciences and art preservation (Stifter, 2007).

Basic Principle of OCT

The technique evolved from low coherence interferometry and was initially intended to measure axial distances in the eye. The basic principle is similar to ultrasound technology. However, instead of sound waves light is used to generate an image. The speed of light is much higher than that of sound waves. Thus, an interferometric technique is needed in order to distinguish between light that has traveled different distances in the micrometer range. Fig. 1(A) shows a scheme of an OCT interferometer. Light is emitted from an OCT light source and is split by the beam splitter into two arms, the reference arm and the sample arm, respectively. In the reference arm, the light is back reflected by the reference arm mirror. In the sample arm the beam is deflected on a scanning unit (for x- and y-scanning) before the light is sent to the sample. The light is backscattered from the sample, de-scanned and brought to interference with light from the reference arm at the beam splitter. The interfering light is then detected by the detector. It is very common to use fiber optics for the interferometer part. This eliminates the need for interferometer alignment and enables the fabrication of very compact systems. There are several techniques available for OCT.

Fig. 1 (A) Scheme of an optical coherence tomography (OCT) interferometer. BS denotes the beam splitter of the interferometer. For time domain optical coherence tomography (TD-OCT) the reference mirror is mounted on a translation stage. (B) Measured intensity I at the detector (interference pattern) when the mirror is moved in axial direction (reflectivity in sample and reference arm are equal) full width at half maximum (FWHM) denotes the full width at half maximum of the coherence function which is defined as axial resolution in OCT. (C) Measured interference pattern when a glass plate with thickness d is measured (n denotes the refractive index of the glass plate).

Timed Domain OCT

Initially the so-called time domain OCT (TD-OCT) technique has been used. In this technique the interferometer is illuminated with a broadband light source. To generate an A-scan (depth profile) the reference mirror is moved axially. In the case of a mirror in the sample arm, the detector will record an intensity pattern that is shown in Fig. 1(B). Due to the broad bandwidth of the source, interference fringes will only be visible if sample and reference arm lengths are matched (within the coherence gate). Thus light originating from different depths can be separated. In the case of a glass plate the light will be backscattered (or back reflected) at the front and back surface of the plate. During axial scanning of the reference arm mirror two coherence functions (arising at the surface and back surface of the glass plate) as illustrated in Fig. 1(C) will be detected. The distance between the two signals corresponds to the optical thickness of the plate (i.e., the geometrical thickness multiplied with the refractive index of the plate). The full width at half maximum (FWHM) of the coherence function is defined as the axial resolution of OCT and equals the round trip coherence length ($= 1/2$ of the coherence length) of the light source.

The A-scan rate of this technique is limited by the inertia of the mirror to a few 100 Hz. However, the method can be highly sensitive. Motion of the mirror will introduce a Doppler frequency shift for each wavelength. Thus, a carrier frequency for the OCT signal is generated which allows for band pass filtering of the signal. This procedure filters $1/f$ noise out and increases the sensitivity. Depending on the bandwidth of the light source and the speed of motion a certain electronic signal bandwidth needs to be detected. Faster speeds will require larger electronic bandwidths (of the detector and amplifying electronics) and thus lower system sensitivity.

To overcome the limitation given by the inertia of the mirror, a galvanometer scanning mirror and a grating (rapid scanning optical delay line) can be placed in the reference arm. Instead of a translational motion in spatial domain, this configuration allows for a rotational motion in wavelength domain. The method has the advantage that the group delay (axial scanning of the sample) and the phase delay (modulation frequency of the OCT signal) can be adjusted independently. Therefore the imaging speed can be improved up to a few kilohertz. TD-OCT detects only light backscattered from within the coherence volume of the sample. The coherence volume is defined through the round trip coherence length and the transverse resolution of the system. Light from other depths (outside the coherence volume) is rejected which limits the sensitivity of the method. However, the depth range of the system depends on the travel range of the reference mirror. Thus, in principle very long axial distances without loss in sensitivity can be scanned with TD-OCT.

Fourier Domain OCT

With the development of Fourier domain (FD) OCT the sensitivity could be greatly improved. The gain in sensitivity can be directly translated into imaging speed that allows A-scan rates an order of magnitude higher than in TD-OCT. Two different FD-OCT schemes are possible. The spectral domain (SD) OCT technique uses a similar broadband light source as in TD-OCT. However, instead of a single detector at the interferometer exit the light is spectrally dispersed through a grating and detected with a line scan camera (cf. Fig. 2(A)). Thereby, the reference arm mirror is kept stationary. In this way light from the entire sample depth is recorded simultaneously which results in a sensitivity advantage compared to TD-OCT.

In case of a mirror in the sample arm (same light power returning from sample and reference arm) the spectrometer camera will detect an interference pattern that is displayed in Fig. 2(B). The modulation of the spectrum arises from constructive and destructive interference for each wavelength and depends on the path length difference between sample and reference arm beam. Thus the frequency of the modulation depends on the amount of path length difference. Smaller differences result in low frequencies, while larger differences cause higher frequencies. In addition, the spectrum (and the interference pattern) is detected in the wavelength domain. Thus, each modulation frequency that corresponds to a certain depth will have a chirp along the spectrum. To remove this chirp, the spectrum needs to be transformed into k -space ($= 1/\lambda$ -space). Associated with this chirp will

Fig. 2 (A) Scheme of a spectral domain optical coherence tomography (SD-OCT) instrument using a spectrometer in the detection arm (BS, beam splitter). (B) Measured interference pattern when a mirror is placed in the sample arm (light power returning from sample and reference arm are equal). (C) Fast Fourier transformation of the spectrum measured in (B) corresponding to a depth profile.

be a drop of sensitivity (sensitivity fall off) with depth because of the finite width of the detector elements (camera pixels). Higher frequency components (constructive and destructive interference of neighboring wavelengths) will therefore be detected by a single detector element and thus not be visible. It should be noted that FD-OCT requires a minimum detection speed. Jitter within the interferometer or axial movement of the sample (in case of in vivo imaging) will cause a change (phase shift) in the interference pattern which degrades the visibility of the interference pattern when this change occurs during the exposure time of the camera. In order to avoid this “fringe washout” the exposure time should be shorter than 1 ms.

In the case displayed in [Fig. 2\(B\)](#) one arm is only slightly longer than the other. At this point it should be noted that it is not possible to distinguish (without any other means) between positive (reference arm is longer) or negative (sample arm is longer) path length differences because both will result in the same frequency modulation of the spectrum. In order to generate an A-scan the interference pattern (modulated spectrum) needs to be Fourier transformed. The corresponding depth profile is plotted in [Fig. 2\(C\)](#). Because of the inability to distinguish between positive and negative frequencies, the transformation of the spectrum yields in fact two depth profiles that are mirrored around zero delay. Zero delay refers to the position where sample and reference arm lengths are exactly matched. The total number of sample points after Fourier transformation stays constant. However, this means that the number of sample points per A-scan is only half the number of camera pixels. Because the mirrored A-scan does not contain additional information it is very common in OCT to simply omit this part as is done in [Fig. 2\(C\)](#).

The depth range of a SD-OCT system depends on the spectral resolution of the spectrometer as increasing depth is associated with higher modulation frequencies that need to be sampled according to the Nyquist theorem. This resolution is determined by the dispersion properties of the grating (number of lines that are illuminated on the grating), the spectrometer optics and the number of pixels that are available on the line scan camera. According to [Leitgeb et al. \(2003\)](#) the maximum depth range can be calculated via

$$z_{\max} = \frac{\lambda^2}{4\delta\lambda} \quad (1)$$

where λ and $\delta\lambda$ denote the wavelength and the spectral resolution, respectively. A typical OCT configuration uses a light source with a central wavelength of 840 nm, a bandwidth of 50 nm, and a 2048 pixel camera. Assuming that 150 nm bandwidth is imaged onto the camera and that the separation between spectral lines (corresponding to the resolution provided by the grating) is smaller than the size of a pixel an imaging depth of 2.4 mm is achieved. Back reflections from larger imaging depths will appear attenuated as aliasing frequencies and may cause unwanted artifacts inside an OCT image.

Another technique for realizing FD-OCT is swept source (SS) OCT. SS-OCT uses fast (wavelength) tunable lasers as light source in combination with a single (fast) photo detector. During a laser sweep the interference pattern is recorded depending on wavelength and separated in time. The pattern will be similar to the one displayed in [Fig. 2\(B\)](#). It should be noted that the instantaneous power at each wavelength can be higher compared to SD-OCT which compensates for the nonparallel data acquisition scheme of SS-OCT compared to SD-OCT. Similar as in SD-OCT, light backscattered from the entire sample depth contributes to the interference pattern and the depth profile is reconstructed in a similar way via Fourier transformation of the recorded spectral information. The instantaneous linewidth of the source determines the instantaneous coherence length and defines the depth range of the system. The instantaneous linewidth thus plays an equivalent role as the spectral resolution of SD-OCT. Within this range light from the reference arm and sample arm are coherent and can interfere. However, the instantaneous line width is a completely different measure as the round trip coherence length. The latter is defined by the FWHM of the laser sweep, while the former is the width of a laser line emitted at a certain wavelength within the sweep. [Fig. 3\(A\)](#) illustrates the emission of a SS laser.

The output power of many swept laser sources fluctuates. In order to compensate for this fluctuations balanced photo detection is employed. [Fig. 3\(B\)](#) shows a schematic of a fiber-based SS-OCT instrument. The light emitted from the SS is already confined in a single mode fiber. Before the entrance of the interferometer the light traverses a fiberized circulator and is split thereafter by a 50:50 beam splitter into reference and sample beam, respectively. The light back reflected from both arms is recombined by the 50:50

Fig. 3 (A) Illustration of a swept source (SS) laser sweep. The sweep range determines the axial resolution of the system. The instantaneous line width (drawn not to scale) determines the imaging depth provided by the light source. (B) Representative scheme of a SS optical coherence tomography (OCT) instrument based on fiber optics and balanced photo detection. BS 50:50, fiber beam splitter; GS, galvanometer scanner.

beam splitter and is detected with a balanced photo detector. The circulator ideally transmits nearly 100% of the light from the light source to the interferometer, while nearly 100% of the light coming from the interferometer is transmitted to the detector. There are several advantages of SS-OCT compared to SD-OCT. In SD-OCT the light is detected with a spectrometer. The efficiency of the spectrometer cannot be 100% which results in a lower sensitivity compared to SD-OCT. In addition the wavelength sweep can be performed in $1/\lambda$ space which results in an elimination of the frequency chirp that is present in spectrometer-based systems and correspondingly into an elimination of the sensitivity drop with depth. Finally, the spectrometer needs to be perfectly aligned in order to achieve a high sensitivity which sets high demands, from a technical point of view, on the spectrometer design in commercial instruments. No such alignment is required for SS-OCT instruments.

Resolution

The FWHM of the interference pattern (cf. Fig. 1(B)) defines the axial resolution of OCT and is inversely proportional to the bandwidth of the light source. In case of a Gaussian-shaped spectrum the resolution can be calculated via following equation (Drexler and Fujimoto, 2015):

$$\Delta z = \frac{2 \ln(2) \bar{\lambda}^2}{n \pi \Delta \lambda} \quad (2)$$

where $\bar{\lambda}$ denotes the central wavelength, $\Delta \lambda$ the bandwidth, and n the refractive index of the medium. As can be seen from this equation, the resolution in OCT depends on the central wavelength of the light source and the corresponding bandwidth. Fig. 4 shows the axial resolutions for three wavelength regions that are commonly used in OCT. Standard OCT resolution refers to bandwidths around 50 nm corresponding to an axial resolution between 5 and 15 μm . The use of larger bandwidths (100 nm or more) is known as ultrahigh resolution OCT and requires ultra-broadband light sources, such as titanium sapphire laser or supercontinuum light sources. Important for achieving the resolution in OCT that is provided by the light source is a sufficient optical transparency of the optical components and matching of dispersion (see below) introduced in reference and sample arm, respectively. Especially fiberized interferometers may cause unwanted effects because single mode propagation (multimode propagation results in coherent image artifacts) depends on the size of the core diameter in respect to the wavelength. Thus larger wavelengths will be stronger attenuated if the core size is chosen to ensure single mode propagation for the shortest wavelengths.

The transverse resolution mainly depends on the imaging optics in the sample arm. In order to achieve maximum fringe visibility it is common in OCT to use light with high spatial coherence. Light emitted from a single mode fiber has this property. Because of its directionality, divergence, and Gaussian intensity profile, the beam propagation can be described using Gaussian optics. In many OCT systems the objective lens is not the limiting aperture as the beam is scanned over this lens in order to achieve transverse scanning of the sample. Hence, the beam remains Gaussian and the resolution can be calculated via the FWHM of the Gaussian beam waist ω_0 and the angular spread θ_s of the Gaussian beam (Fercher, 2010):

$$\Delta x = 2 \sqrt{\ln 2} \omega_0 = 2 \sqrt{\ln 2} \frac{\bar{\lambda}}{\pi \theta_s} \quad (3)$$

$\bar{\lambda}$ denotes the central wavelength of the beam. Strictly speaking, this resolution can be obtained only at the focal (or certain depth) plane. Outside this focal plane the resolution is degraded. A measure for the imaging depth where the resolution is degraded only by a factor of $\sqrt{2}$ is the Rayleigh range z_R . Twice this range defines the depth of focus (DOF), which can be calculated with

$$2z_R = \text{DOF} = 2 \frac{\bar{\lambda}}{\pi \theta_s^2} \quad (4)$$

Fig. 4 Axial resolution of an optical coherence tomography (OCT) system depending on the bandwidth and the central wavelength for three commonly used wavelength regions. Standard OCT uses a bandwidth between 30 and 70 nm, which results in a resolution below 20 μm . Ultrahigh resolution (UHR) OCT refers to the use of larger bandwidths (> 100 nm) and corresponding resolutions that are below 5 μm .

Thus for high-resolution systems only part of the imaged volume will be in focus and imaged sharply. For an OCT system at 1300 nm and 20 μm transverse resolution the DOF will be 2 mm. This DOF will be reduced to 20 μm in the case of 2 μm transverse resolution. Hence, the imaging optics needs to be carefully designed in order to optimize the OCT performance. Several methods have been proposed to maintain high transverse resolution throughout the imaging depth. These are based on a dynamic shift of focus with the coherence gate (only possible for TD-OCT) or on the use of special illumination techniques (such as Bessel beams).

Sensitivity

Several noise sources influence the sensitivity in OCT. Receiver noise from the photo detectors, excess noise arising from fluctuations in light power, and shot noise that originates from the quantum nature (and random arrival) of photons. Ideally, an OCT system is limited by shot noise only. This limit can be reached through the coherent amplification process inherent to OCT as the light power returning from the reference arm greatly exceeds the power returning from the sample. In the case of sufficient light power from the light source, the amount of light returning from the reference arm can be optimized in order to reach the shot noise limit. In TD-OCT the shot noise limited sensitivity depends on the detection bandwidth and the power efficiency of the interferometer (Izatt *et al.*, 2015):

$$\text{Sensitivity} = \frac{\rho P_s}{2e\Delta B_{\text{TD}}} \quad (5)$$

where ρ denotes the quantum efficiency of the detector, P_s is the light power returning from the sample arm (with a 100% reflective mirror as sample), e is the electron charge ($e = 1.6 \cdot 10^{-19}$ C), and ΔB_{TD} is the electronic detection bandwidth of the TD-OCT systems. The light power returning from the sample depends on the power incident on the sample, the interferometer configuration, and the optical losses within the system. Let us consider a fiber-based Michelson interferometer with a 50/50 splitting ratio and 4 mW of optical power (central wavelength at 1300 nm with a bandwidth of 50 nm) on the sample. The light is emitted from a single mode fiber. Thus the coupling efficiency (of the light returning from the sample) will be $\sim 50\%$. Another 50% of the light is lost due to the fiber beam splitter which results in an optical power returning from the sample arm (with a 100% reflective mirror as sample) of 1 mW. When the above mentioned TD-OCT instrument is operated at 1 kHz A-scan rate and 3 mm depth range a minimum electronic bandwidth of 800 kHz will be required. This results in a sensitivity of the OCT system (assuming 0.8 quantum efficiency of the detector) of 103 dB.

In FD-OCT the sensitivity can be expressed in a similar way (Leitgeb *et al.*, 2003):

$$\text{Sensitivity} = \frac{\rho P_s}{4e\Delta B_{\text{FD}}} M \quad (6)$$

with ΔB_{FD} the electronic bandwidth of FD-OCT systems (inversely proportional to the exposure time of the camera in SD-OCT) and M the number of spectral channels of the FD-OCT systems. By comparing this equation with Eq. (5) we can see that the sensitivity of FD-OCT is a factor of $M/2$ larger than in TD-OCT. Thus, for a FD-OCT instrument operating with the same light source and interferometer as before will have an improved sensitivity. Nevertheless, following issues need to be considered. The light returning from the sample will be slightly attenuated by the efficiency of the spectrometer (this typically lies in the range of 60%) and the exposure time of the camera will be shorter than the time corresponding to the A-scan rate because the camera requires a certain readout time. For an A-scan rate of 70 kHz we assume that 1000 pixels on the camera are (equally) illuminated and that the camera requires 4 μs for readout. This results in an exposure time of $\sim 10 \mu\text{s}$. The detection bandwidth B of FD-OCT is given by (Leitgeb *et al.*, 2003)

$$B_{\text{FD-OCT}} = \frac{2z_R}{l_c \tau} \quad (7)$$

with z_R denoting the depth range of the system and l_c the double pass coherence length. τ is the exposure time of the camera. In our case ($z_R = 6 \text{ mm}$, $l_c = 15 \mu\text{m}$, and $\tau = 10 \mu\text{s}$) the detection bandwidth is 80 Mhz which results in a shot noise limited sensitivity of 108 dB. Thus, a higher sensitivity can be achieved with this SD-OCT system although the imaging speed is increased by a factor of 70.

Dispersion

Dispersion describes the effect of a wavelength dependent refractive index of a medium. For example, the refractive index of water (cf. Fig. 5) is not constant and decreases with wavelength. For OCT dispersion mismatch between the interferometer arms results in a degradation of the axial point spread function. This is associated with a degradation of axial resolution and sensitivity. Thus the interferometer arms need to be balanced which is normally achieved by inserting corresponding materials that are present in the sample arm (such as lenses for scanning optics) into the reference arm of the interferometer. For compensating dispersion of the eye cuvettes that are filled with water are commonly used. FD-OCT records spectral data. Therefore it is possible to compensate for dispersion in post-processing.

Wavelength Range

The choice of imaging wavelength in OCT depends on the investigated sample as well as on the availability of light sources. For a high penetration depth the total attenuation coefficient of tissue at the imaging wavelength should be minimal. Both, absorption and scattering contribute to the total attenuation coefficient. Water is the main constituent of tissue (apart from teeth

Fig. 5 The wavelength dependence of the refractive index of water in the visible and near-infrared (NIR) region. Data from Hale, G.M., Querry, M. R., 1973. Optical-constants of water in 200-nm to 200- μm wavelength region. *Applied Optics* 12(3), 555–563.

Fig. 6 Absorption coefficient of water and scattering coefficient of dense tissue. The three main optical coherence tomography (OCT) imaging wavelengths (840, 1060, 1300 nm) are outlined in the graph. Data from Hale, G.M., Querry, M.R., 1973. Optical-constants of water in 200-nm to 200- μ m wavelength region. *Applied Optics* 12(3), 555–563.

or bones) and its absorption properties will be dominating. As can be seen in [Fig. 6](#) the absorption coefficient of water strongly increases from visible light to infrared light. On the other hand, scattering gradually decreases in this wavelength range. At the 1300 nm wavelength region the contribution of scattering and absorption are largely within the same range. Thus, this wavelength region is the preferred choice for imaging dense tissue such as human skin as for shorter wavelengths the penetration will be limited by scattering, while for longer wavelengths absorption will be dominating. Imaging at 1300 nm requires detector materials that are sensitive in this region. These are much more expensive than comparable materials that are sensitive in the visible range. As such the preferred OCT imaging technology will be based on SS-OCT because this technology requires a single-balanced detector (instead of a detector array as in SD-OCT) and provides some benefits (as outlined above) compared to the SD-OCT counterpart.

For imaging the retina, the light has to traverse the ocular media (eye length of ~ 2 cm) twice which significantly changes the situation. The scattering properties of the retina are of less importance compared to the transmittance of the light through the eye. Ocular media are very weakly scattering (apart from pathologies such as cataract). Thus the imaging wavelength should be as close to the visible range as possible to minimize absorption by water. However, for highly sensitive measurements the quantum efficiency of the detector should be high. The used detector material, silicon, has a peak around 900 nm and levels off toward shorter wavelength. Thus imaging wavelength close to the maximum of the quantum efficiency of the detector is desirable. An additional aspect is that in the visible range the photoreceptors of the retina will be very sensitive to light (tails of the absorption spectra reach into the infrared region). Hence, the subjective perception of the light power will increase rapidly at wavelength regions that are close or within the visible range. This is associated with increasing subject discomfort during imaging, even though the light levels that are sent to the eye have to be below the limits for safe exposure. In addition dispersion is more pronounced for shorter wavelength regions. Because of these issues the wavelength region around 840 nm has been found as compromise and is widely used in OCT for retinal imaging. Since line scan cameras in this wavelength region are easily available and relatively cheap, the preferred imaging technique in this wavelength region is SD-OCT.

Nevertheless, another wavelength region at 1060 nm which is around a local minimum of the water absorption spectrum (cf. [Fig. 6](#)) has gained interest in recent years. Due to the longer wavelength region the penetration depth within the retina can be increased and the influence of media opacities (such as cataract) on the image quality will be lower. Another advantage of this wavelength region is the availability of fast SSs. Thus high sensitivity can be maintained throughout the imaging depth which further improves the retinal image quality. Due to technical issues (dispersion introduced by fiber optics), SSs at 840 nm are relatively slow compared to their counterparts at 1060 or 1300 nm.

OCT Angiography

In recent years, OCT angiography (OCTA), a method to visualize vessel structure within tissue, has gained increasing interest. There are many different approaches to realize OCTA. The underlying basic principle, however, is the same for all methods. The idea is that two (or more) measurements (A-scans or B-scans) are taken at the same location but separated in time. By comparing these measurements changes (intensity or phase or both) caused by blood flow can be detected. The time separation between these

measurements needs to be short enough in order to minimize the influence of sample motion and long enough in order to ensure sufficient changes introduced by blood flow. With A-scan rates of 100 kHz or more the most common OCTA technique is based on recording several B-scans at the same location. This, however, increases the overall measurement time.

The major benefit of OCTA is that it provides information on the microvascular perfusion of tissue noninvasively. In addition, due to the spatial separation of capillaries, these can be visualized even though the lateral extension lies below the transverse resolution of the system. Other techniques that are capable to provide information on the vascular structure require the application of contrast agents. Some subjects may show allergic reactions or other complications after administration of such contrast agents. Thus state of the art angiographic imaging is always associated with residual risk factors. Another benefit of OCTA lies in the fact that depth resolved information on the vasculature is provided. This allows for a separation between individual vascular beds and thus an improved image contrast. It should be noted, however, that OCTA is not able to detect vessel leakages because the technique relies on motion contrast. Within leakages motion occurring between individual B-scan recordings will be too slow compared to subject motion to be detected in vivo. However, in vitro experiments have shown that without bulk sample motion slow fluid motion (such as Brownian motion) can be visualize with OCTA techniques.

Imaging of Human Skin

The human skin is easily accessible with optical methods. In clinical routine, lesions will be first inspected visually with high magnification using a microscope (dermatoscope). In the case of suspicious lesions a biopsy will be taken which will be sliced and prepared for histologic examination. The cellular details provided by this histologic examination can then be used to determine the malign or benign status of a lesion and finally determines the further clinical procedure. OCT may represent an alternative to the histologic examination as it provides in vivo and noninvasively cross-sectional images of skin. Current studies focus on improving the sensitivity and specificity of OCT methods for detecting malign tissue (Ulrich *et al.*, 2016). Thereby, additional contrast mechanism such as polarization sensitive OCT or OCTA are used to gather additional information. Especially OCTA provides essential additional information as tumors, such as basal cell carcinoma (BCC) are known to present with increased vascularization.

Using fiber-based or handheld systems practically every location can also be reached with OCT. In order to minimize scattering and absorption, the preferred imaging wavelength for human skin will be in the 1300 nm range. The penetration depth of OCT in skin is in the order of 1–2 mm. Fig. 7 shows a representative B-scan image of a finger recorded with a 1310 nm SD-OCT instrument. The A-scan rate of the instrument was 91 kHz. The image consists of 500 A-scans and was recorded in ~5 ms. The bandwidth of the light source was 50 nm which results in an axial resolution of 10 μ m in tissue (assuming a refractive index of 1.4). The power onto the skin was 8 mW. Individual layers of the skin can be clearly seen in Fig. 7 and are labeled in the image.

Supplementary material related to this article can be found online at <http://dx.doi.org/10.1016/B978-0-12-803581-8.09787-3>.

An interesting skin region is the nail fold of a finger. In this region capillaries are close to the surface (close to the nail some capillaries extend parallel to the surface) and can be investigated with optical methods. In order to assess the status of the capillary network, capillaroscopy is used in clinical routine. This method examines the skin with a microscope after applying a contrast agent (such as oil) to the skin region. Using OCTA this network can be visualized completely noninvasively and without the

Fig. 7 Representative B-scan image recorded at 1300 nm of the inner side of a finger. Superficial layers down to deeper layers of the dermis can be visualized. The multimedia file (media 1) shows a fly through of B-scans of the entire three-dimensional (3D) data set.

Fig. 8 Representative optical coherence tomography (OCT) images recorded in the nail fold region of a healthy volunteer. (A) OCT-intensity B-scan (averaged over 5 B-scans). (B) Depth integrated en-face intensity image. The arrow indicates the location of the B-scan displayed in (A). (C) Depth integrated en-face intensity image and overlaid (red) vessel map.

application of a contrast agent. **Fig. 8** shows representative image data recorded with the SD-OCT instrument described above. The intensity B-scan (**Fig. 8(A)**) clearly shows different structures such as the nail plate and different skin layers of the nail fold. The banding structure within the nail plate is an artifact that originates from birefringence of the plate. The sensitivity of the system is sufficient to penetrate through the nail plate as structures underneath the plate can be seen. The axial displacement of the nail plate beneath the nail fold (cf. right hand side in **Fig. 8(A)**) is caused by the increased optical path length that is introduced by light propagation through the overlying nail fold tissue. The en-face intensity projection clearly shows the different regions of the nail fold and nail plate. **Fig. 8(C)** shows a composite image where the depth integrated vessel structure is overlaid to the intensity image of **Fig. 8(B)**. In this image the capillary network can be clearly seen. Close to the nail plate individual capillary loops can be seen which are typical for this skin region.

Imaging of Human Retina

The human retina consists of several layers and represents an essential part for the vision process. All layers that can be seen in histology can be visualized with OCT. **Fig. 9** shows a representative OCT B-scan image of the fovea region with a labeling of the different retinal layers. In healthy subjects the fovea is the location of best visual acuity. In this region the highest density of cone photoreceptors can be found. These cells are responsible for photopic vision and can be distinguished into three types (sensitive in the short, medium, and long wavelength region). In the fovea no rod photoreceptors (responsible for scotopic vision) are present. The light is incident from the top of this image and has to penetrate different retinal layers until it is detected by the photoreceptors. The pigments of the photoreceptors are located within the outer segments of cones and rods. The image was recorded with a research grade prototype SD-OCT instrument operating at 863 nm with a bandwidth of 60 nm which resulted in an axial resolution of $\sim 4 \mu\text{m}$ in tissue (assuming a refractive index of 1.4). The A-scan rate was 70 kHz and one B-scan consisting of 1024 A-scans was recorded in ~ 15 ms. Although the axial resolution is sufficient to resolve individual retinal layers, individual cells (such as photoreceptors) cannot be visualized. In order to increase the transverse resolution, aberrations that are introduced by imperfections of the eye optics need to be compensated for. This can be done with the implementation of adaptive optics, a technology known from astronomy (Pircher and Zawadzki, 2007).

Many commercial OCT devices for imaging the retina are available. **Fig. 10** shows representative data recorded with a commercial SD-OCT instrument. The instrument provides a scanning laser ophthalmoscope (SLO) overview mode that is used for retinal tracking. The location of the recorded B-scan is marked with a green line in the SLO image. The image quality is very similar to the previous image. The entire 3D data set can be viewed in media 2.

Supplementary material related to this article can be found online at <http://dx.doi.org/10.1016/B978-0-12-803581-8.09787-3>.

In order to outline the difference of retinal images recorded at different wavelengths, **Fig. 11** shows a retinal image recorded at 1040 nm. Compared to the previous images enhanced penetration into the choroid and even into the sclera can be seen. Otherwise all retinal layers can be seen with similar quality. The image was recorded with a research grade SS-OCT instrument operating at 100 kHz A-scan rate and 20×20 field of view. The axial resolution of the system was $5.6 \mu\text{m}$ in tissue.

Through a change in the scanning pattern (recording of several B-scans at the same location) angiographic data can be retrieved. **Fig. 12** shows representative data of a healthy volunteer recorded with a commercial instrument. The en-face projection images were generated through depth integration over the depth extension indicated with white arrows in **Fig. 12(A)**. **Fig. 12(B)** shows cross-sectional angiographic data (red) overlaid to the intensity image. The contrast of retinal vessels is greatly increased using the angiographic data evaluation. The en-face projection of the intensity images (cf. **Fig. 12(C)**) shows larger vessels as shadows.

Left: overview scanning laser ophthalmoscope (SLO) image. Right: optical coherence tomography (OCT) B-scan recorded at the location indicated in the left image with the green arrow. The multimedia file (media 2) shows a fly through of B-scans of the entire 3D data set.

However, the entire vascular structure can be seen in the corresponding OCTA projection map. This map clearly shows the avascular zone of the fovea region. From these maps deteriorations (such as non-perfused areas) from the normal vasculature structure can be easily determined.

Fig. 13 shows representative image data of patients with age related macular degeneration (AMD). AMD is regarded as one of the major causes of blindness in the industrialized world. The disease mainly affects the macula region (containing the fovea) of subjects that are older than 60 years. AMD can be differentiated into several forms: dry AMD and wet AMD. The latter is the most severe form which results (untreated) into a rapid degradation of visual acuity. An early indicator of AMD is the presence of Drusen. Drusen are elevations of the retinal pigment epithelium (RPE)/photoreceptor bands because of accumulation of retinal debris underneath these layers. **Fig. 13(A)** shows a typical example of OCT images recorded in a patient with Drusen. The elevations of the photoreceptors cause image distortions and degradation in visual acuity of the patient. At locations of the Drusen an additional layer (Bruch's membrane) can be seen. In the healthy case, this layer is obscured by the overlying RPE. Due to the highly scattering of the pigments within the RPE, this layer appears as broadened diffuse layer although it is a mono cellular layer. The 3D visualization of Drusen allows for a quantitative assessment of the size and volume of the Drusen. As such the effect of therapeutic interventions on the Drusen size can be precisely monitored.

The most severe form of AMD is choroidal neovascularization (CNV). In this case new vasculature is generated within the retina and leakages of these lead to damage of the sensitive neural tissue of the retina. **Fig. 13(B)** shows a representative B-scan of the fovea region of a patient with CNV. Scarring of retinal tissue and associated disintegration of photoreceptors is very often accompanied by this disease. Using OCT the size of edema or cysts can be quantified. In addition vascular growth can be determined using OCTA. Therapeutic intervention (such as anti-vascular endothelial growth factor (anti-VEGF) therapy) can be easily monitored and the technology can be meanwhile regarded as gold standard for this kind of diagnosis and for treatment control.

Fig. 11 Retinal image of the fovea of a healthy volunteer recorded with a swept source optical coherence tomography (SS-OCT) instrument at 1040 nm. Enhanced penetration into the choroid and sclera can be observed.

The arrows indicate the image depth that was used to generate the en-face images in (C) and (D). (B) Central B-scan of the volume scan and overlaid vessel structure (in red) retrieved with the angiography algorithm. (C) En-face intensity image (white=high intensity, black=low intensity) generated through depth integration over the area indicated in (A). En-face vessel map generated through maximum intensity projection of the angiographic data within the area indicated in (A).

Fig. 13 Representative optical coherence tomography (OCT) B-scans (averaged over 50 frames) at 840 nm of patients with age related macular degeneration (AMD). (A) OCT B-scan image of Drusen (some are indicated by white arrows). The black arrow indicates Bruch's membrane. (B) OCT B-scan image of a choroidal neovascularization (CNV). Images are displayed on a logarithmic intensity scale.

There are many other retinal diseases where OCT plays a key role in diagnosis. A summary of the impact of OCT to all these diseases will be beyond the scope of this article. Nevertheless, one specific example should be mentioned: Glaucoma, a disease that is associated with visual field defects and one of the major causes for blindness worldwide. At an early stage of the disease, these defects occur in the periphery of the retina which is not easily noticeable by patients themselves because for reading etc. only the fovea region is used. Before changes in the visual field can be detected, a loss of retinal nerve fiber tissue (loss in layer thickness) will occur. The 3D imaging capabilities of OCT enable a precise measurement of the retinal nerve fiber layer thickness. Thus OCT provides an excellent indicator for early signs of Glaucoma and for monitoring therapeutic success.

Conclusion and Outlook

OCT is a very powerful imaging technology. With the development of FD-OCT imaging speed could be greatly improved and A-scan rates in the megahertz range have become possible. This paved the way for many new applications of OCT. This article focused on skin and retinal imaging but many more applications of OCT are available. Associated with the improved imaging speed is the possibility to investigate dynamic processes or to increase the contrast through the introduction of angiographic evaluation of OCT data. The noninvasive visualization of capillaries in tissue, such as skin or retina, opens completely new perspectives for clinical research. The high clinical demand of this technology manifests itself through the rapid commercialization of OCTA for both, skin, and retinal imaging. Thereby, OCT certainly plays a key role for accurate diagnosis especially in ophthalmic routine. Nevertheless, there are new developments in the field. Currently new SSs are developed that provide higher speeds (A-scan rates) and very long coherence lengths. Meanwhile, imaging depth ranges of some meters have been demonstrated with OCT. This opens new possibilities such as imaging of the whole eye (from the cornea to the retina) with a single SS-OCT system. In addition further parallelization of OCT is investigated. Line field OCT, for example, records one B-scan in parallel. Thereby SD-OCT (this requires an area detector in the spectrometer) or SS-OCT can be used. The latter uses a SS in combination with a line scan camera. Very high speeds (several volumes per second) can be achieved using a full-field illumination in combination with a SS and a very fast area camera. The demands on the camera are very high because the phase stability (to avoid "fringe washout") requires the recording of a volume within a short time frame (ideally below 1 ms). In order to have sufficient sampling points in depth (determined by the number of spectral lines) the frame rate of the camera needs to be in the order of 50 kHz. Apart from the high imaging speeds that are possible and that have been demonstrated for in vivo retinal imaging, the full-field technique provides phase stability over the entire field of view (in lateral direction). OCT provides direct access to the phase of the electric light field and computational techniques can be applied in order to compensate for aberrations introduced, for example, by the eye. Thus high resolution can be achieved even without the use of hardware-based adaptive optics. In addition, the focal plane of the image can be adjusted in post-processing. As such, an entirely sharp volume can be obtained with high transverse resolution despite of a limited DOF.

Apart from these developments, OCT has become a valuable tool in cardiovascular research. Using fiberized probes, OCT imaging can be done from inside the body, for example, within a coronary artery. As such plaques, deposits, or stents within the artery can be visualized in vivo. Key element for this development is the high imaging speed provided by OCT. Currently clinical trials are performed to demonstrate the benefit of cardiovascular OCT compared to state of the art examination tools.

Another development in the field is the combination of OCT with other imaging technologies. For example, the combination of OCT with photo acoustics has gained increasing interest. The photo acoustic technique relies on absorption of the probing light beam and provides a higher penetration depth but lower resolution than OCT. Therefore vasculature that is located deeper within

tissue can be visualized. The combination with OCTA enables the visualization of the entire vascular network as superficial capillaries are detected with OCT, while the deeper vascular structure is detected with photo acoustics.

TIRF Microscopy and Variants

Daniel Axelrod, University of Michigan, Ann Arbor, MI, United States

Introduction

Total internal reflection fluorescence microscopy (TIRFM) is a method of illuminating a fluorescent sample so that only the zone proximal to the solid support (the “substrate”) will be excited. This high excitation selectivity greatly reduces background fluorescence from regions farther from the substrate. TIRFM has found many applications in studies of cell/substrate contact, intercellular organelles near those contact regions, and exo-and endocytosis, as well as single molecules studies where out-of-focus background would otherwise make detection difficult.

Numerous reviews of TIRFM have been written (Schneckenburger, 2005; Axelrod, 2014), including a chapter in the Encyclopedia of Cell Biology, also published by Elsevier/Academic Press (Axelrod, 2016). Those works (and their references) and the references in this article should be consulted for mathematical details of the basic theory and optical configurations. The emphasis here is on qualitative effects and intuitive explanations, with no equations presented. This chapter will focus on TIR-related issues of lateral and axial resolution, polarization, multiphoton variations, refractive index measurement, scattering, and combinations of TIRFM with other optical techniques.

Qualitative Basic Principles

TIR occurs at a planar interface between two dielectrics (defined as $z=0$) of different refractive index when the angle of incidence as measured from the direction normal to the interface in the higher index material exceeds some critical angle. From the viewpoint of simple ray optics and Snell's Law, at that critical angle, the refracted beam propagating into the lower index material refracts away from the normal and skims along the surface. At higher angles, the beam reflects 100% back into the higher index material. From the viewpoint of wave optics, the incident plane waves approaching the interface at subcritical angles change direction at the interface due to their increased speed in the lower index medium. However, the spacing of the wavefronts on both sides of the interface, as they intersect the surface, must be equal. That requirement, along with the fixed wavelength for propagation in the low index medium (set by the frequency and speed of light there) determines the orientation of wavefronts in the low index medium. At the critical angle, the wavefronts in the lower index material are oriented normal to the interface. At higher incidence angles, the geometry would force the spacing of the wavefronts to be closer than can be supported as propagating light in the lower index material, so instead, the wavefronts becoming exponentially decaying in amplitude with distance along the normal direction (the “ z -direction”) to the substrate (Axelrod, 2013). This spatially-decaying field in z is called the “evanescent field” of TIR. It still has wavefronts moving along the surface with an amplitude at $z=0$ at least as large as the incident field's amplitude (and usually higher), and those sinusoidal electric field fluctuations are fully capable of exciting light-absorbing (and possibly fluorescing) molecules. The evanescent field can also be scattered by refractive index variations in the low index material and thereby partially converted back into propagating light. Those two mechanisms – absorption and scattering – of the evanescent field, decrease the amplitude of the reflected beam to less than 100%, but that decrement typically is very small.

Lateral Resolution

In its standard, high aperture microscope objective-based form, TIRF is made possible by focusing the incident beam to a small spot at the objective's back focal plane, sufficiently far off-axis so the beam emerges collimated from the objective, and heads toward the sample at greater than the critical angle. For this to work, the objective aperture must be greater than the refractive index of the medium on the low density side of the interface (1.33 for water) and preferably at least 1.4. In the space between the BFP and final emergence, the beam expands from its focus, so TIRF is necessarily a wide-field method, possibly illuminating the entire field of view. Reducing the area of illumination is certainly possible (by decreasing the angle of convergence/divergence) while retaining the incident beam's focus at the objective back focal plane (BFP). But as that convergence angle decreases, the size of the focal spot at the BFP necessarily increases by diffraction. The result is that the angle of incidence starts to spread, and some light may even spread into sub-critical angles, thereby polluting the purity of the evanescence.

But for some purposes, a very small lateral area of illumination at the TIR/sample plane is desirable. One such purpose is improve lateral resolution by combining TIRF with structured illumination microscopy (SIM). In standard SIM (Gustafsson *et al.*, 2000; Hirvonen *et al.*, 2009), excitation field is given a periodic illumination (in one or two dimensions). Then at least three successive images are recorded, each with the periodicity shifted by 120 deg in phase; a computer algorithm then recombines these images into a rendition of the original image with substantially increased resolution. (Qualitatively, this works because two fluorescent points spaced apart by a sub-resolution distance will “see” different excitation intensities on the steep slopes of the

periodic illumination, and that difference will change or even reverse as the phase is shifted.) One commercially-available way of producing a periodicity is simply to project onto the sample the shadow of a grating positioned at an equivalent sample plane in the excitation path. But the finer the periodic spacing, the higher will be the ultimate reconstructed resolution. By interfering pairs of oppositely directed and mutually coherent TIR beams (Chung *et al.*, 2007; Kner *et al.*, 2009; Fiolka *et al.*, 2012; Beach *et al.*, 2014), a striped interference pattern in the evanescent field can be generated with a spacing that is significantly smaller than any that could be produced by either a projected grating or by interfering subcritical propagating beams.

This TIR-SIM procedure produces resolution improvement in one dimension only, the dimension transverse to the interference stripes. But two additional oppositely-directed coherent TIR beams (all split from the same laser source) can be introduced from the orthogonal direction, producing an interference checkerboard. This leads to improved resolution in both dimensions in the sample plane.

Conceptually extending this approach, evanescent fields could be configured to approach from many azimuthal directions simultaneously. These would all constructively interfere completely in only one location: at the very center of the field. In the most extreme case, an azimuthal circular ring of supercritical illumination will form a very tiny evanescent spot in the center, with a radius only about 2/3 of that obtainable by focusing subcritical laser beam (Axelrod, 2013). That spot would have not only the thin $\lambda/5$ to $\lambda/10$ axial decay length of standard wide-area TIRF but also an extremely small lateral size, thereby defining an illumination volume of only $\sim 0.005 \mu\text{m}^3$. Such a small volume could be used for scanning (Chon and Gu, 2004; Terakado *et al.*, 2009), for highly confined FRAP, and for FCS.

To create this highly concentrated TIR illumination pattern, the incident light must be confined to a supercritical radius ring at the back focal plane. If the light is focused to a sharp annulus in that BFP region, the polar angle of incidence at the sample (and thereby the evanescent field depth at the sample) will be a well defined value. If the light is merely limited to that region but not focused there, the polar incidence angle (and evanescent field depth) will span a range of values. This is the approach used by Chon and Gu (2004); Terakado *et al.* (2009). The polarization of the ring at the BFP should be such that any azimuthal direction will produce an evanescent field polarization that can interfere with that of every other azimuthal direction, as done by Terakado *et al.* (2009); otherwise, the smallest possible spot at the sample plane will not be produced. The only possible BFP polarization that can do this is radial polarization, which can be implemented by commercially available circular grating plates (Beresna *et al.*, 2011).

In standard intersecting beam TIR-SIM pairs with a finite number of azimuthal angles, the best resolution depends on how small can be the spacing of the interference fringes. Use of the highest refractive index substrate helps, because that decreases the wavelength of the incident light in the substrate. Another approach is to use a substrate that is imprinted with a periodic pattern spacing even smaller than the spacing of intersecting TIR beams. This can improve the resolution even farther. A grating also gives the optical system a resonance that increases the amplitude of the evanescent field for particular incidence angles and wavelengths. This occurs, for example, if the periodic grating spacing is an integral multiple of the incident light wavelength as measured along the TIR surface (Sentenac *et al.*, 2009).

TIR Polarization

The evanescent field is polarized according to the polarization of the incident beam. S-pol incident light (say, in the y direction, for incident light in the x-z plane) gives rise to s-pol evanescence (in this case, the y direction). P-pol incident light (say, in the x-z plane of incidence) gives rise to a p-pol evanescent field. The p-pol takes the form of an elliptical polarization, mainly along the z-direction but with some amplitude in the x-direction at a 90 deg phase difference. The characteristic decay distance of the evanescent electric field in the axial (z) direction is the same regardless of polarization.

The p-pol ability to produce a polarization in the z-direction is unique: standard EPI-illumination with excitation light directed along the axial direction produces only polarizations oriented in the sample plane, the x-y directions. That z-direction polarization cannot excite fluorophores whose dipoles lie parallel to the sample plane. But any deviation from parallelism can be excited. For example, a planar membrane labeled with a fluorophore (such as a carbocyanine dye with a double hydrocarbon tails such as diI or diD coupled by a conjugated bridge) whose excitation dipole lies in the local plane of the membrane will not be excited if the membrane itself lies parallel to the TIR substrate. But if the membrane is wavy or folded or has protrusions or indentations, those region will selectively “light up” under p-pol TIRF, against a dark background. This effect has been used to detect sites of endo- and exocytosis as they occur on living secretory cells (Steyer and Almers, 1999), and also to study the interaction and kinetics of fusion between lipid vesicles and planar supported membranes (Oreopoulos and Yip, 2009; Kiessling *et al.*, 2010). The technique requires that two images be recorded, one with p-pol, and one with s-pol for normalization. Optical designs to speed the switching and image acquisition have been devised (Johnson *et al.*, 2014).

Variable Polar Angle Illumination, Including Subcritical

The depth of the evanescent field is a function of incidence polar angle, decreasing rapidly from (theoretically) infinite right at the critical angle, down to about a single wavelength of light at about one degree higher than the critical angle, and farther down to about a tenth of the wavelength at skimming (90 deg) polar incidence angle. (However, the intensity of the evanescent field drops

monotonically with increasing incidence angle.) Another chapter in this Encyclopedia describes how this variation may be used to determine z-distance separation of a single fluorophore from a TIR surface, and previous reviews contain mathematical details. In principle, the z-dependent concentration $C(z)$ of a fluorophore near a substrate could be inferred by performing an inverse Laplace transform to the TIRF intensity vs. polar incidence angle I vs. θ profile. In practice, various reasonable guesses for $C(z)$ are tested by comparing their predicted I vs. θ profiles against actual measured profiles (Olveczky *et al.*, 1997; Oheim *et al.*, 1998). Variable-angle TIRF has also been used to measure the distribution of z-distances of whole secretory granules from the cell/substrate contact region (Rohrbach, 2000).

If the polar incidence angle is made to be slightly less than the critical angle, the incident beam refracts into the sample at a very high (but less than 90 deg) polar angle. If the subcritical incident beam were truly an infinitely-broad plane wave, as generally assumed in basic optical theory for TIR, then the z-depth in the lower index medium would be infinite. But in practice, a refracted beam skimming along the surface above the substrate has a finite depth. That depth is not easily controlled in commercial TIRF setups. But it can be estimated by viewing a fluorescent sample under epi-illumination with the angle of incidence adjusted to zero degrees (i.e., straight up in an inverted microscope, called “EPI-fluorescence”). The illuminated region will be roughly circular with fuzzy edges but with some characteristic radius on the sample. That radius (usually many micrometers) will be the approximate z-depth of the field of a barely subcritical beam when viewed at its position of emergence from the substrate. The emerging beam will form a “pencil” of light slowly diverging up from the substrate. By viewing the illuminated region “downbeam”, several micrometers from where it emerged from the substrate, the full diameter of the beam propagates in the lower density medium. By laterally shifting the emergence location from the region under observation, the height of that pencil above the substrate can be adjusted. This allows the ability to explore fluorescence from regions in that shaft of light at user-controllable varying depths into the sample, depths that are inaccessible to standard TIRF and yet do not excite as much out-of-focus background as does standard “straight-up” EPI. With a custom setup based around a free laser beam, rather than commercial setup based around an optical fiber, the radius of the illumination region can be controlled by changing the angle of convergence/divergence of the incident beam at the objective BFP: the smaller that angle, the smaller the radius and consequently the smaller the depth of the subcritical refracted beam. It should be possible to increase the lateral extent of the illumination without increasing the z-depth (i.e., to produce a sheet rather than a pencil) by use of a cylindrical lens.

Barely subcritical illumination has been given a variety of names in the literature: leaky TIRF, quasi-TIRF, pseudo-TIRF, and Highly Inclined and Laminated Optical sheet (HILO), and Variable Angle Epifluorescence microscopy, the last two of which are the most scientifically accurate since subcritical illumination is not TIR at all (Konopka and Bednarek, 2008; Lu *et al.*, 2013; Sun *et al.*, 2011; Tokunaga *et al.*, 2008).

Somewhat related to high angle subcritical illumination is “Light Sheet Microscopy”, in that a relatively thin sheet of illumination (but not as thin as in TIR) is imposed on the sample at an adjustable height from the substrate. The optical setup can be elaborate, involving two objectives trained upon the sample from orthogonal directions, one for sheet illumination, the other for detection, with a specially configured sample holder at the intersection of the two objectives’ focal planes (Weber *et al.*, 2014). Light-sheet microscopy has also been adapted for two-photon excitation, which produces a thinner effective sheet with less background (Zong *et al.*, 2015).

Even without varying the incidence angle, but just by setting it a slightly supercritical angle (to achieve a fairly deep evanescent field), the z-position of discrete sources can be deduced (at least over a couple of wavelength distance range), by analyzing the height and breadth of point spread function of the source (Mondal and Hess, 2017).

Two Photon TIRF

All of the above variants of TIRF are in the realm of linear optics (except for the very last one), in which the observed fluorescence is proportional to the first power of the illumination intensity. Multiphoton microscopy, by producing emission proportional to at least the second power of the illumination, has been used to greatly improve axial resolution in scanning focal-spot microscopies. It is reasonable to think that two-photon TIRF excitation should have the ability to halve the effective evanescent field depth and thereby produce even more z-selectivity than standard TIRF. In practice, the standard multiphoton illumination source is a pulsed laser with a near IR emission. In linear mode, that would produce a deeper evanescent field than would visible light, because the evanescent field depth is proportional to wavelength. In two-photon mode, the evanescent field depth is indeed halved, but that only brings it back down to what would have been obtained from single photon visible light.

The real advantage of multiphoton TIRF is further suppression of background scattering. Scattering from a variety of sources (see sections below) can be significant, but generally it is less intense than the evanescent field itself (at least near $z=0$). With its non-linear favoring of the brightest places, multiphoton techniques give an advantage to the pure evanescent field over background scattering (Oheim and Schapper, 2005; Lane *et al.*, 2012).

The Reflected Beam in TIR

The depth of the evanescent field is a function of the local refractive index on the low-index side of the interface. For any fixed supercritical incidence angle and particular substrate, the depth increases as the refractive index increases, and the dependence is

rather steep for barely supercritical angles. Unfortunately, the sample's refractive index is usually not known accurately, and may even vary laterally with heterogeneous samples. TIR itself, without the fluorescence, can provide the unknown information.

In TIRF, attention is on the evanescent field, and upon the detection of fluorescence that it excites. But the (nonfluorescent) reflected beam itself contains information about the sample. By replacing the standard dichroic mirror (used to reflect the incident beam up through the objective to the sample and block the transmission of the reflected beam) with a standard 100% mirror positioned only partway across the aperture, the reflected beam can be captured. The microscope/detector optical system that normally would image the fluorescence will now image the reflected beam itself. The image is not sharp (because only a fraction of the objective aperture is used), but it has an interesting feature. At image locations corresponding to locations in the sample where the refractive index is low (say, off-cell on a cell culture), TIR is achieved and the reflection is bright whereas locations with low refractive index are subcritical and the reflection is dim. As the incidence angle is increased stepwise over a stack of images, the transition from subcritical to supercritical is quite distinct, and the transition occurs over a specific narrow range of angles that is very sensitive to local refractive index. By analyzing the image stack, the spatially-resolved refractive indices of a cell culture's contact regions with the substrate can be calculated. A bonus result is a measure of the separation between the bottom of the cell and the substrate because increased separation affects the steepness of the local reflected intensity increase with angle ([Bohannon et al., 2017](#)).

In principle, the reflected beam's polarization also contains information about sample refractive index. If the incident beam is linear polarized at 45 deg (i.e., half s-pol and half p-pol), the two polarizations suffer different phase delays upon TIR. The reflected beam then will be elliptically polarized, to an extent that depends on local refractive index of the sample.

A coherent collimated supercritical angle incident beam before the TIR surface is a plane wave, but interaction with the laterally variable sample index sample distorts the wavefront flatness. By interfering the reflected beam with a plane wave reference beam from the same source, a hologram of the sample can be recorded digitally ([Ash et al., 2010](#)).

Supercritical Angle Emission

As discussed in another article in this Encyclopedia, an excited fluorophore embedded in a low refractive index near a higher index planar substrate will produce an emission pattern that is very different from what it would produce in isolation: see [Axelrod \(2013\)](#) for mathematical details. Part of this effect is simple refraction of the emitted light into the substrate, thereby changing its propagation direction. All of the propagating emission light is bent into angles that are "subcritical", leaving higher polar emission "supercritical" angles dark. But a major part of the effect is due to the existence of the fluorophore's "near field", evanescent light that does not propagate away from the fluorophore vicinity. If the substrate is close enough (within about a wavelength), it will capture some of the near field, convert it to propagating light, and send it into those high supercritical polar angles in the substrate material. In fact, the brightest emission propagates exactly at the border between sub and supercritical, at the "critical" angle itself. The exact critical angle is quantitatively related to the refractive index of the material in which the fluorophore is embedded.

To measure that critical angle, the sample's emission is collected with a high aperture objective, often the same as one that would be used for TIR excitation (i.e., NA generally greater than 1.4). The objective's back focal plane reveals a one-to-one mapping of emission angles into radial positions. By recording images of the brightest ring in the back focal plane, and measuring its radius, the sample's refractive index can be computed ([Brunstein et al., 2017](#)). Unfortunately, spatial information is lost, because emission light from any location in the image plane passes through all areas of the back focal plane. However, if the excitation region on the sample could be restricted and scanned, then spatially-localized refractive index information could be recovered.

TIR Scattering

An important limitation of TIRF is scattering of the incident light. Part of this scattering originates in the excitation path of the optical system itself, particular in objective-based TIRF. [Mattheyses and Axelrod \(2005\)](#) found this to constitute about 10% of the intensity at $z=0$. This is probably much less in prism-type TIRF because the excitation path there is largely out of the field of view. [Brunstein et al. \(2014a,b\)](#) found that the scattering originating in the optical system is generally larger than the scattering of evanescent light by a cell culture sample, at least for flat and confluent cultures. However, for thicker or denser cells, sample-induced scattering could be greater. This is a problem because the scattered light can excite fluorescence at z -distances well beyond the reach of the evanescent field itself.

One kind of scattering is generated when an "object", a portion of the sample generally larger than one wavelength, has a refractive index too high to support TIR at the incidence angle used. That higher refractive index can be spaced away from the TIR surface within about a wavelength, and still capture some of the evanescent field energy and convert it to propagating light: this is called "frustrated TIR". That propagating light can then scatter or even become trapped in structures that cause it to total reflect multiple times (such as in spherical beads). Another complication occurs because frustrated TIR disrupts the evanescent field, leaving downbeam objects in the sample in a shadow. It also can lead to multiple reflections between the sample object and the TIR surface, so that the object no longer "sees" a pure exponentially decaying field.

Of particular interest is scattering resulting from refractive index gradients in the sample, even if all regions have a low enough refractive index to support TIR at the given incidence angle. The simplest case is a sphere residing in an evanescent field. (The

sphere may be considered a simplified model of a biological cell in a TIRF experiment.) This is a special case of Mie scattering, which results from a propagating plane wave hitting a dielectric object larger than a small fraction of the wavelength. The results of such a calculation ([Ganic et al., 2002](#)) show that the scattering pattern is very different for propagating plane wave scattering vs. evanescent scattering; much of the symmetry is lost in the evanescent case. The angular pattern is also very dependent on the incident polarization. An alternative calculation ([Bekshaev et al., 2013](#)) recasts the plane wave to have an imaginary incidence angle; this is equivalent to an evanescent wave. In both cases, the results explicitly shown are for the case where the refractive index of the spheres is high enough to cause “frustrated” TIR, but the mathematical techniques should be valid also for spheres with much lower index. Neither approach accounts for optical interactions with the TIR surface (such as multiple reflections, capture of evanescent fields on the surface of the sphere by the TIR substrate, etc.), nor for multiple scattering, refocusing, and shadowing among nearby spheres. There is room for useful theoretical work in this area.

Interactions between the TIR surface and the sphere are taken into account by [Liu et al. \(2000\)](#). The radius of the sphere, in combination with the wavelength, leads to sharp resonances in the intensity of scattering, which also depends on separation distance of the sphere to the substrate compared to the radius. The calculations, however, assumed that the sphere was made of the same material as the planar substrate, and therefore is not directly relevant to practical TIRF, where the biological cell under view has a refractive index much lower than the TIR substrate so that an evanescent field can exist inside the cell.

An alternative approach to the TIR scattering problem dispenses with the single sphere and instead postulates a rough surface ([Nieto-Vesperinas and Sanchez-Gil, 1992](#)). In the theory, the roughness could be periodic, or a known function, or a randomly generated function. However, predicting scattering in practical TIRF is a somewhat different case, because the “roughness” is not in the (high index) substrate, but in a lower index layer (the cells) adhered to a smooth substrate.

TIR fluorescence microscopy was originally an outgrowth of prism-based TIR illumination in which the (non-fluorescent) scattering was collected and imaged through a microscope ([Ambrose, 1956](#)). TIR scattering, both static and dynamic (in which coherent scattered light from multiple scattering centers interferes and causes random intensity fluctuations), can be used to observe the behavior – positions and motions – of small objects or colloidal particles near the TIR surface ([Sigel, 2009](#)).

TIR Combined With FRAP or FCS or FLIM

A very early application of TIRF microscopy was actually not for imaging at all, but for measuring the dynamics of biomolecules at surfaces: on/off chemical kinetic rates and surface diffusion. When looking at a fluorescent solution with subcritical angle illumination (“EPI”) through a microscope, the fluorescence looks unchanging and uniform (apart from interference fringes if a coherent laser source is used). But when the incidence angle is increased to the critical angle and beyond, the view quickly changes to a more speckly appearance that also “twinkles” as molecules diffuse in and out of the thin evanescent region. By measuring the amplitude and rapidity of these fluctuations in a small lateral region (by autocorrelation of the fluorescence intensity), the absolute concentration, the reversible binding rates, and any surface diffusion can all be inferred ([Thompson et al., 1981, 2009](#); [Thompson and Steele, 2007](#)), a technique called TIR-Fluorescence Correlation Spectroscopy (TIR-FCS).

A different but related procedure, called TIR-Fluorescence Recovery After Photobleaching (TIR-FRAP) also measures kinetic rates and diffusion but calls for photobleaching the region near the substrate with a bright flash of TIR “bleach” illumination and then monitoring the post-bleach fluorescence recovery with a much dimmer TIR “probe” illumination. To see diffusion in a short experimental time, it is useful to reduce the area of illumination. One way is to shape it into a line ([Burghardt and Axelrod, 1981](#)). Another is to intersect two TIR beams, forming interference stripes, much in the manner of structured illumination but for a different purpose ([Fulbright and Axelrod, 1993](#)).

TIR-FRAP has been applied to measuring the diffusion of fluorescent-marked proteins inside secretory granules of living cells ([Ngatchou-Weiss et al., 2014](#)). These spherical granules are small (~ 300 nm in diameter), but the evanescent field depth is even smaller (usually <100 nm). Therefore, the TIR bleaching flash will photobleach mainly those proteins in the part of the granule most proximal to the TIR substrate. Recovery will occur during the probe phase of the experiment due to diffusive redistribution of protein within the granule, and its rate can be interpreted in terms of a diffusion coefficient. Care must be taken, as in all FRAP experiments, to account for spontaneous “reversible” recovery after photobleaching that may occur in the millisecond to tens of millisecond time scale, even in the absence of diffusion.

The nearby presence of a dielectric surface can affect the fluorescence lifetime of a fluorophore. This occurs by several possible mechanisms. One of them is the interaction of the surface with the fluorophore’s near field. This provides an additional path for energy to be drained from the excited state, shortening the lifetimes. Another mechanism is the change in the chemical environment near a surface: viscosity, ionic strength, accessibility of quenchers, etc. Since much biological fluorescence microscopy observes cells very near a supporting substrate (the coverslip), fluorescence lifetime imaging microscopy (FLIM) techniques have been combined with TIRF to specifically study the surface effects. The setup and applications are reviewed in [Gadella \(2009\)](#).

TIRF on Single Molecules

Detection of single molecules with single attached fluorophores is challenging in part because the number of photons available from a single fluorescent molecule before it photobleaches away is quite limited, typically less than one million, and many of these

photons may be absorbed or may miss the detector system. With few available photons, shot noise in the signal (due to the randomness of photon emission and detection) makes it imperative that other extraneous noise sources be reduced. One of the most common features in fluorescence microscopy is background, and even if it is constant in intensity, it can still produce its own shot noise that will bury the signal from the single fluorophore. TIRF has been effective in suppressing background, so it is used commonly in single molecule fluorescence detection. For reviews of the single molecule field in general, see [Lord et al. \(2010\)](#) and for a theoretical focus on the optical aspects, see [Axelrod \(2012\)](#).

A particularly unique aspect of single molecule studies is the ability to “see” the orientation of an immobilized molecule, not just to detect its existence. Some information about orientation can be gleaned from viewing the emission focused at the sample plane with polarizing filters, but the information can be ambiguous. As an alternative, analysis of the azimuthal distribution of emission at the back focal plane (BFP) of the objective ([Burghardt and Ajtai, 2009](#)) removes the ambiguity.

Introduction

Fluorescence microscopy is one of the most commonly used techniques for studying biological samples. It allows one to observe live samples in real time; the technical simplicity of fluorescence imaging techniques makes it accessible for a broad community of life-science researchers; and finally, specific labelling allows one to directly visualize sub-cellular structures. Moreover, in contrast to X-ray, electron, or atomic force microscopy, optical microscopy allows one to perform 3D imaging of thick samples up to hundreds of micrometers. However, the wave nature of light limits the spatial resolution of a conventional fluorescence microscope, i.e., it cannot resolve structures smaller than the diffraction limit. In the visible spectral range, this corresponds to a spatial resolution of roughly half a micrometer along the optical (z -) axis, and of about a quarter of a micrometer in the x - y plane. Abbe's equation,

$$d = \frac{\lambda}{2n \sin \alpha} \quad (1)$$

which was formulated in 1873, relates the resolution d of a lens with its numerical aperture $NA = n \cdot \sin(\alpha)$, and with the wavelength λ of light. **Fig. 1** shows a simulated diffraction limited focal spot formed by focusing a linearly polarized light of 488 nm with a perfectly designed lens of 1.2 NA into water. These are the parameters of a typical microscope that is used for the biological imaging, and the size of the shown focal spot defines the resolution of the system.

For more than a century, the diffraction barrier imposed by the wave nature of light seemed to be insurmountable. The fundamental step towards a change of perception of optical resolution was made only by the end of the 20th century, when 4Pi microscopy enhanced the axial (along optical axis) resolution by almost a factor of 7 (Hell and Stelzer, 1992). This invention was followed by the invention of numerous fluorescence imaging techniques, which meanwhile allow one to achieve nearly nanometer resolution (Hell, 2003, 2009; Huang *et al.*, 2009). All existing super-resolution microscopy methods can be mostly divided into the two general groups according to their fundamental principle of resolution enhancement: deterministic, and stochastic techniques (Hell, 2003, 2009; Huang *et al.*, 2009). Increase of optical resolution in deterministic methods is based on the non-linearity of fluorescence excitation. This group of methods includes STED, I⁵M, RESOLFT, SIM and their derivatives. The second group of super-resolution imaging techniques employs reversible stochastic photo-switching of fluorophores between photo-active and inactive states, which can be partially tuned using various physico-chemical parameters. Among these methods are STORM, dSTORM, PALM, GSD, SPDM, SOFI and variants thereof.

Whereas some of the above techniques squeeze the lateral resolution down to some tens of nanometers, the much less axial resolution remains a key limiting factor for applications where z -sectioning of a sample is required. This drawback of almost all super-resolution microscopy methods stimulated the appearance of another class of high-resolution axial imaging methods, either independent or complementary to the methods that enhance lateral resolution.

To avoid confusion, it should be noted that not all of the high-resolution axial imaging methods, which will be discussed below, can be technically attributed to the family of super-resolution microscopy. Whereas the term "super-resolution microscopy" implies a resolution of two or more closely located emitters located *on the same axis*, these techniques axially localize *single*

Fig. 1 The side view of the simulated diffraction limited focal spot created by 488 nm linearly polarized light when focused in water with a 1.2 NA objective lens. The dashed curves schematically show the direction of light focusing. Calculations are done by the methods of Jörg Enderlein, see Ref. Enderlein *et al.* (1999).

fluorophores (or in more general case fine structures) with nanometer accuracy. Later in the text, we will not emphasize this difference; however, it is important to keep it in mind to understand the limitations of the techniques discussed below.

Existing high-resolution axial imaging methods are based on several general approaches. First, the axial localization of a fluorophore can be determined by detecting it with different positions of the focal plane (biplane imaging (Juette *et al.*, 2008)), or by tailoring the shape of the point spread function (PSF) (astigmatic imaging (Huang *et al.*, 2008), helical wavefront shaping (Pavani *et al.*, 2009)). With such methods, one achieves ca. 70 nm axial resolution and ca. 30 nm lateral resolution. In all cases, the axial resolution is typically worse by a factor of 3–5 than the lateral one.

The second general approach is deducing the axial position of an emitter from relative intensities of single-fluorophore images when employing an interferometric detection system. Interferometric PALM (iPALM) (Shtengel *et al.*, 2009) and 4pi-STORM (Aquino *et al.*, 2011) approach single nanometer z-localization accuracy. However, the high technical complexity of the required optical system, and the need for tedious sample preparation and adjustment limit their applicability for routine microscopy measurements. Technically simpler coherent optical microscopy methods such as RCM (Limozin and Sengupta, 2009), or iSCAT (Kukura *et al.*, 2009) routinely achieve nanometer or even sub-nanometer localization accuracy of scattering/reflecting objects along the optical axis. However, the drawbacks of these methods are the lack of specificity of the imaged structures, and the reduced sensitivity when compared with most fluorescence-based methods.

In this article, we will focus on three distinct techniques for high resolution axial imaging, which combine unprecedented nanometer resolution with technical simplicity: Supercritical Angle Fluorescence (SAF) (Ruckstuhl and Verdes, 2004; Deschamps *et al.*, 2014), variable-angle Total Internal Reflection Fluorescence (TIRF) (Cardoso Dos Santos *et al.*, 2016; Stock *et al.*, 2003), and Metal Induced Energy Transfer (MIET) (Chizhik *et al.*, 2014; Karedla *et al.*, 2014; Baronsky *et al.*, 2017) microscopy. Despite the differences in their technical principle, all three methods are based on the same common effect of evanescence of light close to an interface. This general principle is in contrast to all other super-resolution microscopy techniques, which achieve resolution enhancement by reversible switching between different states of fluorescence emitters (either stochastically or deterministically). The axial localization methods discussed here are based on evanescent light, either in emission (SAF and MIET), or in excitation (variable angle TIRF).

In this article, we will discuss the physical principle of these methods, their technical implementation, applications, advantages, limitations, and potential future perspectives. In view of the numerous excellent articles and comprehensive reviews about each of these techniques, we will here not focus much on the mathematical formalism of the methods, but rather on recent technical implementations and an overview of recent applications that have not been discussed in other reviews.

Variable-Angle Total Internal Reflection Fluorescence Microscopy

In contrast to standard epifluorescence microscopy, in total internal reflection fluorescence (TIRF) microscopy the incident angle of the plane-wave excitation light is chosen above the critical angle of total internal reflection between the coverslide and the sample medium (see Fig. 2). Due to the fact that the refractive index n_2 of an aqueous solution is lower than that of glass, i.e., $n_1 > n_2$, this results in total internal reflection of the incident light at all angles that are greater than the critical angle

$$\theta_c = \arcsin(n_2/n_1) \quad (2)$$

Fig. 2 (a)–(d) Schematic of various prism-based TIRF excitation/detection systems. (e) Schematic of prismless TIRF excitation/detection scheme, where a high NA objective lens is used for transmitting both excitation and emission light. The optical components inside the objective lens are not shown; the light path is shown schematically.

Despite being totally reflected, the incident light generates an evanescent electromagnetic field that extends into the sample and decays exponentially with the distance from the interface according to

$$I(z) = I_0 \exp[-z/d(\theta)] \quad (3)$$

The penetration depth $d(\theta)$ of the electric field $I(z)$ at wavelength λ is given by [Axelrod et al. \(1984\)](#)

$$d(\theta) = \frac{\lambda/4\pi}{\sqrt{n_1^2 \sin^2 \theta - n_2^2}} \quad (4)$$

Exponential decay of the field intensity results in a confinement of the excitation volume within ca. the first 100 nm above the sample surface. Confining illumination of a sample within a narrow region allows one to enhance the signal-to-noise ratio by suppressing the background signal and out of focus fluorescence and to limit the photo-damage of the specimen, thus making TIRF an ideal tool for imaging cellular structures near the sample surface. The idea of using TIRF to illuminate cells in close contact with the sample surface was first proposed by [Ambrose \(1956\)](#) and later developed by [Axelrod \(1981\)](#). We will omit here further details on TIRF microscopy and its variants, which are extensively described in the article by Daniel Axelrod. In the current article, we will focus on one of its advanced varieties that allow for extracting the fluorophore-substrate separation distance with axial resolution of 10 nm for certain types of samples.

The exponential decrease of the evanescent field upon TIRF illumination of the sample allows one to estimate the axial localization of a fluorophore by measuring its relative brightness. However, quantitative interpretation of a TIRF image for extracting the distance between an emitter and the substrate surface is far from being trivial ([Cardoso Dos Santos et al., 2016](#)). The contrast of TIRF images depends on several parameters, such as the local concentration of fluorophores, their orientation, absorption cross section, and angular emission distribution, as well as on local variations of the fluorophore's quantum yield and the sample's refractive index ([Chizhik et al., 2011](#); [Mertz, 2000](#)).

The situation becomes even more complicated by the fact that some of these parameters can vary as a function of height ([Chizhik et al., 2014](#); [Mertz, 2000](#); [Enderlein et al., 1999](#); [Enderlein, 1999](#)). This complication can be addressed by recording a series of TIRF images at different incident angles of the incident light. Since all the above parameters do not depend on θ , their values will not change by varying the angle of incidence. By including all the unknown parameters in a new factor $\chi(x, y, z)$, one can rewrite [Eq. \(3\)](#) as

$$I(x, y, z, \theta_i) = \chi(x, y, z) \gamma(\theta_i) \exp(-z/d(\theta_i)) \quad (5)$$

where $\gamma(\theta_i)$ is the correction factor that takes into account the variation of the field intensity at the substrate-sample interface as a function of the angle of incidence θ_i ([Axelrod et al., 2002](#)). Taking the logarithm of [Eq. \(5\)](#), one obtains

$$\ln \frac{I(x, y, z, \theta_i)}{\gamma(\theta_i) - \gamma(\theta_1)} = \ln[\chi(x, y, z) \gamma(\theta_1)] - \frac{z}{d(\theta_i)} \quad (6)$$

The logarithm on the left side of [Eq. \(6\)](#) depends linearly on $d^{-1}(\theta_i)$. Therefore, by using a linear fit in each pixel of the fluorescence image measured at different angles of incidence, one can retrieve the fluorophore-substrate distance, without requiring any information on parameters related to the molecular parameters, such as quantum yield, absorption cross-section, or concentration. This technique, known as variable-angle TIRF (vaTIRF), was introduced in the mid-eighties ([Lanni et al., 1985](#); [Gingell et al., 1985](#)) for studies of sub-cellular structures.

One of the advantages of vaTIRF is that it allows one to simultaneously determine the value of the effective refractive index (n_2 in [Eq. \(4\)](#)) of the sample, which includes the combined influence of any water gap between a cell membrane and the substrate surface, and the cytoplasm inside the cell. This index determines the penetration depth $d(\theta)$ of the evanescent field ([Cardoso Dos Santos et al., 2016](#)).

VaTIRF was used for quantification of the membrane height on focal adhesion zones ([Burmeister et al., 1994](#)), for mapping the topography of cells above a substrate ([Olveczky et al., 1997](#)), for studying axial motion of secretory granules in the ventral side of living cells ([Loerke et al., 2002](#)), and to investigate the influence of 5-aminolevulinic acid on the adhesion of tumor cells ([Lassalle et al., 2007](#)).

Experimentally, the first realizations of vaTIRF were based on an optical coupling of the substrate to a glass or quartz prism of cubic, trapezoidal, hemi-cylindrical or hemi-spherical shape ([Fig. 2\(a–b\)](#)). One of the key challenges is to keep the position of the illuminating light spot on the sample constant while changing the angle of incidence. This is possible only when using a hemi-spherical or hemi-cylindrical prism or a multiple focus laser scanning system ([Stock et al., 2003](#)). A drawback of all these vaTIRFM systems is that when a prism is used to generate the evanescent wave, the microscope objective is then mounted on the opposite side of the sample for fluorescence collection, which often diminishes the image quality, for instance in case of low sample transparency or strong light scattering. To address this issue, a prism-less approach in TIRF has been proposed ([Axelrod, 2001](#)). Indeed, a prism-less setup based on an inverted microscope equipped with a high numerical aperture (NA) objective ($NA > 1.4$) allows for obtaining images with the full resolution defined by the NA. In this configuration, the objective is used both to create the evanescent excitation and to collect the signal ([Fig. 2\(e\)](#)). The prism-less approach simplifies installation and adjustment of the optical system which is required for tuning incidence angle of the excitation light. Recently, [Boulanger et al. \(2014\)](#) demonstrated the superior capability of a prism-less setup in vaTIRFM by imaging the cortical actin network. Jaffiol and co-workers used a similar system for studying adhesion of MDA-MB-231 cancer cells to a glass substrate ([Cardoso Dos Santos et al., 2016](#)). By recording a

series of 10 TIRF images with different incidence angles of excitation light, the authors achieved an axial resolution close to 10–20 nm that makes vaTIRF suitable for quantifying cell adhesion structures or cell topography. Sequential vaTIRF imaging with selective photobleaching of molecules within the lower layers close to the interface can be used for straightforward observation of deeper structures within a sample without masking signals from farther distances by the brighter signals closer to the substrate (Fu *et al.*, 2016).

Super-Critical Angle Fluorescence Microscopy

Almost all fluorophores can be considered as ideal electric dipole emitters. Along with the far-field component, the dipole also has a near-field part which is not connected to far-field radiation, but which can strongly interact with nearby structure and interfaces. Let us consider a fluorophore that is located in close proximity to an interface separating two media with different refractive indices n_1 and n_2 . The electric field of the emitting fluorophore can be represented as a superposition of plane waves, where each of these plane waves is refracted according to Snell's law when travelling from medium with refractive index n_2 into the medium with refractive index n_1 ($n_2 < n_1$). As a result, the emission into medium 1 is restricted within a cone limited by the critical angle

$$\theta_c = \arcsin(n_2/n_1) \quad (7)$$

This component is referred to as under-critical angle fluorescence (UAF). However, if the fluorophore-interface distance is smaller than the fluorescence wavelength, then additional super-critical angle fluorescence (SAF) emission is observed (Enderlein *et al.*, 1999) due to the coupling of evanescent near-field components of the dipole field into medium 1. As a result, one can now also observe, in medium 1, emission along angles larger than the critical angle θ_c .

Fig. 3(a) and (b) show the angular distribution of emission for an isotropically oriented molecule that is located directly at the glass-water interface (a), or separated by a third of its emission wavelength (b). Thus, displacing the fluorophore by only a few tens of nanometers away from the interface leads to a strong angular redistribution of emission, a large part of which can be found

Fig. 3 Polar plots of the emission direction of molecules with isotropically oriented transition dipole (a) at the water/glass interface and (b) a surface distance equal to a third of the emission wavelength. (c) Dependence of SAF emission on the molecule's axial position. Calculations are done by the methods of Jörg Enderlein, see Ref. Enderlein *et al.* (1999).

Fig. 4 (a) Schematic of the SAF and UAF fluorescence detection system. (b) Angular distribution of emission of a fluorophore at different axial positions and the corresponding distributions of the SAF and UAF at the back focal plane of the objective lens. Calculations are done by the methods of Jörg Enderlein, see Ref. Enderlein *et al.* (1999).

above the critical angle of 61.1° for the given ratio of refractive indices. This modulation of emission can be directly visualized by collecting the fluorescence with a high NA objective lens and measuring the profile of the collimated beam with a sensitive EMCCD chip. Fig. 4(a) shows a schematic of such a measurement. The dashed ring corresponds to the photons emitted at the critical angle. All the light which is detected inside this ring is the under-critical fluorescence. The light that is detected beyond the dashed ring corresponds to the super-critical fluorescence. Depending on the axial position of the emitter, the ratio of the super- and under-critical fluorescence changes (Fig. 4(b)).

It should be emphasized that the dependence between the axial position of the emitter and the angular distribution of the emission is analogous to and the reverse of the exponential decay of a TIRF excitation intensity. In that case, there is a close relationship between the angle of incidence and the penetration depth of the evanescent light above the interface, as we have seen in the previous section (vaTIRF microscopy).

The number of photons emitted beyond the critical angle is maximized when the fluorophore is directly bound to the surface, and it equals $\sim 34\%$ in case of a random dipole orientation at a glass-water interface (Ruckstuhl *et al.*, 2003). Moving the molecule away from the interface leads to a steep decrease of the intensity of supercritical fluorescence (Fig. 3(c)), which drops by a factor of 2 when the emitter is separated by nearly one sixth of the emission wavelength.

The quantitative measurement of the fluorophore's axial position requires either the determination of the supercritical-to-undercritical angle fluorescence intensity ratio, or the measurement of the absolute intensity of the supercritical angle fluorescence. The core idea of SAF microscopy and the first technical realization of the corresponding optical system which allows for collecting the fluorescence emitted above the critical angle was proposed by the group of Stefan Seeger (Enderlein *et al.*, 1999). The fluorescence detection system consisted of a parabolic glass element (Fig. 5(a)), which acts as a TIR mirror that collects the fluorescence light around the angles of maximum emission. Ruckstuhl *et al.* have used this light collection scheme for simultaneous measurement of both under- and supercritical angle fluorescence (see ref. Ruckstuhl and Verdes (2004)). One of the drawbacks of the system is that the paraboloid glass segment also serves as the substrate, which however can be simplified by using a coverslip that is placed on the paraboloid's front face with index-matching immersion oil. Recently, Hill *et al.* have proposed the use of low-cost disposable biochips for supercritical angle fluorescence detection for multiplexed clinical diagnostic applications (Hill *et al.*, 2011), which simplified the application of parabolic light collectors for routine measurements.

The more critical issues of using the parabolic light collector are low compatibility with standard microscopes and the impossibility to take wide-field images (Enderlein *et al.*, 2011). In recent years, the parabolic light collector has been replaced by high NA objectives which allow also for wide field imaging. For collecting all the under-critical fluorescence, one needs an objective the numerical aperture of which is equal or larger than the critical TIR angle between the sample and the objective's immersion medium. A simple calculation shows that for emitters bound to a glass-water interface, one has to use at least a NA of 1.33 for collecting all the under-critical angle fluorescence, which is distributed within a cone of opening angle 61.1° . Collection of the supercritical angle emission requires a large value of the numerical aperture. For this reason, SAF microscopy has become

Fig. 5 (a) Schematic the parabolic collector for detection of the SAF. (b) Schematic of the high NA objective lens-based vSAF light collection scheme. Fluorescence is split in two parts: in the first detection channel, the EPI part is measured; in the second channel, only the UAF part is recorded (the SAF component is blocked in the back focal plane). As the result of the subtraction one obtains the virtual mask where only the SAF component is conserved.

widespread with the accessibility of TIRF objective lenses, which can possess NA values up to 1.49. This corresponds to a collection angle of about 79° and allows one to collect nearly all the supercritical angle fluorescence.

The first realization of SAF microscopy based on collection of both super- and under-critical fluorescence with a commercial 1.49 NA objective lens has been demonstrated in the group of Emmanuel Fort (Barroca *et al.*, 2012). A modified method that is referred to as virtual SAF (vSAF) is based on measuring fluorescence wide-field images both over all emission angles, and only over UAF emission angles (Fig. 5(b)). The latter was done by mechanically blocking the SAF part. As a result, the images that are obtained with the full angular distribution of emission allow for maximizing the lateral resolution, while calculating the difference of emission in the two channels results in the SAF image.

The use of a standard objective lens for SAF microscopy allows one to combine SAF microscopy which enhances axial resolution with super-resolution imaging techniques that increase the lateral resolution. By combining dSTORM and SAF microscopy, Bourg *et al.* have achieved close to 20 nm isotropic three-dimensional localization precision of fluorescent molecules in the basal cell membrane and on F-actin fibers within the first 150 nm above the substrate surface (Bourg *et al.*, 2015). Simultaneously, Ries and co-workers have used a similar experimental approach for imaging immunostained clathrin-coated pits and microtubules (Deschamps *et al.*, 2014).

Metal-Induced Energy Transfer Microscopy

As was predicted by Purcell (1946), placing a fluorescent molecule in the vicinity of a metal surface quenches its fluorescence and decreases its excited state lifetime. The mechanism of this phenomenon is similar to that of Förster resonance energy transfer (FRET): energy from the excited molecule is transferred, via electromagnetic coupling, into plasmons of the metal, where energy is either dissipated or re-radiated as light. The fluorophore-metal interaction was extensively studied in the 1970s and 1980s (Drexhage, 1974), and a quantitative theory of this interaction was developed on the basis of semi-classical quantum optics (Enderlein, 1999; Barnes, 1998). One of the key parameters that determine the character of the interaction between a quantum emitter and a metal structure is the size of the structure. If the metallic nanostructure is smaller than the wavelength of light that is emitted by the fluorophore, the fluorophore's radiation leads to a uniform oscillatory displacement of electrons inside the nanostructure, leading to strong restoring forces that act on these charges. These restoring forces become biggest at a certain

oscillation frequency, which is called plasmon resonance. Furthermore, these coherent oscillations of free electrons in metallic nanoparticles generate a highly localized electric field in close proximity to the particle's surface. Depending on the type of metal or the nanoparticle's shape and size, the plasmon resonance can be tuned to different spectral ranges for maximizing fluorophore-particle interaction. Interaction of fluorophores with localized surface plasmons has found numerous applications, with fluorescence enhancement being the most important one. Here, we will not further focus on the details of this kind of fluorophore-metal interaction and redirect the reader to the numerous existing extensive reviews.

A fundamentally different type of the fluorophore-metal interaction occurs when the fluorophore is located in close proximity to a smooth metal surface. The fluorophore's radiation creates charge density oscillations in the metal surface that are called propagating plasmons. Here, we will show how the interaction of fluorophore with a smooth metal surface can be used for axial localization of a fluorophore with nanometer accuracy. The core idea is that this interaction accelerates the return of an excited fluorescent molecule to its ground state, which manifests itself as a shortening of its excited state lifetime (also called fluorescence lifetime) (Chizhik *et al.*, 2014; Karedla *et al.*, 2014). Owing to the fact that the energy transfer rate is dependent on the distance of a molecule from the metal layer, the fluorescence lifetime can be directly converted into a distance value (Fig. 6). The theoretical basis for this conversion is the perfect quantitative understanding of the interaction between a quantum emitter and a metallic surface (Enderlein, 1999). It is important to emphasize that the energy transfer from the molecule to the metal is dominated by the interaction of the molecule's near-field with the metal, and is thus similar to FRET. However, due to the planar geometry of the metal film, which acts as the acceptor, the distance dependency of the energy transfer efficiency is much weaker than the sixth power of the distance, and shows a monotonous relation between lifetime and distance within roughly the first 150–200 nm above the surface for fluorescence in the visible spectral range. The distance range where a monotonous relation is observed is proportional to the wavelength of emission. Therefore, one can extend it by using a fluorophore with emission in the red or near-IR spectral region.

One of the key advantages of this method, which is called metal-induced energy transfer (MIET), is that it does not require any hardware modification to a conventional fluorescence-lifetime imaging microscope (FLIM), thus preserving its full lateral resolution. Fig. 7 schematically shows the key elements of the microscope that are required for MIET imaging. The only additional

Fig. 6 Calculated dependence of molecule's excited state lifetime on its axial position over the metal film. Curves are calculated for an emission wavelength of 650 nm and a gold film thickness of 20 nm deposited on the glass cover slide. Calculations are done by the methods of Jörg Enderlein and Daja Ruhlandt, see Ref. Karedla *et al.* (2015).

Fig. 7 Scheme of experimental setup for live cell MIET imaging.

requirement for MIET, when compared to conventional FLIM, is the presence of a thin semitransparent gold film (typically 10–20 nm thick) deposited on the glass cover slide supporting the sample.

Using a high NA objective lens (preferably at least $NA=1.4$) one achieves two essential goals that are needed for MIET imaging. Firstly, since the measurements are done within a layer of ca. 150 nm height above the surface, the supercritical fluorescence constitutes a significant part of the total signal and should be collected by a high-NA objective to maximize fluorescence collection efficiency (see Section Super-Critical Angle Fluorescence Microscopy). Secondly, high NA objectives allow for minimizing the axial extension of the excitation focus, allowing for preferentially exciting molecules only within the MIET range, thus enhancing signal-to-noise ratio. As a result, when focused on the sample surface, the focused light excites only molecules within the first ~ 200 nm above the sample. As a result, because the apical cell membrane is typically at least 500 nm away from the substrate, only dye molecules within the basal membrane are efficiently excited and detected.

For evaluating MIET measurements, one has to model the emission properties of a fluorescing molecule over a metal surface. The molecule is assumed to be an electric dipole emitter. Let us consider the emission of a single dipole emitter with orientation angles (α, β) , where β denotes the inclination towards the vertical axis and α the orientation angle around that axis. The electric field amplitude of the dipole's emission into direction (θ, ϕ) is given by the general formula

$$E_{em} = e_p \left[A_{\perp} \cos \beta + A_{\parallel}^c \sin \beta \cos((\phi) - \alpha) \right] + e_s A_{\parallel}^s \sin \beta \sin((\phi) - \alpha) \quad (8)$$

where the $A_{\perp}$, $A_{\parallel}^c$, and $A_{\parallel}^s$ are functions of emission angle θ but not on α , β or ϕ . Explicit expressions for $A_{\perp}$, $A_{\parallel}^c$, and $A_{\parallel}^s$ can be found by expanding the electric field of the dipole emission into a superposition of plane waves, and the tracing each plane wave component through the planar structures using Fresnel's relations (for details see Enderlein *et al.* (1999), Enderlein (1999), Enderlein and Ruckstuhl (2005), Enderlein (2000)). It is important to note that the functions $A_{\perp}$, $A_{\parallel}^c$, and $A_{\parallel}^s$ depend also on the emission wavelength.

Knowing the electric field amplitude of the emission into a given direction $(\theta, (\phi))$, one can then derive the total power of emission as

$$S_{total}(\beta, \alpha) \propto B_{\perp} \cos^2 \beta + B_{\parallel} \sin^2 \beta \quad (9)$$

with the weight factors $B_{\perp}$ and $B_{\parallel}$ that take into account the absorption of emitted energy into the metal layer (Enderlein *et al.*, 1999). Knowing the total emission power S_{total} , one can then calculate the lifetime of the emitter by

$$\tau/\tau_0 = S_0 / [(\phi)S_{total} + 1 - (\phi)] \quad (10)$$

where (ϕ) is the quantum yield, τ_0 the free lifetime, and S_0 the total emission power of the emitter in free space (sample space).

For finally calculating the actual lifetime-distance curve, one has to average the result over all possible molecular orientations and also the emission spectrum of the emitter.

The applicability of MIET for live-cell imaging has been recently shown by mapping the basal membrane of living cells with nanometer accuracy (Chizhik *et al.*, 2014). Knowledge of the precise cell-substrate distance as a function of time and location with unprecedented resolution provides a new means to quantify cellular adhesion and dynamics, as is required for a deeper understanding of fundamental biological processes such as cell differentiation, tumor metastasis and cell migration.

As a biological model system three adherent cell lines were chosen: MDA-MB-231 human mammary gland adenocarcinoma cells and A549 human lung carcinoma cells, which are able to form metastasis in vivo models, as well as MDCK II from canine kidney tissue as a benign epithelial cell line. Interestingly, significant differences in the cell-interface distance between a normal epithelial cell and cancerous cell lines were observed (Chizhik *et al.*, 2014). Recently, Baronsky *et al.* have used MIET imaging for studying the epithelial-to-mesenchymal transition of NMuMG cells (Baronsky *et al.*, 2017).

Fig. 8 shows the measured intensity and lifetime images that were used to obtain the 3D reconstruction of the basal cell membrane. Because the variation of the fluorescence intensity is not only dependent on the metal-induced quenching, but also on the homogeneity of labelling, exclusively the lifetime information was used for reconstructing a three-dimensional map of the

Fig. 8 Simultaneously acquired fluorescence intensity (a) and lifetime (b) images of the basal membrane of living NMuMG cells grown on a gold-coated glass cover slide. (c) Three-dimensional profile of the basal cell membrane computed from fluorescence lifetime image. Scale bars: 20 μm .

basal membrane. On the other hand, the intensity distribution was used to discriminate the membrane fluorescence against the background. Regions with no cells are difficult to identify from the lifetime images alone, as the lifetime values can become exceedingly scattered at low signal-to-noise ratios.

The axial resolution of the recorded images can be determined by calculating the standard deviation of cell-substrate distance (Chizhik *et al.*, 2014). The resolution depends on the photon rate and varies between 2 nm and 4 nm for typical fluorescence intensities measured and can be further enhanced to 1 nm by increasing the number of detected photons.

Karedla *et al.* (2014) have used MIET microscopy for axial localization of single molecules immobilized on the surface. The standard deviation for the observed single-molecule lifetime values is less than 0.1 ns, which corresponds to an axial localization accuracy of better than 2.5 nm for horizontal dipoles.

Although, we have focused on the application of MIET to map the membrane of a living cell and the single molecule axial localization, demonstrating its versatility, relative technical simplicity, and its applicability for life-science, the potential scope of applications of MIET is much greater. The distance range covered by MIET nicely bridges (and complements) the realm of conventional FRET and all the recently developed super-resolution imaging techniques. Although MIET has to rely on a perfect theoretical understanding of the fluorophore-metal interaction, which is certainly more involved than that of FRET, this is no serious obstacle in the current age of powerful desktop computers. In contrast to FRET, the infamous orientation-factor problem is greatly relaxed because one has to know only the relative orientation of one species of fluorescent molecules with respect to the planar metal film. Moreover, in contrast to FRET, one needs to label only one site of a sample with one sort of fluorophore, instead of double-labelling with a donor and acceptor. MIET is exceedingly simple to set up and neither requires modification of the FLIM system nor preparation of complex sample substrates. Coating glass cover slides with a thin metal film is the only prerequisite of the technique. Thus, the technical simplicity of MIET will allow its application in a wide range of studies where nanometer resolution is required.

Introduction

The basic construction and imaging properties of the optical microscope, one of the most important optical instruments, are described. But the restrictive meaning of a microscope as a device that the user looks down to see a magnified image is far from the present terminology that includes scanning systems (where the image is stored in a computer), nonvisible radiation, such as electrons or X-rays, and a variety of different contrast mechanisms.

According to the *Oxford English Dictionary* a microscope is 'an instrument magnifying objects by means of lenses so as to reveal details invisible to the naked eye'. Thus, basically a microscope forms a magnified image of an object. The first microscopes used visible light and formed an image showing variations in the intensity of light scattered by the object. This intensity is in general related to the optical properties of the object in a complicated way.

Nowadays there are many different types of microscope. Our understanding of a microscope must therefore be generalized in the following ways.

- The microscope may not be a conventional imaging system using lenses or mirrors. For example, it may be a scanning imaging system. A confocal system is a combination of a conventional and a scanning system. Another important category of microscopes is that of probe microscopes, including near-field optical microscopes. Some probe microscopes, for example the atomic force microscope (AFM) do not even seem at first glance to rely on the direct use of radiation.
- The microscope may not use visible light, but other electromagnetic radiation, or even other forms of radiation.
- The image can be formed using a variety of different contrast mechanisms. Some of these, such as phase contrast, are designed to image particular optical properties of the sample. Others image the generation of a form of radiation when the object is stimulated by another form of radiation. In particular, in principle, virtually any form of spectroscopy can be the basis of building up an image by measuring the spatial variations in the signal.

Different Forms of Microscopes

The Conventional Microscope

In a simple microscope, an objective lens forms a real, magnified, and inverted image of an object. In a compound microscope, an eyepiece is added, forming a virtual image that is viewed by eye to give real image on the retina. The eye can be replaced by CCD camera to record moving or still images. In early microscopes, the objective lens and eyepiece are mounted in the two ends of a brass tube. The objective screws into the tube using an RMS (Royal Microscopical Society) thread (0.8" Whitworth 36 threads per inch), until its mounting face is flush with the end of the tube. The length of the tube is the mechanical tube length. The distance from the mounting face of the objective to the plane of the real image is the optical tube length, which varied according to different manufacturers in the range 160–210 mm. Now most objectives have infinity tube length, so that they collimate the light from the object. The collimated light is brought to a focus by an additional tube lens. An objective of correct tube length should always be used as otherwise spherical aberration is introduced. As the objective, tube lens, and eyepiece are designed together as a system, great care should be exercised when mixing components from different manufacturers.

Abbe showed that in order to form a perfect lateral image the objective must satisfy a different condition called the Herschel condition. Otherwise the image of an off-axis point will suffer from coma. An aberration-free system satisfying the sine condition is called an aplanatic system. A microscope produces a three-dimensional (3D) image of a 3D object. A point of the object closer to the lens appears further from the lens in the image. If the lateral magnification is M , the longitudinal magnification is approximately equal to M^2 . However, it can be shown that it is impossible to devise an instrument that can produce a perfect 3D image of a 3D object, because to have a perfect transverse image the system must satisfy Abbe's sine condition, but to have a perfect axial image the system must satisfy the Herschel condition. These two conditions are not mutually compatible. Actually, we find that the longitudinal magnification is not exactly equal to M^2 , and is not even constant in space. Different depths of the object are imaged differently: the microscope objective only produces a good image for one plane of focus, and other planes will exhibit spherical aberration. However, all of these problems can be overcome by bringing the part of the object under observation into focus, without refocusing the eye or other detector. A 3D image can thus be generated by scanning the object stage in the axial direction, and recording a stack of images from different depths in a computer. For modern objectives of infinite tube length, focusing can be alternatively achieved by piezoelectric scanning of the objective lens.

Resolution

For an object consisting of a single bright point object in a dark background, the image produced by a perfect microscope, according to paraxial diffraction theory, is the so-called Airy disk, consisting of a bright central spot, surrounded by a series of rings. The intensity in a meridional cross-section through the Airy disk is the same for any aperture of objective, or wavelength of light, but its width varies. The intensity of the first bright ring is 1.75% of that at the peak. The radius of the first dark ring of the Airy disk is

$$r_0 = \frac{0.61\lambda}{n \sin \alpha} \quad (1)$$

where λ is the wavelength, n is the refractive index of the immersion medium, and α is the angle subtended at the edge of the objective aperture. The radius depends on $n \sin \alpha$, which is called the numerical aperture and should be as large as possible for good resolution. Thus, high-magnification lenses often use an immersion fluid, usually oil with a refractive index of 1.518 (ISO 8036/1).

The optical coordinate v is defined as

$$v = \frac{2\pi}{\lambda} r n \sin \alpha \quad (2)$$

so that the dark ring of the Airy disk occurs at a value of v of $2\pi \times 0.61 = 3.83$. Resolution is sometimes expressed in terms of the full width at half maximum (FWHM) of the image of a point object, which is 3.232 in optical coordinates. A full nonparaxial theory does not give a very different figure.

Resolution of a microscope is often specified by two-point resolution, which describes whether the image of two points can be distinguished from that of a single point. According to the Rayleigh criterion of two-point resolution, two points are just resolved if the second point is placed on the first dark ring of the first. The separation is then $0.61\lambda/(n \sin \alpha)$. A cross-section through the image in an incoherent optical system of two bright point objects of equal strength and different separations is shown in Fig. 1. The intensity in the image between the points decreases as the separation is increased. The ratio of the intensity midway between the points to that at the points for the Rayleigh criterion to be satisfied is then found to be 0.735.

The concept of resolution should be distinguished from sensitivity or precision. An object much smaller than the resolution limit can still be detected, perhaps weakly, in a microscope: this detection of weak contrast depends on the sensitivity of the microscope rather than its resolution. The size of an object can also be measured with a precision much greater than the resolution of the microscope.

Fig. 1 A cross-section through the image of two equal point objects in an incoherent microscope. The separation of the points is that for the Rayleigh criterion to be satisfied, and for changes of ± 10 , 20% of the Rayleigh separation.

Fig. 2 Geometry of the Köhler illumination system. In practice an arrangement with a smaller number of lenses is usually used.

Illumination

If the object is not self-luminous, in order to be imaged in a microscope it must be illuminated. A semitransparent object, such as a biological slice, is illuminated in transmission. For observation of bulk objects, or surfaces, we use illumination in the reflection geometry, called epi-illumination. Either a tungsten halogen lamp or an arc source is usually used. In critical illumination, the source is focused on to the object by a condenser lens. The disadvantage of this approach is that variations in emission of the source are imaged directly into the image. Cheaper microscopes avoid this problem by using a diffuser. Better microscopes use instead the Köhler illumination system, where the source is placed in the front focal plane of the condenser lens. **Fig. 2** shows a Köhler illumination system in which the source is imaged into the front focal plane of the condenser lens by another, projector, lens. The system incorporates a separate field stop and aperture stop. In practice, the size of the field stop should be reduced to illuminate as small a region of the object as necessary in order to minimize stray light. An important part of setting up a microscope to operate properly consists in centering the aperture stop of the condenser. This is often done using a so-called Bertrand lens that allows imaging of the aperture stop.

Image formation

The Rayleigh criterion was originally specified for an incoherent optical system. It is thus applicable in fluorescence microscopy, as fluorescence is an incoherent process as two fluorescent point objects fluoresce independently. But for the image of a trans-illuminated object, the resolution depends on the coherence of the illumination. This is controlled by the numerical aperture of the condenser lens as compared with that of the objective. The ratio of these numerical apertures is called the coherence parameter, S , so that

$$S = \frac{n_c \sin \alpha_c}{n \sin \alpha} \quad (3)$$

For $S=0$ the illumination is purely coherent, while for $S \rightarrow \infty$ imaging becomes purely incoherent, thus corresponding to the Rayleigh criterion, so S should really be called an incoherence parameter. An important in-between case is when $S=1$, when the apertures of objective and condenser are equal. This is termed matched, full, or complete illumination. According to the generalized Rayleigh criterion, the points are just resolved when the ratio of the intensity midway between the points to that at the points is 0.735, which is called the generalized Rayleigh criterion. We require that the distance between the points is as small as possible when this occurs. The generalized Rayleigh separation is the same for incoherent illumination and for $S=1$, and corresponds to a distance of $2\nu_0=3.83$ in optical coordinates. Note, however, that for other separations of the points, the ratio is different for these two cases: it is not true, but often erroneously stated, that $S=1$ corresponds to incoherent imaging. Resolution improves as the aperture of the condenser is increased ($2\nu_0=5.15$ in optical coordinates for coherent illumination) reaching a maximum when $2\nu_0=1.46$, when resolution is 9% better than for incoherent imaging ($2\nu_0=3.58$). This maximum in resolution is achieved when the numerical aperture of the condenser is larger than that of the objective, which is not physically achievable if the objective has the highest possible numerical aperture. Similarly, it is impossible to achieve incoherent illumination with very large objective numerical apertures.

The effect of coherence on the resolution of an image depends on the form of the object, and on the particular resolution criterion employed. In practice, contrast also depends on the aperture of the condenser. Usually, opening the condenser improves resolution, but reduces contrast, so there will be an optimum condenser aperture size.

Abbe theory of microscope imaging

Abbe argued that for coherent illumination of a grating, the grating spectra can be observed in the back focal plane of the objective. The tube lens then forms an image from the grating components. Thus, this is an early description of Fourier optics. The strength of the grating components can be altered in the back focal plane to give various optical effects, such as phase contrast. Abbe's theory was not properly appreciated at the time because it was known that in practice, resolution could be improved by using a larger condenser aperture, which does not give coherent illumination. There was much controversy about the merits of Köhler versus critical illumination, and different sizes of condenser aperture.

We now know that Köhler and critical illumination are in principle equivalent. The aberrations of the condenser lens are not important, so that the source and condenser together behave simply as a partially coherent effective source. Imaging can still be described by Fourier optics within the framework of partially coherent imaging theory.

Although Köhler and critical illumination are equivalent in principle, Köhler illumination is in practice better because of its improved illumination uniformity.

Depth of focus

The longitudinal image of a point object is found to be approximately invariant when expressed in terms of an optical coordinate u , defined as

$$u = \frac{8\pi}{\lambda} z n \sin^2 \frac{\alpha}{2} \quad (4)$$

The axial resolution, and thus also the depth of focus, varies strongly with aperture. The FWHM for longitudinal imaging is 11.13 in optical coordinates.

Microscope objectives

Because microscope objectives often have large apertures, aberrations will be very strong, unless the objective is designed correctly. The basic design principle for a high aperture lens is the aplanatic front element (Fig. 3). It is found that all rays from a point A in a sphere of refractive index n , where A is a distance r/n from its center, appear to come from a point B, distance m , without any aberration. This principle is used by employing a front element that has one surface of the same radius of curvature as the sphere. The front surface is a sphere centered on A (Fig. 3(b)), so that the rays are not deviated on crossing it.

A low-power achromat uses just two components with different optical dispersion to cancel chromatic aberration and correct for other aberrations (an achromatic doublet). For higher powers, two separated doublets are necessary. For the highest apertures, an aplanatic front is used. However, this can never converge the light, but only makes it less divergent. It is thus used together with an achromatic doublet. For oil immersion, the interface between the oil and the front element is not very important, so it is made planar to simplify manufacture. In practice, it is usually made planar even for a dry lens, and the resulting aberrations cancelled out elsewhere in the objective. Apochromats, corrected for three colors, use more elements, which may include two or more stages of aplanatic front. The final objective thus consists of a number of elements that must be accurately aligned relative to one another. The objective is adjusted by the manufacturer to give a good star image (image of a point object). First a spacer is selected to

Fig. 3 The principle of the aplanatic front: (a) an aplanatic surface; (b) a meniscus lens that acts as an aplanatic system.

optimize spherical aberration. Then a sleeve is adjusted to make the objective parfocal with others. Finally a screw is used to center the assembly to remove coma.

Conventional and Scanning Microscopes

Conventional microscope

Various different types of transmission microscope are illustrated in Fig. 4. We consider image formation in a conventional microscope as illustrated schematically in Fig. 4(a), showing a microscope with critical illumination. A large area incoherent source is focused by the condenser lens on to the specimen, illuminating a comparatively large area of the specimen, corresponding to the whole field of view of the objective. Information from each illuminated point in the specimen is simultaneously transmitted by the objective lens to form the primary image. The objective is responsible for forming the image, with the condenser playing only a secondary role in determining the resolution of the system, through control of the coherence of the illumination. Fig. 4(b) shows a conventional microscope in which the image is measured point by point by a detector. In practice this could be achieved by using a CCD detector.

Scanning microscope

An image can be generated by a scanning system, as illustrated in Fig. 4(c). A probe of light is formed by demagnification of a source, and is scanned over the object in a raster. The transmitted (or reflected) light is detected by a photodetector and thus builds up an image. The size of the probe of light limits the resolution of the system, that is, the smallest detail in the object that can be seen in the image. It should be noted that the magnification of the image is given simply by the ratio of the distance scanned in the image to the distance scanned by the probe. It is thus unrelated to the demagnification of the source. The image magnification can be altered without changing the lens and is not in any way related to the resolution.

It has been shown that the imaging properties of scanning and conventional microscopes are identical under analogous conditions, this being known as the principle of equivalence. This property is based on the principle of reciprocity, which is a very general physical law that holds even with diffraction, absorption, multiple scattering, and stray light. The principle of equivalence is generally valid except if there are nonreciprocal magnetic or polarization effects, or energy losses involved (such as in fluorescence microscopy, and with inelastic scattering in electron microscopy).

Scanning systems exhibit a number of important advantages over conventional systems. Broadly, these are based on two classes of property. First, in a scanning system the image is in the form of an electronic signal. As a result, this is advantageous for quantitative measurements, as well as for image processing, including image enhancement, image restoration, and image analysis. Second, in a scanning system the object is illuminated by a focused spot, which extends the range of imaging modes available.

Confocal microscope

Finally in Fig. 4(d), we combine the arrangements of Figs. 4(b) and (c) to give a confocal scanning optical microscope, in which a point source illuminates just a small region of the object, and a confocal point detector detects light from this illuminated region.

Fig. 4 Different geometries of transmission microscope: (a) a conventional microscope; (b) a conventional microscope with a point detector; (c) a scanning microscope; (d) a confocal microscope.

If the point source and detector are scanned in unison, a two-dimensional image is generated. However, this system now behaves very differently from the previous ones. The confocal microscope is thus not a special case of the general partially coherent conventional imaging system. From the symmetry of Fig. 4(d), it is clear that the two lenses play an equal part in the imaging process. This results in an improvement in resolution. In fact, the confocal system behaves as a coherent imaging system, but with a sharper effective point spread function than in a conventional coherent microscope.

Although Fig. 4 is drawn for the transmission geometry, in practice most confocal systems operate in the reflection or epi-illumination mode, in which the same objective lens is used both for illumination and detection. For a specimen placed in the focal plane, the properties of confocal transmission and reflection systems are identical. However, once the object is moved from the focal plane, certain differences arise: in particular in confocal reflection a strong optical sectioning effect occurs that allows a single section through a thick object to be imaged. This is the major advantage of the confocal microscope arrangement. Fig. 4 also applies equally well to fluorescence imaging. However, in this case, because of the incoherent nature of fluorescence emissions after excitation by coherent light, imaging is then incoherent.

Confocal microscopes can be achieved by using either a point detector, in practice performed by placing a pinhole in front of a photodetector, or by using a coherent detector. Such a coherent detector, sensitive to the amplitude of the incident radiation, is not directly available for light, but is available for acoustic radiation, as in a scanning acoustic microscope. For light, a confocal effect can also be achieved by using an interferometric method to synthesize a coherent detector. Thus, in interference microscopes using the high aperture condenser and objective lenses, an optical sectioning effect arises similar to that in the confocal microscope. Another way of producing a coherent detector is to use a single-mode optical fiber.

Probe Microscopes

Scanning tunneling microscope

The scanning tunneling microscope was the first of the family of probe microscopes, relying on a fundamentally different principle from the usual forms of microscope. A physical tip in the nanometer range is brought close, also in the nanometer range, to a conducting sample. If an electric potential is applied, electrons can tunnel across between the sample and the tip. By scanning the tip mechanically across the sample, an image can be generated with a resolution in the subnanometer range. The surface topography can also be measured with subnanometer sensitivity. While interference microscopy can measure surface topography with subnanometer sensitivity, in this case the profile is averaged over the lateral resolution of the microscope, of the order of the wavelength in dimensions. The scanning tunneling microscope can image individual atoms. The signal is related to the work function of the material. Altering the bias voltage allows the band structure of the material to be investigated.

Atomic force microscope

In the atomic force microscope, the force between the surface and the tip is measured using a cantilever beam and used to build up an image. Atomic force microscopy can be performed in either a contact or noncontact mode. It can be used with insulating specimens. Optical methods, often using a position-sensitive detector, are used to measure displacements of the cantilever.

Near-field scanning optical microscope (NSOM)

In a near-field scanning optical microscope, a very small tip or aperture is scanned relative to the specimen to attain resolution greater than the classical limit set by the wavelength of the radiation. As Fig. 5 shows, various different designs of near-field

Fig. 5 Different forms of near-field microscope: (a) illumination-mode NSOM; (b) collection-mode NSOM; (c) a near-field probe used for both illumination and collection in a confocal arrangement; (d) photon tunneling microscope (PTM). Reproduced with permission from Sheppard CJR (1978) The scanning optical microscope. *The Physics Teacher* 16: 648–651. © 1978 American Association of Physics Teachers.

microscope have been proposed. It is evident that these again form into the conventional/scanning categories described earlier. The sample can be illuminated using the near-field probe, as in Fig. 5(a). This is called the illumination-mode NSOM. Or the sample can be uniformly illuminated, and a signal detected using a near-field probe as in Fig. 5(b), giving a collection-mode NSOM. Or a confocal arrangement can be used, with a near-field probe used for both illumination and collection (c). In this case, an uncoated tip can be used; as otherwise the detected signal will be very small. Finally, Fig. 5(d) shows the photon tunneling microscope (PTM), in which the sample is illuminated with evanescent waves produced by total internal reflection and an uncoated tip used to probe the evanescent field in the presence of the sample.

Different Types of Radiation

Electromagnetic Radiation

UV radiation and X-rays

The first microscopes used visible light, but, in fact, we do not need to use visible light, but can use any electromagnetic radiation, over a broad range of different available wavelengths. In Fig. 6 we show the wavelength of the electromagnetic spectrum, illustrating how the wavelength in air varies with frequency. Instead of using visible light, shorter wavelengths allow greater resolution to be achieved. Ultra-violet light is commonly used to excite fluorescence. X-rays have also successfully been used to image biological samples.

IR and microwave radiation

In the longer wavelength region, infra-red radiation is used for observation of semiconductors or for molecular spectroscopic imaging. Imaging of emitted midinfra-red radiation can show up variations in temperature, such as hot spots in semiconductors. Microwaves have also been used, but resolution is limited by the long wavelength. For this reason microwaves (and mid-IR) have also been used for near-field microscopy.

Other Radiation

Electron microscope

The other important class of radiation that can be used for illumination is matter waves. The most common of these, of course, is electrons, the wavelength of which, as a function of acceleration voltage, is shown in Fig. 7. The bend in the curve at very high

Fig. 6 The wavelength of different forms of electromagnetic radiation and acoustic radiation. Reproduced with permission from Sheppard CJR (2002) *The generalized microscope*. Fig. 7 The wavelength of matter waves (electrons and protons) as a function of accelerating voltage. Reproduced with permission from Sheppard CJR (2002) *The generalized microscope*. In: Diaspro A (ed.) *Confocal and Two-Photon Microscopy: Foundations, Applications and Advances*, pp. 1–18. New York: Wiley-Liss.

voltages is caused by relativistic effects. The wavelength of the electrons is very small: even for 100 V electrons, the wavelength is only 0.1 nm. But aberrations caused by the electron lenses limit resolution so that at present atomic resolution is only just achievable, even with much higher voltages.

In a transmission electron microscope (TEM), a beam of electrons is produced by an electron gun. The specimen is illuminated via a condenser lens (or lenses). Usually these are magnetic lenses in which a current in a coil produces a magnetic field that focuses the electrons. The electrons that are transmitted through the specimen are then focused by a series of lenses to form a final image that can be viewed directly on a phosphor screen. An X-ray detector can be used to characterize the elements in the specimen. An electron-energy-loss spectrometer, together with a detector, can measure the energy of the electrons in a particular region of the image.

Other matter radiation

Instead of electrons, other particle beams can be used for illumination. [Fig. 7](#) shows the wavelength of a beam of protons, as function of the accelerating voltage. Because of the larger mass of protons, relativistic effects are not apparent for protons in the curve in [Fig. 7](#). Microscope images have also been formed using ions, and even neutral particles such as neutrons. Neutral atom microscopes are also under development.

Acoustic radiation

Instead of electromagnetic waves, acoustic radiation can be used to form a scanning acoustic microscope (SAM). Ultrasonic waves are focused into a water immersion medium. Mechanical scanning is again used to build up an image. [Fig. 6](#) shows the wavelength of the acoustic wave as a function of frequency. By using microwave frequencies, wavelengths, and therefore resolution, in the submicron range, can be generated. The SAM acts as a confocal microscope because the detector is sensitive to the amplitude of the acoustic wave. The acoustic microscope provides information on variations in the elastic properties (viscosity and elasticity) of the sample.

Different Contrast Mechanisms

The bright field microscope detects the intensity of the light transmitted through the object. A microscope with a condenser aperture of appreciable size behaves as a partially coherent system, and the image will, in general, depend on the phase of the light coming from the object as well as its intensity. Many objects are weakly scattering, so the contrast of this phase information is weak. In this case, the microscope effectively images variations in the transmittance or reflectance of the sample. Different designs of microscope can be used to image various properties of the object, thus providing new and complementary information. Phase contrast microscopy provides but one example of a different contrast mechanism. In fact, in general, any physical or chemical interaction of the illuminating radiation with the sample can be used as the basis for a contrast mechanism. These different contrast mechanisms can be performed in either a conventional or scanning arrangement, or in a confocal system.

Phase Contrast Microscopy

Phase contrast is a widely used technique in both biological microscopy (in transmission) and materials microscopy (in reflection). Its importance in biological microscopy stems, firstly, from the fact that contrast may otherwise be too weak to be visible, but secondly because the phase variations are caused by changes in optical thickness, related to physical density. In reflection microscopy, phase is related to surface height variations, but also depends on the optical material properties of the sample.

Polarization Microscopy

The polarization state of light transmitted through or reflected from a sample can also be changed. This change is detected in polarization microscopy, for example by placing the sample between crossed polarizers. The birefringence detected can be either material birefringence, or form birefringence (caused by the shape of the microstructure). Polarization microscopy is widely used in biological microscopy, and in mineralogy.

Fluorescence Microscopy

In fluorescence microscopy, electrons excited by illumination decay to the ground state and emit photons of light. Auto-fluorescence is natural fluorescence of the sample. Fluorescent dyes can be used as labels for particular biological or chemical constituents. Fluorescence microscopy is usually performed in the epi-illumination geometry to assist rejection of light from the source. Often it is performed in a confocal microscope, allowing 3D localization of the fluorescent labels.

Raman Microscopy

Raman spectroscopy can be performed on a microscopic scale to produce images of presence of particular molecular bonds. It is usually performed in a scanning system, often of the confocal type.

This is one example of the wider class of spectroscopic microscopies: in principle, any form of spectroscopy can be used as the basis for a microscope contrast mode.

Nonlinear Microscopy

Another class of contrast mechanisms is based on nonlinear optical interactions. Again, any nonlinear mechanism can be used as the basis for a contrast mechanism. These include two- (or multiphoton) fluorescence, second- (or higher-order) harmonic generation, sum or difference frequency generation, and coherent anti-Stokes Raman scattering (CARS). Probably other nonlinear optical mechanisms will be exploited in microscopy in the future.

Other Contrast Mechanisms

The contrast mechanisms described above, all rely on illumination and detection of light. But in many other modes, radiation of one form can be converted into another. These include cathodoluminescence microscopy (electrons to light), X-ray microanalysis (electrons to X-rays), photo-emission microscopy (light, usually UV, to electrons), photo-acoustic microscopy (light to ultrasonics), photothermal microscopy (light to thermal waves), optical or electron beam induced current (OBIC/EBIC). Again, in many of these, the illuminating or emitted radiation can be focused, or a combination can be used in a confocal arrangement.

Introduction

It is probably fair to say that the development and wide commercial availability of the confocal microscope has been one of the most significant advances in light microscopy in the recent past. The main reason for the popularity of these instruments derives from their ability to permit the structure of thick specimens of biological tissue to be investigated in three dimensions. It achieves this important goal by resorting to a scanning approach together with a novel (confocal) optical system.

The traditional wide-field conventional microscope is a parallel processing system which images the entire object field simultaneously, which is a severe requirement for the optical components. We can relax this requirement if we no longer try to image the whole object at once. The limit of this relaxation is to require a good image of only one object point at a time. The price that we have to pay is that we must scan in order to build up an image of the entire field.

A typical arrangement of a scanning confocal optical microscope is shown in Fig. 1 where the system is built around a host conventional microscope. The essential components are some form of mechanism for scanning the light beam (usually from a laser) relative to the specimen and appropriate photodetectors to collect the reflected or transmitted light. Most of the early systems were analog in nature, but it is now universal, due to the serial nature of the image formation, to use a computer both to drive the microscope and to collect, process, and display the image.

In the beam scanning confocal configuration of Fig. 1, the scanning is typically achieved by using vibrating galvanometer-type mirrors or acousto-optic beam deflectors. The use of the latter gives the possibility of TV-rate scanning, whereas vibrating mirrors are often relatively slow when imaging an extended region of the specimen, although significantly higher scanning speeds are achievable over smaller scan regions. We should note that other approaches to scanning may be implemented, such as specimen-scanning and lens-scanning. These methods, although not generally available commercially, do have advantages in certain specialized applications. Since this article is necessarily limited in length much additional material may be found in other sources listed in the Further Reading at the end of this article.

Fig. 1 Schematic diagram of a confocal microscope.

Image Formation in Scanning Microscopes

We will not discuss the fine detail of the optical properties of confocal systems. However, the essence is shown in Fig. 1 where we see that the confocal optical system consists simply of a point source of light which is then used to probe a single point on the specimen. The strength of the reflected or fluorescence radiation from the single object point is then measured via a point, pinhole detector. The confocal – point source and point detector – optical system therefore merely produces an ‘image’ of a single object point and hence some form of scanning is necessary to produce an image of an extended region of the specimen. However, the use of single-point illumination and single-point detection results in novel imaging capabilities which offer significant advantages over those possessed by conventional wide-field optical microscopes. In essence, these are enhanced lateral resolution and, perhaps more importantly, result in a unique depth discrimination or optical sectioning property. It is this latter property which leads to the ability to obtain three-dimensional images of volume specimens.

The improvement in lateral resolution may at first seem implausible. However, it can be explained simply by the principle which states that resolution can be increased at the expense of field of view, which can then be increased by scanning. One way of taking advantage of this principle is to place a very small aperture extremely close to the object. The resolution is now determined by the size of the aperture rather than the radiation. In the confocal microscope we do not use a physical aperture in the focal plane but rather use the back-projected image of a point detector in conjunction with the focused point source. Fig. 2 indicates the improvement in lateral resolution that may be achieved.

The confocal principle was introduced in an attempt to obtain an image of a slice within a thick specimen which was free from the distracting presence of out-of-focus information from surrounding planes. The confocal optical systems fulfills this requirement and its inherent optical sectioning or depth discrimination property has become the major motivation for using confocal microscopes, and is the basis of many of the novel imaging modes of these instruments. The origin of the depth discrimination property may be understood easily from Fig. 3, where we show a reflection-mode confocal microscope and consider the imaging of a specimen with an undulating surface. The full lines show the optical path when an object feature lies in the focal plane of the lens. At a later scan position, the object surface is supposed to be located in the plane of the vertical dashed line. In this case, simple ray tracing shows that the light reflected back to the detector pinhole arrives as a defocused blur, only the central portion of which is detected and contributes to the image. In this way the system discriminates against features which do not lie within the focal region of the lens. A very simple method of both demonstrating the effect and giving a measure of its strength is to scan a perfect reflector axially through focus and measure the detected signal strength. Fig. 4 shows a typical response. These responses are frequently termed the $V(z)$, by analogy with a similar technique in scanning acoustic microscopy. A simple paraxial theory

Fig. 2 The point spread functions of the conventional and confocal microscopes showing the improvement in lateral resolution which may be obtained in the confocal case.

Fig. 3 The origin of the optical sectioning or depth discrimination property of the confocal optical system.

Fig. 4 The variation in detected signal as a plane reflector is scanned axially through focus. The measurement was taken with a 1.3 numerical aperture objective and 633 nm radiation.

Fig. 5 The optical sectioning width as a function of numerical aperture. The curves are for red light (0.6328 μm wavelength). Δz is the full width at the half-intensity points of the curves of $I(u)$ against u .

models this response as

$$I(u) = \left[\frac{\sin(u/2)}{u/2} \right]^2 \quad (1)$$

where u is a normalized axial coordinate which is related to real axial distance, z , via

$$u = \frac{8\pi}{\lambda} n z \sin^2(\alpha/2) \quad (2)$$

where λ is the wavelength and $n \sin \alpha$ the numerical aperture. As a measure of the strength of the sectioning, we can choose the full width at half intensity of the $I(u)$ curves. **Fig. 5** shows this value as a function of numerical aperture for the specific case of imaging with red light from a helium neon laser. These curves were obtained using a high aperture theory which is more reliable than **Eq. (1)** at the highest values of numerical aperture. We note, of course, that these numerical values refer to nonfluorescence imaging. The qualitative explanation of optical sectioning, of course, carries over to the fluorescence case but the actual value of the optical sectioning strength is different in the fluorescence case.

Applications of Depth Discrimination

Since this property is one of the major reasons for the popularity of confocal microscopes, it is worthwhile, at this point, to review briefly some of the novel imaging techniques which have become available with confocal microscopy.

Fig. 6 illustrates the essential effect: **Fig. 6(a)** shows a conventional image of a planar microcircuit which has deliberately been mounted with its normal at an angle to the optic axis. We see that only one portion of the circuit, running diagonally, is in focus.

Fig. 6 (a) Conventional scanning microscope image of a tilted microcircuit: the parts of the object outside the focal plane appear blurred. (b) Confocal image of the same microcircuit: only the part of the specimen within the focal region is imaged strongly.

Fig. 7 An idealization of the optical sectioning property showing the ability to obtain a through-focus series of images, which may then be used to reconstruct the original volume object at high resolution.

Fig. 6(b) shows the corresponding confocal image: here the discrimination against detail outside the focal plane is clear. The areas which were out of focus in **Fig. 6(a)** have been rejected. Furthermore, the confocal image appears to be in focus throughout the visible band, which illustrates that the sectioning property is stronger than the depth of focus.

This suggests that if we try to image a thick translucent specimen, we can arrange, by the choice of our focal position, to image detail exclusively from one specific region. In essence, we can section the specimen optically without having to resort to mechanical means. **Fig. 7** shows an idealized schematic of the process. The portion of the beehive-shaped object that we see is determined by the focus position. In this way it is possible to take a through-focus series and obtain data about the three-dimensional structure of the specimen. If we represent the volume image by $I(x, y, z)$, then by focusing at a position $z=z_1$, we obtain, ideally, the image $I(x, y, z_1)$. This, of course, is not strictly true in practice because the optical section is not infinitely thin.

It is clear that the confocal microscope allows us to form high-resolution images with a depth of focus sufficiently small that all the detail which is imaged appears in focus. This suggests immediately that we can extend the depth of focus of the microscope by adding together (integrating) the images taken at different focal settings without sacrificing the lateral resolution. Mathematically, this extended-focus image is given by

$$I_{\text{EF}}(x, y) = \int I(x, y, z) dz \quad (3)$$

As an alternative to the extended-focus method, we can form an auto-focus image by scanning the object axially and, instead of integrating, selecting the focus at each picture point by recording the maximum in the detected signal. Mathematically, this might be written as

$$I_{\text{AF}}(x, y) = I(x, y, z_{\text{max}}) \quad (4)$$

where z_{max} corresponds to the focus setting giving the maximum signal. The images obtained are somewhat similar to the extended focus and, again, substantial increases in depth of focus may be obtained. We can go one step further and turn the microscope into a noncontacting surface profilometer. Here we simply display z_{max} .

It is clear by now that the confocal method gives us a convenient tool for studying three-dimensional structures in general. We essentially record the image as a series of slices and play it back in any desired fashion. Naturally, in practice it is not as simple as this, but we can, for example, display the data as an $x-z$ image rather than an $x-y$ image. This is somewhat similar to viewing the specimen from the side. As another example, we might choose to recombine the data as stereo pairs by introducing a slight lateral offset to each image slice as we add them up. If we do this twice, with an offset to the left in one case and the right in another, we

obtain, very simply, stereo pairs. Mathematically, we form images of the form:

$$\int I(x \pm \gamma z, y, z) dz \quad (5)$$

where γ is a constant. In practice it may not be necessary to introduce offsets in both directions to obtain an adequate stereo view.

Our discussion so far on these techniques has been by way of a simplified introduction. In particular, we have not presented any fluorescence images. The key point is that, in both brightfield and fluorescence modes, the confocal principle permits the imaging of specimens in three dimensions. The situation is, of course, more involved than we have implied. A thorough knowledge of the image formation process, together with the effects of lens aberrations and absorption, is necessary before accurate data manipulation can take place.

In conclusion to this section it is important to emphasize that the confocal microscope does not produce three-dimensional images. It essentially produces very high-quality two-dimensional images of a (thin) slice within a thick specimen. A three-dimensional rendering of the entire volume specimen may then be generated by suitably combining a number of these two-dimensional image slices from a through focus series of images.

Fluorescence Microscopy

We now turn our attention to confocal fluorescence microscopy, because this is the imaging mode which is usually employed in biological applications. Although we have introduced the confocal microscope in terms of bright-field imaging the comments we have made concerning the origin of the optical sectioning, etc., carry over directly to the fluorescence case although the numerical values describing the strength of the optical sectioning are, of course, different and we will return to this point later.

If we assume that the fluorescence in the object destroys the coherence of the illuminating radiation and produces an incoherent fluorescent field proportional to the intensity of the incident radiation, $I(v, u)$, then we may write the effective intensity point spread function, which describes image formation in the incoherent confocal fluorescence microscope, as

$$I(v, u) I\left(\frac{v}{\beta}, \frac{u}{\beta}\right) \quad (6)$$

where the optical coordinates u and v are defined relative to the primary radiation and $\beta = \lambda_2/\lambda_1$ is the ratio of the fluorescence to the primary wavelength. We note that $v = (2\pi/\lambda)r \sin \alpha$, where r denotes the actual radial distance.

This suggests that the imaging performance depends on the value of β . In order to illustrate this we show in Fig. 8 the variation in detected signal strength as perfect fluorescent sheet scans through focus. This serves to characterize the strength of the optical sectioning in fluorescence microscopy in the same way that the mirror was used in the brightfield case. We note that the half-width of these curves is essentially proportional to β and so for optimum sectioning the wavelength ratio should be as close to unity as possible.

We have just discussed what we might call one-photon fluorescence microscopy in the sense that a fluorophore is excited by a single photon of a particular wavelength. It then returns to the ground state and emits a photon at the (slightly longer)

Fig. 8 The detected signal as thin fluorescent sheet is scanned axially through focus for a variety of fluorescent wavelengths. We note that if we measure the sectioning by the half width of these curves, the strength of the sectioning is essentially proportional to β .

fluorescence wavelength. It is this radiation which is detected via the confocal pinhole. Recently, however, much interest has centered on two-photon excitation fluorescence microscopy. This process relies on the simultaneous absorption of two, longer wavelength photons, following which a single fluorescence photon is emitted. The excitation wavelength is typically twice that used in the one-photon case. The beauty of the two-photon approach lies in the quadratic dependence of the fluorescence intensity on the intensity of the illumination. This leads to fluorescence emission which is always confined to the region of focus. In other words the system possesses an inherent optical sectioning property. Other benefits of two-photon fluorescence over the single photon case include the use of red or infra-red lasers to excite ultra-violet dyes, confinement of photo-bleaching to the focal region (the region of excitation), and the reduced effects of scattering and greater penetration. However, it should also be remembered that, compared with single photon excitation, the fluorescence yield of many fluorescent dyes under two-photon excitation is relatively low.

In order to make a theoretical comparison between the one- and two-photon modalities, we shall assume that the emission wavelength λ_{em} is the same, irrespective of the mode of excitation. Since the wavelength required for single-photon excitation is generally shorter than the emission wavelength, we may write it as $\gamma\lambda_{em}$ where $\gamma < 1$. Since two-photon excitation requires the simultaneous absorption of two photons of half the energy we will assume that the excitation wavelength may be written as $2\gamma\lambda_{em}$ which has been shown to be a reasonable approximation for many dyes.

If we now introduce optical coordinates u and v , normalized in terms of λ_{em} , we may now write the effective point spread functions in the one-photon confocal and two-photon case as

$$I_{1p-conf} = I\left(\frac{v}{\gamma}, \frac{u}{\gamma}\right) I(v, u) \quad (7)$$

and

$$I_{2p} = I^2\left(\frac{v}{2\gamma}, \frac{u}{2\gamma}\right) \quad (8)$$

respectively. We note that although a pinhole is not usually employed in two-photon microscopy it is possible to include one if necessary. In this confocal two-photon geometry the effective point spread function becomes

$$I_{2p-conf} = I^2\left(\frac{v}{2\gamma}, \frac{u}{2\gamma}\right) I(v, u) \quad (9)$$

If we now look at Eqs. (7) and (8) in the $\gamma = 1$ limit, we find that

$$I_{1p-conf} = I^2(v, u) \quad (10)$$

and

$$I_{2p} = I^2\left(\frac{v}{2}, \frac{u}{2}\right) \quad (11)$$

We now see that because of the longer excitation wavelength used in two-photon microscopy the effective point spread function is twice as large as that of the one-photon confocal in both the lateral and axial directions. The situation is somewhat improved in the confocal two-photon case but it is worth remembering that the advantages of two-photon excitation microscopy are accompanied by a reduction in optical performance as compared to the single-photon case.

From the practical point of view it is worth noting that the two-photon approach has certain very important advantages over one-photon excitation, in terms of image contrast, when imaging through scattering media apart from the greater depth of penetration afforded by the longer wavelength excitation. In a single-photon confocal case it is quite possible that the desired fluorescence radiation from the focal plane may be scattered after generation in such a way that it is not detected through the confocal pinhole. Since the fluorescence is generated throughout the entire focal volume it is also possible that undesired fluorescence radiation, which was not generated within the focal region, may be scattered so as to be detected through the confocal pinhole. In either case this leads to a reduction in image contrast. The situation is, however, completely different in the two-photon

Fig. 9 The transfer function for a conventional fluorescence microscope for a number of values of defocus (measured in optical units). We notice that the response for all nonzero spatial frequencies decays with defocus.

Fig. 10 The image of a one-dimensional single spatial frequency bar pattern for varying degrees of defocus. We note that for sufficiently large values of defocus the bar pattern is not imaged at all.

Fig. 11 (a) Shows the optical system of the structured illumination microscope together with experimentally obtained axial responses in (b) which confirm the optical sectioning ability of the instrument.

case. Here the fluorescence is generated only in the focal region and not throughout the focal volume. Furthermore since all the fluorescence is detected via a large area detector – no pinhole is involved – it is not so important if further scattering events take place. This leads to high-contrast images which are less sensitive to scattering. This is particularly important for specimens which are much more scattering at the fluorescence ($\lambda/2$) wavelength than the excitation (λ) wavelength.

The Use of Structured Illumination to Achieve Optical Sectioning

An alternative approach to obtain optical sectioning is to use structured illumination in a conventional microscope. This approach is attractive since the conventional light microscope already possesses many desirable properties: real-time image capture, standard illumination, ease of alignment, etc. However, it does not produce optically sectioned images in the sense usually understood in confocal microscopy. In order to see how this deficiency may be corrected via a simple modification of the illumination system let us begin by looking at the theory of image formation in a conventional fluorescence microscope and start by asking in what way the image changes as the microscope is defocused. We know that in a confocal microscope the image signal from all object features attenuates with defocus and that this does not happen in a conventional microscope. However, when we look closely at the image formation process we find that it is only the zero spatial frequency (constant) component which does not change with defocus (Fig. 9); all other spatial frequencies actually do attenuate with defocus to a greater or lesser extent. Fig. 10 illustrates this by showing the image of a single spatial frequency one-dimensional bar pattern object for increasing degrees of defocus. When the specimen is imaged in focus, a good image of the bar pattern is obtained. However with increasing defocus the image becomes progressively poorer and weaker until it eventually disappears leaving a uniform gray level. This observation is the basis of a simple way to perform optical sectioning in a conventional microscope.

If we simply modify the illumination path of the microscope so as to project onto the object the image of a one-dimensional, single spatial frequency fringe pattern, then the image we see through the microscope will consist of a sharp image of those parts of the object where the fringe pattern is in focus together with an out-of-focus blurred image of the rest of the object. In order to obtain an optically sectioned image it is necessary to remove the blurred out-of-focus portion as well as the fringe pattern from the in-focus optical section. There are many ways to do this – one of the simplest involves simple processing of three images taken at three different spatial positions of the fringe pattern. The out-of-focus regions remain fairly constant between these images and the

Fig. 12 Two images of the region around the spiracle of a head louse. As in the previous figure, (a) is an autofocus image and (b) shows a mid-focus conventional image. The scale bar depicts a length of 10 μm .

relative spatial shift of the fringe pattern allows the three images to be combined in such a way as to remove the fringes. This permits us to retrieve both an optically sectioned image as well as a conventional image in real time.

Since the approach involves processing three conventional microscope images, the image formation is fundamentally different from that of the confocal microscope. However, the depth discrimination or optical sectioning strength is very similar and this approach, which requires very minimal modifications to the instrument, has been used to produce high-quality three-dimensional images of volume objects which are directly comparable to those obtained with confocal microscopes. A schematic of the optical arrangement is shown in [Fig. 11\(a\)](#), together with experimentally obtained axial responses in [Fig. 11\(b\)](#). It will be noted that these responses are substantially similar to those obtained in the true confocal case. As an example of the kind of images which can be obtained with this kind of microscope, we show in [Fig. 12](#) two images of a spiracle of a head louse. The first is an auto-focus image of greatly extended depth of field constructed from a through-focus series of images. The second is a conventional image taken at mid-focus. The dramatic increase in depth of field is clear when compared with a mid-focus conventional image. We note that these images were taken using a standard microscope illuminator as light source. Indeed, the system is so light efficient that good-quality optical sections have been obtained on transistor specimens using simply a candle as light source!

Imaging using fluorescence light is also possible using this technique. However, an alternative approach that does not require a physical grid is possible if a laser is used as the light source. In this system the laser illumination is split into two beams which are allowed to interfere at an angle in the fluorescent specimen. This has the effect of directly 'writing' a one-dimensional fringe pattern in the specimen. Spatial shift of the fringe pattern is achieved by varying the phase of one of the interfering beams. As before, three images are taken from which both the optically sectioned image and conventional image may be obtained. The beauty of this approach is that no imaging optics are required at the illuminating wavelength and system.

Summary

We have discussed the origin of the optical sectioning property in the confocal microscope in order to introduce the range of imaging modes which this unique form of microscope leads to. A range of optical architectures have also been described. By far the most universal is that shown in [Fig. 1](#) where a confocal module is integrated around a conventional optical microscope. Other, more recent, real-time implementations have also been described. A number of practical aspects of confocal microscopy have not been discussed. This is because they are readily available elsewhere, such as advice on the correct choice of detector pinhole size or because they are still the focus of active research, such as the development of new contrast mechanisms for achieving enhanced three-dimensional resolution such as the stimulated emission depletion method, STED or 4-Pi which are still under development but offer great promise.

Atom Optics

AD Cronin and DE Pritchard, Massachusetts Institute of Technology, Cambridge, MA, USA

© 2005 Elsevier Ltd. All rights reserved.

In 1923 Louis de Broglie suggested that particles of matter propagate as waves with a wavelength

$$\lambda_{dB} = h/p \quad (1)$$

where h is Planck's constant and p is the particle's momentum. This breakthrough idea motivated Schrödinger's equation, which is the equation of motion of quantum mechanics.

Schrödinger's equation is a wave propagation equation, and therefore implies the existence of a whole new type of optics – matter wave optics – in which electron waves, neutron waves, atom waves, and entire molecule waves can be manipulated coherently. Such optics enable new measurement technologies and devices that depend on matter wave interference.

Guided by a knowledge of light waves, one can understand that the de Broglie wavelength of a particle sets the scale for focusing, diffraction, and interference. However, there are differences between matter and light. For example, the vacuum is tremendously dispersive for matter waves. In other words, the group velocity for a particle depends on its de Broglie wavelength, while for light waves the group velocity is independent of wavelength.

To illuminate the mathematical connection with light optics, we note the wave equation for light is

$$\nabla^2 \vec{E} = \mu \varepsilon \frac{\partial^2 \vec{E}}{\partial t^2} \quad (2)$$

where $\vec{E} = \vec{E}(\vec{x}, t)$ is the optical electric field, and the parameters μ and ε may vary throughout space, describing an index of refraction. The wave equation for matter waves is Schrödinger's equation:

$$\left(-\frac{\hbar^2 \nabla^2}{2m} + V \right) \psi = i\hbar \frac{\partial}{\partial t} \psi \quad (3)$$

where $\psi = \psi(\vec{x}, t)$ is the probability amplitude, or wavefunction, for a particle of mass m . Here, the potential energy V can vary throughout space, and thus control the phase and amplitude of propagating atoms. Just as density for photons is proportional to $\vec{E}(\vec{x})^2$, the probability density for particles is given by $|\psi(\vec{x})|^2$.

In a vacuum $V=0$ and $(\mu_0 \varepsilon_0)^{-1/2}=c$, and if we assume that both ψ and E have a time dependence described by $e^{-ik\omega}$, the wave equations become

$$\left[\nabla^2 + \frac{\omega^2}{c^2} \right] \vec{E} = 0 \quad (4)$$

and

$$\left[\nabla^2 + \frac{2m\omega}{\hbar} \right] \psi = 0 \quad (5)$$

which look similar, but have a critical difference stemming from the single time derivative in Schrödinger's equation. To see how this makes the vacuum dispersive for matter waves, but not for light, consider a propagating plane wave of either ψ or $\vec{E}$ described by $e^{i(kx - \omega t)}$ (for either kind of wave, $k \equiv 2\pi(\lambda)^{-1}$). Using the wave equation for light waves, the dispersion relation is

$$\omega = ck \quad (6)$$

where c is the phase (and group) velocity of light, which is independent of k . The same plane wave substituted into Schrödinger's equation for matter waves yields the dispersion relation

$$\omega = \frac{\hbar k^2}{2m} \quad (7)$$

This is quadratic for matter waves, which means the group velocity $v_g = d\omega/dk$ is twice the phase velocity $v_p = \omega/k$, and both still depend on k .

From an engineering perspective, matter wave optics consists of lenses, mirrors, beam-splitters, and other components of an optics toolkit. The fact that electrons and neutrons can be transmitted through solid material, and that electrons can be reflected or refracted by static electromagnetic fields, has enabled optical elements to be created for these kinds of matter waves. For atoms, however, finding suitable materials for lenses or mirrors is a daunting task, since with rare exceptions (e.g., cold H on liquid He) atoms thermalize on surfaces rather than elastically bouncing off or passing through them. This was the major obstacle which delayed the blossoming of atom optics until the mid-1980s.

This obstacle has now been circumvented, but only with difficulty. Electromagnetic fields (whose spatial configurations are severely constrained by Maxwell's equations) can change the potential energy of neutral atoms, but since an atom's net charge is zero, provide only a weak and highly dispersive index of refraction based on the atom's polarizability or magnetic moment. However, these effects are tremendously enhanced if the electromagnetic fields oscillate near a transition frequency of the atom.

Hence, propagating waves and standing waves of single-frequency laser light have become standard tools in atom optics. Standing light waves are often referred to as a light crystal, because the periodic potential can diffract atom beams.

An alternative source of atom optical components is based on nanofabrication. Thin sheets of material with patterned holes serve as absorptive atom optics by transmitting atom waves only through the nanometer scale openings. A variety of techniques have been used to make physical diffraction gratings, zone plates, and holograms for atom waves. Methods such as electron beam lithography and ultraviolet photolithography both rely on sophisticated etching procedures to make the final free-standing structures. Thus, in either approach – near-resonant light, or miniature physical structures – current technologies such as the tunable laser or nanofabrication techniques have been required for the development of useful atom optics.

While coherent manipulation of atom waves is often the goal, incoherent manipulations are possible also, e.g., if photons are spontaneously scattered. Dissipative processes offer an additional class of possibilities such as increasing the brightness of an atom source, and are therefore an important part of atom optics. This article excludes atom slowing and trapping, and focuses instead on atom diffraction – a coherent process which can be used to make beam splitters for atom interferometers.

Nanofabricated Atom Optics

Because atoms stick to surfaces, mechanical structures are absorptive atom optics. Yet the de Broglie waves transmitted through slots of a mask are nearly unaffected, provided the mask is thin enough. This is because the van der Waals potential energy of interaction with nearby surfaces falls off rapidly for neutral atoms.

Consider, for example, an atom wave packet being diffracted by a mechanical grating made with physical bars and slots as shown in Fig. 1. Initially, let the atom wave packet have a slowly varying spatial envelope, $f=f(x, y, z)$, and momentum only in the $\hat{x}$ -direction, $\vec{p} = \hbar \vec{k}_0 = \hbar(\lambda_{dB})^{-1} \hat{x}$, so the wavefunction can be written as

$$\psi = f e^{i(k_0 x - \omega t)} \quad (8)$$

Immediately after the grating, only the portions of the wavefunction passing through slots remain nonzero, as depicted in Fig. 2. Here, the wavefunction is now periodic both due to the grating lattice vector $k_g \hat{y}$ and the initial wavevector $k_0 \hat{x}$. According to the Schrödinger equation, a periodicity in any direction implies a momentum in that direction. Thus, variation of ψ in the $\hat{y}$ variation gives rise to a new momentum distribution.

The square wave modulating the envelope of the wave packet can be described by a Fourier sum times the incident wavefunction

$$\psi = f e^{i(k_0 x - \omega t)} \sum_{n=-\infty}^{\infty} a_n \cos(nk_g y) \quad (9)$$

Fig. 1 Scanning electron microscope image of a silicon nitride diffraction grating for atom waves. The bars (light) absorb, and the slots (dark) transmit atom waves. The grating period is 100 nm, the open fraction is 0.67, and the free-standing bars are supported every 5 μm with a thicker strip of silicon nitride material. The grating was fabricated by Tim Savas and Henry I Smith at MIT NanoStructures laboratory.

Fig. 2 Schematic diagram of an atom wavepacket passing through an absorbing grating, as seen from above. The atom wavepacket is depicted before and after passing through the grating from left to right.

where $k_g = 2\pi(d_g)^{-1}$ is the grating lattice vector. The only other physical parameter of the grating is the open fraction, γ , and this determines the Fourier amplitudes a_n

$$a_n = \frac{\sin(n\pi\gamma)}{n\pi} \quad (10)$$

From the principle of superposition (which is applicable here because the Schrödinger equation is linear) the wavefunction can be written as a sum of traveling waves with wavevectors $\vec{k}_n$:

$$\psi = f \sum_{n=-\infty}^{\infty} a_n e^{(i\vec{k}_n \cdot \vec{r} - \omega t)} \quad (11)$$

$$\vec{k}_n = \frac{k_0 \hat{x} + nk_g \hat{y}}{N} \quad (12)$$

where, just as in standard optics, the factor N serves to keep $|\vec{k}_n|$ on a spherical shell, i.e., the grating does not add energy to the atom.

Inserting this expression for the wavefunction into Schrödinger's equation we get the dispersion relation for matter waves and a different group velocity, v_n , for each k_n

$$\hbar\omega = \frac{\hbar^2 k_n^2}{2m} \quad (13)$$

$$v_n = \frac{d\omega}{dk_n} = \frac{\hbar k_n}{m} = p_n/m \quad (14)$$

Thus, diffraction through a grating puts an atom into a coherent superposition of different momenta, each separated by $\sim \hbar k_g \hat{y}$. Some time later, the atom will be in a coherent superposition of multiple locations, and the far-field probability density will be peaked at integer multiples of the diffraction angle

$$\theta_D = \frac{k_g}{k_0} = \frac{\lambda_{dB}}{d_{\text{grating}}} \quad (15)$$

where d_{grating} is the lattice spacing of the grating and the small-angle approximation for $\sin(\theta)$ has been used. Exactly as in light optics, these diffraction gratings are good momentum spectrometers, i.e., the diffraction angle is a measure of longitudinal momentum. (Contrary to light optics, group velocity can also be used to measure matter wave momentum.) Coherence between the diffraction orders remains until a perturbation occurs which would (even in principle) be sufficient to determine which path the atom took. This assertion has been tested with atoms in an interferometer (discussed below).

Atom flux in the n th diffraction order is given by

$$I_n = \left(\frac{\sin(n\pi\gamma)}{n\pi} \right)^2 \quad (16)$$

To resolve the diffracted orders the initial transverse momentum distribution of the atoms must be smaller than k_g , and the time until the far-field observation must be sufficiently large given the beam width. At intermediate times, the atom waves are in the Fresnel diffraction region where the Talbot effect can be observed. This effect causes the atom waves to form a replica of the grating in free space at integer multiples of the Talbot length, $Z_T = 2d_{\text{grating}}^2 \lambda_{dB}^{-1}$.

Fig. 3 shows the far-field diffraction pattern from a beam of sodium (^{23}Na) atoms using a material grating with a period of 100 nm. The atom beam velocity peaked at 1500 ms^{-1} corresponds to a de Broglie wavelength of $0.11 \text{ \AA}$ thus, $\theta_D \approx 10^{-4} \text{ rad}$. (The beam of 3000 ms^{-1} atoms diffracts at half this angle.) The spread in longitudinal velocity of $\sigma_v/v \approx 6\%$ can be deduced from the data because it slightly increases the width for higher order diffraction peaks. The open fraction of the grating, $\gamma \approx 60\%$, can also be determined from the diffraction data, because it determines the relative intensity of the orders. Effects of the atoms' finite size and interaction with the grating bars make small corrections to this simple theory.

Fig. 3 Diffraction data from a beam of sodium formed by passing atoms through two collimating slits followed by a nanofabricated diffraction grating. The momentum of the atoms determines their de Broglie wavelength, and thus their diffraction angle $\sin(\Theta_D) = \lambda_{dB}/d_{\text{grating}}$. These data were obtained at MIT by the authors.

Fig. 4 Diffraction data using a mixed beam of sodium atoms (Na) and sodium dimer molecules (Na₂). From this source molecules have the same speed as atoms, thus twice the momentum. Thus, molecule waves are diffracted at half the diffraction angle compared to atom waves. These data were obtained at MIT by the authors.

Nanofabricated atom optics differ from those based on light forces in a number of ways: they are amplitude structures (with corresponding loss of transmission intensity), they are species-independent, their scale size can be several times smaller than attainable with light, and they can be arbitrarily patterned since they are fabricated by electron beam lithography. Insensitivity to species is demonstrated in Fig. 4, where a beam of Na₂ molecules and Na atoms is diffracted and separated by a nanofabricated diffraction grating. The flexibility of electron beam lithography has allowed fabrication not only of diffraction gratings, but also of spherical and cylindrical zone plates, as well as a combination of lens and a hologram that generates a focused atom image. One stunning application laid to rest a long-standing argument concerning whether a stable bound state of the ⁴He₂ dimer exists. For

Fig. 5 Diffraction of helium atoms and helium molecules through a nanofabricated grating. These data, reproduced with permission from Wieland Schoellkopf, were obtained at the Max-Planck-Institute in Göttingen.

this a diffraction grating was used to separate and resolve $^4\text{He}_2$ and more massive clusters (Fig. 5). Subsequently a nano-sieve was used to estimate the size of the $^4\text{He}_2$ dimers to be $62 \pm 10 \text{ \AA}$.

Standing Waves of Light

In contrast to nanofabricated structures, standing waves of near-resonant light are phase gratings for atoms. The optical electric field dynamically polarizes the atoms and causes a shift to the ground state energy (the ac-Stark shift). For optical electric fields oscillating above (below) the atomic resonance frequency, the ac-Stark shift increases (decreases) potential energy for atoms and in either case perturbs the de Broglie wave phase.

In many respects, the interaction of an atom with a standing light wave is richer than the more familiar topic of light-atom interactions in a traveling light wave. Part of this richness reflects two ways in which a standing wave can be considered, either as two counter-propagating traveling waves or as a single, stationary standing wave. The standing wave-atom interaction is capable of transferring momentum in well-determined quantities, coherently splitting atomic wave packets, and generating forces much larger than possible with spontaneously scattered light. Not surprisingly, this interaction has many distinct facets that only appear in different regimes of the interaction parameters (intensity, detuning, and pulse duration) and atomic parameters (mass, initial momentum with respect to the standing wave, and excited state natural lifetime).

We begin with the Bragg scattering of atoms from a standing wave light grating. Although it can be difficult to realize the physical conditions that assure its occurrence, pure Bragg scattering is simpler than intermediate cases involving spontaneous decay (from light too close to resonance) or Kapitza-Dirac diffraction (from shorter interaction times).

Consider a standing wave light grating formed by two counter-propagating plane waves (traveling parallel to the z -axis) of equal amplitude, E_0 , wavevector, k , frequency, ω , polarization vector, $\hat{e}$, and temporal envelope function, $f(t)$:

$$\vec{E}(z, t) = E_0 f(t) \sin(kz - \omega t) \hat{e} + E_0 f(t) \sin(kz + \omega t) \hat{e} \quad (17)$$

$$= 2E_0 f(t) \sin(kz) \cos(\omega t) \hat{e} \quad (18)$$

We would like to work with momentum states as our atomic basis, thus it is easiest to consider the description of the electric field driving the transitions in terms of two counter-propagating traveling waves of definite momentum (Eq. (17)), as opposed to the single standing wave they jointly form (Eq. (18)).

Momentum is transferred by paired stimulated absorption and emission processes, resulting in a transfer of photons between the traveling waves. An N_B^{th} order diffraction process transfers N_B photons from one traveling wave to the counter-propagating traveling wave and changes the atomic momentum by $2N_B \hbar k \hat{z}$. Furthermore, atomic population is transferred only between $|g, -N_B \hbar k\rangle$ and $|g, +N_B \hbar k\rangle$, where $|g(e), \pm N \hbar k\rangle$ denotes a two-level atom in its ground (excited) state with momentum $\pm N \hbar k$ parallel to the standing wave axis. The excited state remains nominally unpopulated so long as the temporal envelope function, $f(t)$, does not have strong frequency components near the laser detuning

$$\delta = \omega - \omega_0 \quad (19)$$

where ω_0 is the unperturbed frequency of the atomic transition. Furthermore, for a given initial state $(|g, -N_B \hbar k\rangle)$ the uniqueness of the final state $(|g, +N_B \hbar k\rangle)$ occurs because of the fundamental assumption that makes Bragg scattering so simple to describe; the uncertainty in the photon energy driving the transitions is small compared to the energy separation between neighboring momentum states. A quantitative discussion of the validity of this assumption will be given later.

We now calculate the probability, $P_1^B(\tau)$, of the first order ($N_B = 1$) Bragg process. Scattering transfers an atom from $|g, -\hbar k\rangle$ to $|g, +\hbar k\rangle$ when the atoms interact with a constant light intensity for a time τ (i.e., in Eqs. (17) and (18) $f(t)$ is a square wave of unit amplitude and duration τ). The geometry for Bragg diffraction from a standing wave of light is shown in Fig. 6, and the energy/momentum states involved in the transition are depicted in Fig. 7.

Fig. 6 Two counter-propagating running waves of light superimpose to form a standing wave of light. This 'light crystal' acts as a diffraction grating for atoms, shown here in the configuration for Bragg diffraction.

Fig. 7 Energy vs. momentum diagram describing atomic states involved in Bragg diffraction. The total energy is due to the electronic state ($|g\rangle$, $|e\rangle$) plus the kinetic energy associated with the recoil from photon emission (or absorption). In Bragg diffraction, atoms make a coherent transition from $|g, -\hbar k\rangle \leftrightarrow |g, +\hbar k\rangle$. Reprinted from Gupta S, *et al.* (2001) Coherent manipulation of atoms with standing light waves. *Comptes Rendus de L'Academie des Sciences – Series IV – Physics-Astrophysics* 2:479–495, copyright (2001) with permission from Elsevier.

Considering the electronic degree of freedom, we rewrite the Schrödinger equation as

$$(\mathcal{H}_0 + \mathcal{H}_{\text{int}})|\psi\rangle = i\hbar \frac{\partial}{\partial t} |\psi\rangle \quad (20)$$

where the total Hamiltonian $\mathcal{H} = \mathcal{H}_0 + \mathcal{H}_{\text{int}}$ is a matrix. The wavefunction is a vector of coefficients c_i in the basis $\{|g, -\hbar k\rangle, |e, 0\rangle, |g, +\hbar k\rangle\}$, with normalized population amplitudes for each component:

$$|\psi\rangle = \begin{pmatrix} c_{-1}(t) \\ c_0(t) \\ c_{+1}(t) \end{pmatrix} \quad (21)$$

In the electric dipole approximation, the interaction Hamiltonian is $\mathcal{H}_{\text{int}}(t) = -\vec{\mu} \cdot \vec{E}(t)$, where $\mu = \langle e | q\vec{r} | g \rangle \cdot \hat{e}$ is the electric dipole matrix element connecting the ground ($|g\rangle$) and excited ($|e\rangle$) states of the atom. $\hat{e}$ is the polarization vector of the light and q is the charge of the electron. By momentum conservation, only the plane wave traveling in the $\pm \hat{z}$ direction couples the $|e, 0\rangle \leftrightarrow |g, \pm \hbar k\rangle$ transitions. By using this argument, we are effectively viewing the electric field as a quantum mechanical operator. Expanding the sinusoidal variation of the electric field in terms of complex exponentials and treating the spatially dependent

complex exponential terms as quantum mechanical momentum translation operators yields the interaction Hamiltonian:

$$\mathcal{H}_{\text{int}} = \frac{\hbar\omega_R}{2} \begin{pmatrix} 0 & ie^{i\omega t} & 0 \\ -ie^{-i\omega t} & 0 & ie^{-i\omega t} \\ 0 & -ie^{i\omega t} & 0 \end{pmatrix} \quad (22)$$

For example, $e^{\pm ikz}|g, n\hbar k\rangle = |e, (n\pm 1)\hbar k\rangle$ describes absorption, and for stimulated emission, $e^{\mp ikz}|e, n\hbar k\rangle = |g, (n\pm 1)\hbar k\rangle$. This procedure includes the rotating wave approximation. In addition, we have neglected any frequency components associated with the sudden switch on of the fields and the finite duration of the light-atom interaction. In formulating $\mathcal{H}_{\text{int}}$, the strength of the light-atom interaction is parameterized by the single-photon Rabi frequency:

$$\omega_R = \frac{\mu E_0}{\hbar} \quad (23)$$

Without loss of generality, we will take μ and hence ω_R to be positive, real-valued quantities.

The total Hamiltonian follows simply by including the electronic and kinetic energy terms:

$$\mathcal{H}_0 = \hbar \begin{pmatrix} \omega_{\text{rec}} & 0 & 0 \\ 0 & \omega_0 & 0 \\ 0 & 0 & \omega_{\text{rec}} \end{pmatrix} \quad (24)$$

where the single-photon recoil energy, E_{rec} , of an atom of mass m is given by

$$E_{\text{rec}} = \hbar\omega_{\text{rec}} = \frac{\hbar^2 k^2}{2m} \quad (25)$$

Making the *ansatz* for the solution wavefunction as

$$|\psi\rangle = \begin{pmatrix} c_{-1}(t)e^{-i\omega_{\text{rec}}t} \\ c_0(t)e^{-i\omega_0t} \\ c_{+1}(t)e^{-i\omega_{\text{rec}}t} \end{pmatrix} \quad (26)$$

and substituting into the Schrödinger equation yields three coupled first-order differential equations:

$$\dot{c}_{\pm 1}(t) = \mp \frac{\omega_R}{2} e^{i\Delta t} c_0(t), \quad (27)$$

$$\dot{c}_0(t) = \frac{\omega_R}{2} e^{-i\Delta t} (c_{+1}(t) - c_{-1}(t)), \quad (28)$$

where $\Delta = \delta + \omega_{\text{rec}} = (\omega - \omega_0) + \omega_{\text{rec}}$. Differentiating Eq. (27) and substituting Eq. (28) into the result yields two coupled second-order differential equations:

$$\ddot{c}_{\pm 1}(t) - i\Delta \dot{c}_{\pm 1}(t) + \frac{\omega_R^2}{4} (c_{\pm 1}(t) - c_{\mp 1}(t)) = 0 \quad (29)$$

With the initial conditions:

$$c_{-1}(0) = 1 \quad (30)$$

$$c_0(0) = 0 \Rightarrow \dot{c}_{\pm 1}(0) = 0 \quad (31)$$

$$c_{+1}(0) = 0 \quad (32)$$

and the assumption $\Delta^2 \gg \omega_R^2$, the solutions to Eq. (29) are

$$c_{-1}(t) = e^{-i\frac{\omega_R^{(2)}}{2}t} \cos\left(\frac{\omega_R^{(2)}}{2}t\right) \quad (33)$$

$$c_{+1}(t) = ie^{-i\frac{\omega_R^{(2)}}{2}t} \sin\left(\frac{\omega_R^{(2)}}{2}t\right) \quad (34)$$

where the two-photon Rabi frequency is

$$\omega_R^{(2)} = \frac{\omega_R^2}{2\Delta} \rightarrow \frac{\omega_R^2}{2\delta}, \quad |\delta| \gg \omega_{\text{rec}} \quad (35)$$

with both transitions driven at equal single-photon Rabi frequencies, ω_R .

Substituting the solution of Eqs. (33) or (34) into Eq. (27) yields an expression for the excited state amplitude:

$$c_0(t) = i\frac{\omega_R}{2\Delta} e^{-i\Delta t} e^{-i\omega_R^{(2)}t} \quad (36)$$

This will be important in calculating the rate of spontaneous emission events later.

Fig. 8 Bragg scattering of an atom beam from an optical standing wave. First-order Bragg scattering at (a) lower power, (b) higher power of the laser beams (Pendellösung has set in, increasing the amplitude of the undeflected peak), (c) second-order Bragg scattering. Reprinted with permission from *Physical Review Letters* 60(6): 515–518. Copyright (1998) by the American Physical Society.

The solutions for $c_{-1}(t)$ and $c_{+1}(t)$ oscillate with the interaction duration, τ , yielding the result for the $|g, -\hbar k\rangle \rightarrow |g, +\hbar k\rangle$ transition probability:

$$P_1^B(\tau) = |c_{+1}(\tau)|^2 = \sin^2\left(\frac{\omega_R^{(2)}}{2}\tau\right) \quad (37)$$

Thus, the system oscillates between the two momentum states $|g, -\hbar k\rangle$ and $|g, +\hbar k\rangle$ in a manner analogous to the Rabi oscillation of atomic population between two resonantly coupled states. This solution with oscillatory probabilities for the two Bragg coupled states is known as the Pendellösung and has been observed for atoms, neutrons, and X-rays (Fig. 8). The nice feature here is that the strength of the grating can be actually controlled by the intensity of the light.

Viewing Bragg scattering as a two-photon transition from the initial ground state to the final ground state with opposite momentum, illuminates the close connection with a Raman transition between two internal sub-states of the ground state manifold, each with its own external momentum state. The formalism describing the Raman transition is basically the same as that presented here, except the two transitions can be driven at different single-photon Rabi frequencies, ω_{R1} and ω_{R2} , so that the generic two-photon Rabi frequency is given by $\omega_R^{(2)} = \omega_{R1}\omega_{R2}/2\Delta$, where Δ is the detuning from the intermediate state.

An N_B^{th} order Bragg process (similar to a $2N_B$ -photon Raman process) is a coherent succession of N_B two-photon transitions from $|g, -N_B\hbar k\rangle$ to $|g, +N_B\hbar k\rangle$ with $2N_B - 1$ intermediate states of the form:

$$|e, (-N_B + 1)\hbar k\rangle, |g, (-N_B + 2)\hbar k\rangle, \dots \\ \dots |g, (N_B - 2)\hbar k\rangle, |e, (N_B - 1)\hbar k\rangle$$

Such a process is characterized by a $2N_B$ -photon Rabi frequency given by

$$\omega_R^{(2N_B)} = \frac{[\omega_R]^{2N_B}}{2^{2N_B-1}\Delta_1\Delta_2\cdots\Delta_{2N_B-1}} \quad (38)$$

where Δ_n is the detuning from the n^{th} intermediate state. Fig. 9 shows what this process would look like for an N_B^{th} order Bragg transition where the intermediate state detunings are given by

$$\Delta_n = \begin{cases} \delta + (2N_B n - n^2)\omega_{\text{rec}} & n \text{ odd} \\ (2N_B n - n^2)\omega_{\text{rec}} & n \text{ even} \end{cases} \quad (39)$$

Fig. 9 Energy vs. momentum diagram describing atomic states involved in higher-order Bragg diffraction. Reprinted from Gupta S, *et al.* (2001) Coherent manipulation of atoms with standing light waves. *Comptes Rendus de L'Academie des Sciences – Series IV – Physics-Astrophysics* 2:479–495, copyright (2001) with permission from Elsevier.

Substituting these detunings into Eq. (38) yields the N_B^{th} order Bragg transition $2N_B$ -photon Rabi frequency, $\omega_R^{(2N_B)}$:

$$\omega_R^{(2N_B)} = \frac{[\omega_R]^{2N_B}}{2^{4N_B-3} [(N_B - 1)!]^2 \delta^{N_B} \omega_{\text{rec}}^{N_B-1}} \quad (40)$$

where we have assumed $|\delta| \gg N_B^2 \omega_{\text{rec}}$.

To ensure that the system truly undergoes Bragg scattering, and validate the assumption that only states of equal kinetic energy and opposite momentum are coupled, the overall exposure time, τ , of the atoms to the fields must be limited both from below and above.

The lower bound on τ is necessary to resolve the final momentum state ($|g, N_B \hbar k\rangle$) from neighboring momentum states ($|g, (N_B \pm 2) \hbar k\rangle$) two photon recoil momenta away. Avoiding population transfer into these states requires that the energy separation be resolvable, or

$$\tau(\delta E) \gg h \quad (41)$$

For first-order Bragg scattering processes ($N_B = 1$) the nearest lying momentum states that may be mistakenly populated are $|g, \pm 3 \hbar k\rangle$, for which

$$\delta E = \frac{p_{n=3}^2}{2m} - \frac{p_{n=1}^2}{2m} = 8\hbar\omega_{\text{rec}} \quad (42)$$

Therefore

$$\tau \gg \frac{h}{8\hbar\omega_{\text{rec}}} = \frac{\pi}{4\omega_{\text{rec}}} \quad (43)$$

For sodium atoms (^{23}Na) in 590 nm light, $\tau \gg 6 \mu\text{s}$ is the lower bound required for first-order Bragg scattering.

For all higher-order ($N_B > 1$) Bragg scattering processes, the nearest momentum states are $|g, \pm (N_B - 2) \hbar k\rangle$, which limits the interaction time to

$$\tau \gg \frac{\pi}{2(N_B - 1)\omega_{\text{rec}}} \quad (44)$$

which for $N_B \gg 1$ reduces to

$$\tau \gg \frac{\pi}{2N_B\omega_{\text{rec}}} \quad (45)$$

The upper bound on the interaction duration is necessary to avoid spontaneous emission. The interaction duration must be short enough so that the expected number, N_s , of spontaneous emission events per atom during the time τ is negligible. N_s is simply given by the product of the excited state fraction (Eq. (36)) and the probability of spontaneous decay given that the atom is in the excited state:

$$N_s = |c_0(t)|^2 \Gamma \tau = \frac{\omega_R^2}{4\Delta^2} \Gamma \tau \quad (46)$$

where Γ is the natural decay rate of the excited state. Avoiding spontaneous emission ($N_s \ll 1$) while still having a significant probability for transitions ($\omega_R^{(2N_B)} \tau \simeq \pi$) forces one to work in the regime where $\Delta \gg \Gamma$, which is a practical requirement to avoid spontaneous emission and maintain coherence. For sodium atoms on the 590 nm transition, $\Gamma = 6.3 \times 10^7 \text{ s}^{-1}$, and a typical choice in Bragg diffraction experiments is $\Delta = 50\Gamma$ or $\Delta/2\pi = 500 \text{ MHz}$.

Briefly, to relate Rabi frequency to optical intensity, the transition rate W on resonance with a Lorentzian spectral line is given by Fermi's golden rule:

$$W = \frac{\omega_R^2}{\Gamma} = \frac{\lambda_{\text{photon}}^2}{2\pi} \frac{I}{\hbar\omega} \quad (47)$$

where the last term can be regarded as the cross section for absorption multiplied by intensity in units of photon flux. Hence

$$\omega_R^2 = \Gamma \frac{\lambda_{\text{photon}}^2}{2\pi} \frac{I}{\hbar\omega} \quad (48)$$

For Na atoms in $12 \text{ mW}(\text{cm})^{-2}$ resonant light, $\omega_R = \Gamma = 6.3 \times 10^7 \text{ s}^{-1}$. Both the probability of Bragg scattering and the spontaneous emission increase linearly with $\omega_R^2 \tau \Gamma^{-1}$. However, spontaneous emission decreases as Δ^2 while the Bragg scattering probability decreases as Δ . Thus, as shown in Fig. 10, at sufficient detuning and laser power, Bragg scattering occurs with no spontaneous emission. For reference, $12 \text{ mW}(\text{cm})^{-2} \times 10 \mu\text{s}$ corresponds to $\omega_R^2 \tau \Gamma^{-1} = 630$ for sodium atoms.

Bragg scattering of atoms from a standing light wave was first observed at MIT in 1988. A supersonic atomic beam was diffracted from a standing wave of near-resonant laser light as depicted in Fig. 6. The angle between the atomic beam (of thermal wavelength λ_{dB}) and the light grating (of periodicity $\lambda_L/2$) was tuned to the appropriate Bragg angle, θ_B , where:

$$\lambda_{dB} = \lambda_L \sin(\theta_B) \quad (49)$$

Population transfer corresponding to both first- and second-order Bragg scattering was observed (Fig. 7). The experiment required a sub-recoil transverse momentum spread of the atomic beam in order to resolve the different momentum states in the far field and limit the final state to only one diffracted order. The Pendellösung was observed as an oscillation in population transfer as a function of standing wave intensity, $I \propto \omega_R^{(2)}$, for a fixed interaction time, τ .

Atomic beam diffraction from an optical standing wave is a continuous-wave (CW) experiment in which the selectivity needed for the Bragg process is imposed by good angular resolution of the particle beam and a high degree of parallelism between the light crystal planes. This ensures that of the various final Bragg orders allowed by momentum conservation, only one conserves energy (energy conservation is exact in a CW experiment). For atoms scattering from a light crystal, parallelism of the crystal planes requires highly parallel photon momentum that implies a minimum width of the standing wave (the diffraction limit for the collimated photons). The transit time, τ , of the atoms across this width then exceeds the lower bound given in Eq. (44).

The excellent collimation required of the atomic beam to ensure resolution of the Bragg scattered atoms reduces the intensity of the source by many orders of magnitude. A Bose-Einstein Condensate (BEC) is an attractive alternative source of atoms because its momentum spread is typically an order of magnitude below a single-photon recoil momentum. To Bragg diffract atoms initially in a stationary BEC, it is easier to move the light crystal than to accelerate the condensate. This is done by simply frequency shifting one of the traveling waves so that the resultant standing wave formed by its interference with the unshifted traveling wave moves with the proper velocity ($N_B \hbar k/m$) relative to the stationary atoms to impart the necessary momentum. The Bragg scattered atoms will then have momentum $2N_B \hbar k$ in the laboratory frame. The resonance condition thus becomes a condition on relative detuning, δ_{N_B} , between the two laser beams forming the diffraction grating. For N_B^{th} -order Bragg diffraction, the relative detuning is given by

$$\delta_{N_B} = \frac{2N_B \hbar k^2}{m} = 4N_B \omega_{\text{rec}} \quad (50)$$

Fig. 10 The conditions for which $N_s > 0.02(0.10)$ are hashed in light(dark) gray. ω_R^2/Γ is proportional to optical intensity. The line labeled π -pulse indicates the parameters which cause complete first-order Bragg diffraction. The line labeled 2π -pulse indicates conditions where population is completely transferred back to the initial state (Pendellösung oscillation).

The first demonstration of Bragg scattering in a BEC was at NIST in 1999. They used Bragg scattering mainly as a tool to manipulate the momentum of the BEC, observing up to sixth-order processes. At MIT the interaction time was lengthened (to ≈ 100 times the lower bound of Eq. (44) for first-order Bragg scattering), creating a new type of spectroscopy called Bragg Spectroscopy. It is a spectroscopic measurement of the shift of the Bragg scattering frequency due to the Doppler shift ($k \cdot v$) from the atoms' motion together with any mean field interaction. (These effects can be separated by going to higher-order Bragg scattering to enhance the Doppler shift.)

Bragg Spectroscopy was used to observe the momentum distribution of a BEC in a magnetic trap. The width of the Bragg resonance curve was primarily due to a 2 kHz Doppler-broadening that yielded the momentum distribution of the condensate. The spread in the corresponding velocity distribution was very small ($\approx 0.5 \text{ mm s}^{-1}$), even smaller than allowed by the Heisenberg uncertainty limit for a particle confined in the ground state of a harmonic trap. This reflects the increase in size of the condensate due to the mean field repulsion (^{23}Na , used in the MIT experiment, has a positive scattering length). The distribution was Heisenberg uncertainty limited at the observed size of the BEC, establishing for the first time that the coherence length of the condensate was equal to its size. In addition, the narrow Bragg resonance was shifted by the repulsive interactions within the condensate, resulting in a spectroscopic measurement of the mean-field energy.

Kapitza–Dirac Scattering

Diffraction of neutral atoms from a standing wave of near-resonant light with a short interaction time ($\tau_{KD} \ll 1/\omega_{\text{rec}}$) has come to be called Kapitza–Dirac scattering, in honor of their pioneering suggestion. In 1933, Kapitza and Dirac predicted that an electron beam propagating in a standing light wave would undergo stimulated Compton scattering and be reflected. This process has a tiny cross-section, equal to the classical electron radius squared: $\sigma_{\text{Compton}} = 8\pi/3(e^2/mc^2)^2 \approx 6 \times 10^{25} \text{ cm}^2$, and has only recently been observed using extremely high laser intensities. If the electrons are replaced by atoms, however, the scattering cross-section for resonant light $\sigma_{\text{atom}} = (1/2\pi)\lambda_{\text{photon}}^2 \approx 4 \times 10^{-10} \text{ cm}^2$ is 15 orders of magnitude larger. This large cross-section, together with the ready availability of tunable lasers, has allowed stimulated scattering, both in the Kapitza–Dirac and Bragg regimes, to become the primary tool for the coherent manipulation of atoms.

In Kapitza–Dirac scattering, atomic motion during the interaction time is small compared to the characteristic dimensions of the interaction potential. This is equivalent to the eikonal approximation for scattering or the thin-lens approximation in optics. The idea is that the phase of the incident particle changes along each classical trajectory, but not the amplitude. Thus, there may be momentum transfer perpendicular to the trajectory, but the trajectory is not significantly displaced (until after the interaction is over). Mathematically, this regime can be treated by neglecting the atomic kinetic energy term in the Hamiltonian (the Raman–Nath approximation).

The standing wave interaction may be treated by considering the standing wave (ac-Stark shift) potential resulting from the applied fields given in Eq. (18):

$$V(z, t) = \frac{\hbar\omega_R^2}{\delta} f^2(t) \sin^2(kz) \quad (51)$$

where we have assumed $\delta \gg \Gamma$, because the constraint $N_s \ll 1$ (Eq. (46)) holds in this regime as well, where N_s is the expected number of spontaneous emission events per atom during the time τ . Although we neglect the kinetic energy term in the Hamiltonian, we continue to will treat z in Eq. (51) as an operator.

Given the initial atomic wavefunction in momentum space, $\psi(p_0)$, the atomic wavefunction immediately after the interaction is given by

$$\psi(p) = e^{-\frac{i}{\hbar} \int dt' U(z, t')} \psi(p_0) \quad (52)$$

$$= e^{-i\frac{\omega_R^2}{2\delta}\tau} e^{i\frac{\omega_R^2}{2\delta}\tau \cos(2kz)} \psi(p_0) \quad (53)$$

where $\tau = \int dt' f^2(t')$ and the integral is over the interaction duration. With the use of the identity for Bessel functions of the first kind, $e^{iz \cos(\beta)} = \sum_{n=-\infty}^{\infty} i^n J_n(\alpha) e^{in\beta}$, the atomic wavefunction can be written as

$$\psi(p) = e^{-i\frac{\omega_R^2}{2\delta}\tau} \sum_{n=-\infty}^{\infty} i^n J_n\left(\frac{\omega_R^2}{2\delta}\tau\right) e^{i2nkz} \psi(p_0) \quad (54)$$

$$= e^{-i\frac{\omega_R^2}{2\delta}\tau} \sum_{n=-\infty}^{\infty} i^n J_n\left(\frac{\omega_R^2}{2\delta}\tau\right) \psi(p_0 + 2n\hbar k) \quad (55)$$

States with $2N\hbar k$ of momentum are populated with the probability:

$$P_N = J_N^2(\theta), \quad N = 0, \pm 1, \pm 2, \dots \quad (56)$$

Fig. 11 Two counter-propagating running waves of light superimpose to form a standing wave of light. The more narrow beam shown here represents the configuration for Kapitza-Dirac diffraction.

where

$$\theta = \frac{\omega_R^2}{2\delta} \tau = \omega_R^{(2)} \tau \quad (57)$$

is the pulse area. This leads to a transverse rms momentum of the diffracted atoms that is linearly proportional to the pulse area:

$$p_{\text{rms}} = \sum_{n=-\infty}^{\infty} (n\hbar k)^2 P_n = 2^{1/2} \theta \hbar k \quad (58)$$

The maximum and minimum bounds on the interaction time, τ , and the amount of momentum transfer to the atoms are discussed in the next section.

Kapitza-Dirac diffraction of atoms was first observed at MIT in 1986. Diffraction of a well-collimated (subrecoil) supersonic atomic beam was observed after passage through the tightly focused waist of a near-resonant standing wave (Fig. 11). Significant diffraction into momentum states $|g, \pm 10\hbar k\rangle$ was observed (Fig. 12). Even higher diffracted orders should be observable in the future using laser beams directed at small BECs for somewhat longer times.

Comparison of Atom-Standing Wave Interactions

The atomic motion induced by interaction with a standing light wave varies qualitatively with the interaction parameters. Fig. 13 summarizes the various interaction regimes of an atom with a standing wave in terms of the two most basic parameters: the two-photon Rabi frequency, $\omega_R^{(2)} = \omega_R^2/2\delta$, and the duration of the interaction, τ . To render the plot independent of atomic species, $\omega_R^{(2)}$ is given in units of the single-photon recoil frequency, ω_{rec} , and τ is given in units of the inverse single-photon recoil frequency, ω_{rec}^{-1} . Thus, for ^{23}Na the point (1,1) on Fig. 13 corresponds to (6.4 μs , $2\pi \times 25$ kHz). The product of the two-photon Rabi frequency and the duration of the interaction is the pulse area, $\theta = \omega_R^{(2)} \tau$ (Eq. (57)), which is likewise the product of the pair of coordinates forming a point on the plot.

The lines KD1(KD10) on Fig. 13 show where the first maxima of $P_{1,10} = J_{1,10}^2(\theta)$ (Eq. (56)) occur, corresponding to the maximum possible population transfer into the first and tenth Kapitza-Dirac diffracted order respectively. Since the momentum distribution of diffracted atoms depends only on the pulse area (θ), all Kapitza-Dirac orders are parallel to each other and further offset from the origin in increasing order number.

The Kapitza-Dirac regime ends at large interaction times where the Raman-Nath approximation fails due to motion of the atoms down the slope of the standing wave potential. We show these lines dashed as the interaction time approaches the beginning of the classical oscillation regime, and terminate these lines where the oscillation produces its first focus, at the first focus line. This line corresponds to the atoms completing a quarter period of oscillation in the standing wave potential, $\tau = \tau_{\text{osc}}/4$, where the oscillation time is derived from the approximation that the potential $\langle V(z,t) \rangle_t$ (Eq. (51)) is harmonic about the minimum:

$$\tau_{\text{osc}} = \frac{\pi}{\omega_R} \left(\frac{|\delta|}{\omega_{\text{rec}}} \right)^{1/2} \quad (59)$$

In the shaded region of Fig. 13, the atoms will oscillate classically about the potential minimum, causing a periodic focusing of the atoms alternately in position and momentum space. However, anharmonicities of the potential away from its minimum will degrade the quality of the focusing effects.

Fig. 12 Kapitza–Dirac diffraction of an atomic beam from a standing wavelength grating. The solid lines are experimental data, the dashed lines are theoretical curves. (a) $\theta = 1.69$, (b) $\theta = 2.33$, (c) $\theta = 2.84$. Reprinted with permission from *Physical Review Letters* 56(8): 827–830. Copyright (1986) by the American Physical Society.

The maximum diffracted order that can be significantly populated by the light–atom interaction is limited by energy conservation. Classically, the maximum momentum transfer to the atoms due to the sudden switch on of the standing wave is delivered to atoms that convert the full height of the standing wave potential ($\hbar\omega_R^2/\delta$), into kinetic energy. This gives

$$\frac{p_{\max}^2}{2m} \simeq \frac{\hbar\omega_R^2}{\delta} \Rightarrow p_{\max} \simeq \omega_R \left(\frac{2\hbar m}{\delta} \right)^{1/2} \quad (60)$$

Equating the maximum absorbed momentum, $p_{\max}$, to an integer number of two-photon recoil momenta yields the maximum expected diffracted order, $N_{\max}$:

$$p_{\max} = 2N_{\max}\hbar k \Rightarrow N_{\max} \simeq \frac{\omega_R}{2} (\omega_{\text{rec}}\delta)^{-1/2} \quad (61)$$

This is just half of the square-root of the standing wave potential height measured in units of the single-photon recoil energy:

$$N_{\max} = \frac{1}{2} \left(\frac{\omega_R^2}{\omega_{\text{rec}}} \right)^{1/2} = \frac{1}{2} \left(\frac{\omega_R^{(2)}}{\omega_{\text{rec}}} \right)^{1/2} \quad (62)$$

As the two-photon Rabi frequency is reduced, $N_{\max}$ falls below unity. As a result, there is no longer time for the higher-order multi-photon processes to generate significant amplitudes in diffracted orders with $N > 1$ before dephasing due to the kinetic energy term (Eq. (24)) becomes significant and the higher-order processes become negligible. Only a small population is ever transferred to the $N = \pm 1$ orders and it does not oscillate at ω_{rec} . Therefore the classical oscillation regime does not extend below $N_{\max} \simeq 1$ where it is terminated on Fig. 13.

Classical oscillation would result in atoms with momentum from zero up to the maximum allowed by energy conservation. Therefore, the classical focusing of atoms must be manifest as an atomic population distribution over many of the quantized momentum states (separated by $2\hbar k$) allowed by energy conservation (Eq. (61)). However, as the interaction time lengthens and extends into the Bragg regime, the populated momentum states become restricted by energy conservation until only the oscillatory Pendellösung into and back from only one final state remains. Therefore, we have ended the classical oscillation regime where the Bragg condition (Eq. (44)) is satisfied. The Bragg regime presupposes a smooth light pulse shape. For a pulse with sharp edges, classically oscillatory behavior can still be observed at longer times than included in the shaded region of Fig. 13, which is why we show the large τ boundary of the classical oscillation regime as dashed.

Fig. 13 Atomic diffraction from a standing light wave. The vertical axis is the two-photon Rabi frequency, $\omega_R^2/2\delta$, in units of the single-photon recoil frequency, ω_{rec} , and the horizontal axis is the pulse duration, τ , in units of the inverse single-photon recoil frequency, ω_{rec}^{-1} . The scaling is chosen to eliminate the atomic species dependence of the plot. All coherent momentum transfer processes are destroyed by spontaneous decay, which occurs with probability $N_s=0.1$ along the lines labeled accordingly and parameterized by the given ratio δ/Γ . Lines KD1 and KD10 show conditions for the maximum transfer into the first and tenth Kapitza-Dirac diffracted order respectively. As the interaction time is increased the Raman-Nath approximation is violated (termination of Kapitza-Dirac curves) and the atoms enter the oscillatory regime, executing at least a quarter period of oscillation above the first focus line (shaded area). Cures B1, B2, B3, B10, and B20 correspond to conditions that generate complete Bragg reflection in the first-, second-, third-, tenth-, and twentieth-order respectively. Experimental conditions are shown as points. Filled circles: Kapitza-Dirac diffraction of an atomic beam (Pritchard 1986). Filled squares: Bragg diffraction of an atomic beam (Pritchard 1988). Open squares: Bragg diffraction of a BEC (Phillips 1999). Open circles: transition from Kapitza-Dirac diffraction to oscillation of a BEC in a standing wave light pulse (Phillips 1999). Table 1 Natural parameters and typical experimental parameters involved in standing wave diffraction. The relevant frequencies together with the corresponding times ($1/\omega$) are tabulated. The parameters for ^{23}Na have been used for system dependent quantities

ω	$\omega/2\pi$	$1/\omega$
ω_0	500 THz	0.3 fs
δ (Bragg)	500 MHz	0.3 ns
ω_R (Bragg)	100 MHz	1.6 ns
ω_R (K-D)	100 MHz	1.6 ns
Γ	10 MHz	16 ns
ω_{rec}	25 kHz	6.4 μs
ω_{osc}	1 MHz	160 ns

In the Bragg regime, transfer of population is restricted to (and back from) only one final momentum state. The allowable final states are restricted by limiting the frequency bandwidth (i.e., energy uncertainty) of the light fields in the atomic rest frame. This is accomplished by lengthening the interaction time and smoothing the rise and fall of the electromagnetic fields. The parameters for a first-order Bragg transition (Table 1) are typically $\delta/\Gamma \simeq 50$, $\Gamma\tau \simeq 1$, and $\omega_R/\Gamma \simeq 10$ giving $N_s \simeq 10^{-2}$ and $\omega_R^{(2)}\tau \simeq 1$. Obtaining significant population transfer with higher-order Bragg processes requires larger intensities. Various orders (1, 2, 3, 10, and 20) of Bragg diffraction are shown as lines on Fig. 13 corresponding to $\omega_R^{(2N_B)}\tau = \pi$, where $\omega_R^{(2N_B)}$ is given in Eq. (40). The lines are terminated at the appropriate interaction time determined from the final momentum state resolution condition (Eq. (44)). The Bragg regime extends indefinitely to larger interaction times, which might be termed the region of Bragg spectroscopy. In experiments in this regime with ^{23}Na , atomic velocity resolution below 1 mm s^{-1} was obtained at $\tau = 80\omega_{rec}^{-1}$. The study of adiabatically expanded BECs would require larger interaction times to resolve their smaller velocity spread and weaker mean field shifts.

The Kapitza–Dirac and Bragg regimes assume a different initial atomic momentum (in the rest frame of the standing wave) parallel to the standing wave axis. Kapitza–Dirac scattering assumes no component of the initial atomic momentum along this axis. The efficiency of Kapitza–Dirac diffraction falls rapidly as the initial momentum in units of the photon momentum approaches $1/\omega_{\text{rec}}\tau$. To observe N_B^{th} -order Bragg scattering, the initial atomic momentum along the standing wave axis must have (nonzero) magnitude $N_B\hbar k$. Without adhering to this constraint, no final momentum state will be energetically degenerate with the initial state and the atomic sample will not respond to the presence of the standing wave, even if the interaction parameters are appropriate ($\omega_R^{(2N_B)}\tau \simeq 1$) for N_B^{th} -order Bragg scattering.

The condition $N_s = 0.1$ (Eq. (46)), where N_s is the expected number of spontaneous emission events per atom during the light–atom interaction, is drawn on Fig. 13 for two ratios (30 and 1000) of standing wave detuning, δ , to the atomic excited state natural lifetime, Γ . For fixed $\delta\Gamma$, we see that $N_s \propto \theta$, thus conditions with an increased pulse area (above and to the right of the $N_s = 0.1$ lines) result in a proportionally increased N_s . These $N_s = 0.1$ lines are extended across all regimes of Fig. 13 because restricting spontaneous emission is required for both Kapitza–Dirac and Bragg scattering. As N_s approaches unity, the correct optical potential describing the light–atom interaction no longer is Eq. (51), and scattering of atoms becomes an incoherent process which can lead to new possibilities such as a complex valued optical potential. Thus, while the standing wave fields in pure Bragg or Kapitza–Dirac scattering behaved as phase gratings for atoms, light gratings on resonance can effectively become amplitude diffraction gratings.

Atom Interferometry

In the 19th century, Fizeau (1853), Michelson (1881), Rayleigh (1881), and Fabry and Perot (Fabry 1899) exploited the interference properties of light waves to create the light interferometer which has since resulted in many beautiful experiments and precise measurements. Using technologies invented since the Second World War, the initial ideas of de Broglie and Schrödinger have evolved into construction of interferometers for neutrons, electrons, and atoms. These new interferometers are proving to be valuable tools for probing fundamental physics, for studying quantum mechanical phenomena, and for making inertial measurements.

The scientific value of interferometry with atoms and molecules has long been recognized. In fact, the concept of an atom interferometer was patented in 1973 and it has been extensively discussed since. Atom interferometry offers great richness stemming from the varied internal structure of atoms, the wide range of properties possessed by different atoms (e.g., mass, magnetic moment, absorption frequencies, and polarizability), and the great variety of interactions between atoms and their environment (e.g., static E–M fields, radiation, and other atoms).

Light interferometers are generally based either on achromatic beamsplitters such as half-silvered mirrors or on other semi-transparent membranes whose structure is small compared to the wavelength of the wave they are splitting. Lacking material structures that are either transparent to atoms or smaller than their de Broglie wavelength, diffraction gratings have been pressed into service both as beamsplitters and mirrors for atom waves. This means that atom interferometers are constrained to designs which somehow compensate for the dependence of diffraction angle on the wavelength of the individual atoms. In spite of this challenge, a surprising variety of atom and molecule interferometers have been built since 1991. A majority have used the three-grating configuration in which the first grating splits the incident beam, the second reverses the differential momenta given by the first, and the third recombines the two beams at the location where they overlap. Both material gratings and standing waves of light have been used in the Raman–Nath, Bragg, and adiabatic regimes to obtain interference fringes. Some designs render the interference fringes in position space, others in internal state space.

Fig. 14 shows the MIT setup for a three-grating atom interferometer which features sufficient separation between interfering paths to accommodate an interposed metal foil. This allows different fields or media to act on atom waves only in one of the two arms of the interferometer. Such an interaction region has been used to measure phase shifts due to an electric field applied to only one of the interfering paths. The phase difference between the two paths is then given by the Feynman path integral:

$$\phi = \frac{-i}{\hbar} \int V(x) dt \quad (63)$$

Fig. 14 An interferometer for atoms built with three nanofabricated gratings. Each atom propagates in a superposition of two paths, shown in bold. The beam of atoms is well enough collimated, and the diffraction angle is large enough, that a metal barrier can be inserted between the two paths inside the interferometer. The interference fringes are observed by translating one grating transverse to the atom beam. See for example: Berman PR (ed.) (1997) *Atom Interferometry*. San Diego, CA: Academic Press.

Fig. 15 Interference fringes from atoms. 2π of grating phase corresponds to translating the grating one grating period, or 100 nm. These data were obtained at MIT.

where

$$V = -\frac{1}{2}\alpha E^2 \quad (64)$$

is the potential energy due to the electric field E , and α is the electric polarizability of the atoms. The resulting phase shift of the interference fringes (Fig. 15) has been used to measure the polarizability of sodium atoms to unprecedented accuracy.

Phase shifts have also been measured due a dilute target gas in one arm of the interferometer. In this case there is a complex index of refraction for the forward scattered atoms (some attenuation, and some phase shift) which depends on matter wave wavelength. Recent measurements reveal glory oscillations in the matter wave index of refraction due to passing through a dilute gas, and are a sensitive probe of interatomic potentials.

In the domain of inertial sensing, atom interferometers have been used to the local gravitational acceleration, $\vec{g}$, Newton's constant, G , gravity gradients, $\nabla\vec{g}$, and rotations $\vec{\Omega}$, each with sensitivity rivaling if not exceeding any other method. The Sagnac phase shift, due to rotations, for a two-path interferometer is

$$\phi_S = \frac{4\pi}{\lambda_{dB}v} \vec{\Omega} \cdot \vec{A} \quad (65)$$

where v is the velocity of atoms, $\vec{A}$ is the enclosed area of the interferometer, and $\vec{\Omega}$ is the rotation rate. The two factors in the denominator, λ_{dB} and v , are both $\sim 10^5$ times larger for light than for atoms, which is why atom interferometers have the potential to be 10^{11} times more accurate than optical interferometers. In practice, atom interferometers only outperform laser gyros by a small amount because they have dramatically smaller enclosed areas and particle flux than optical interferometers.

Since the first atom interferometers for Na and He* began working in 1991, others have been made for Li, Ar*, Ca, Cs, K, Mg, Ne*, Rb, and Li₂, Na₂, I₂, C₆₀ and C₇₀ molecules, interferometers starting with trapped atoms have been made for Cs, Ca, He*, Mg, and Rb. Interferometers using Bose-Einstein condensates have been demonstrated with Na and Rb. These lists are still growing. Diffraction from a single grating has been observed for molecules as large as C₇₀ buckyballs, which may someday be used in a three-grating interferometer.

Conclusion

The manipulation of atoms using light forces from standing light waves is a rich subject. The seminal suggestion of Kapitza and Dirac laid dormant for 50 years due to lack of experimental technology. However, in the 1980s this suggestion was realized with atomic sources and considerably extended both experimentally and theoretically. In the early 1990s, coherent standing wave manipulation and nonfabricated atom optics became the two major routes to making atom interferometers. As the new century begins, these techniques are being refined further with improved sources, new detection schemes, and better atom optics. Replacing thermal atomic beams by Bose-Einstein condensates (BECs), as sources of atoms, will revolutionize the field of atom optics just as lasers did in light optics.

Conversely, stimulated light scattering and nanostructures provide new ways to study atomic and molecular properties, such as Bragg spectroscopy for BEC characterization. As progress continues, exciting developments should be forthcoming, such as definitive measurements of the fine structure constant, α , atom gyroscopes that are far superior to the best laser gyroscope technology, and improved studies of BECs. Another area that is on the brink of spectacular development is the confinement of coherent matter waves in atom waveguides and the development of the scientific and technological opportunities that these represent, in analogy to fiber optic waveguides for light.

While we have described the application of nanofabrication techniques to atom optics, it is possible to imagine technology transfer in the other direction. The fundamental problem of fabricating ever smaller structures might be tremendously advanced by

atom optics because the de Broglie wavelength of atoms is so much smaller than that of light, permitting them to be focused to directly deposit much smaller features than possible with photolithography.

Organic Semiconductors

Fang-Chung Chen, National Chiao Tung University, Hsinchu, Taiwan

© 2018 Elsevier Ltd. All rights reserved.

Introduction

Organic semiconductors (OSCs) are receiving increasing attention these days because they have many attractive properties – including light weight, low-cost production, low-temperature processing, mechanical flexibility, and abundant availability – that distinguish them from their conventional inorganic counterparts. The recent successful commercialization of active-matrix organic light-emitting diodes (OLEDs) for high-end smartphone displays suggests that organic compounds have promising prospects for use in various other electrical and optoelectronic devices. For example, the fabrication of solar cells, transistors, photodetectors, and lasers with OSCs can be highly feasible and highly efficient. Another attractive property of OSCs is that they can be processed using simple solution processing techniques (e.g., ink-jet printing, reel-to-reel fabrication), making the fabrication of electronic devices much easier and cheaper. As Professor Heeger said in his Nobel lecture, “I’m convinced that we are on the verge of a revolution in ‘Plastic Electronics’.” We foresee rapid advances in the field of OSCs bringing increasingly more inexpensive, workable, and smart organic devices into our daily lives.

Organic materials are substances comprising mostly carbon and hydrogen atoms; they had been considered for many years to be exclusively electrically insulating. The discovery of electrical conductivity in organic compounds can be traced back to the 1950s; it has opened up a new fascinating field of research. Electroluminescence (EL) from anthracene single crystals was reported by Pope *et al.* in 1963. In the 1970s, Shirakawa, Heeger, and MacDiarmid found that the conductivity of polyacetylene could be increased tremendously – up to a level close to that of a typical metal – after exposure to vapors of chlorine, bromine, or iodine. Such high conductivity from a traditional “insulator” of electricity drew much attention and encouraged the rapid growth of the field of organic electronics. The Nobel Prize in Chemistry in 2000 was awarded to Heeger, MacDiarmid, and Shirakawa for “the discovery and development of conducting polymers.”

Among the various organic electronic devices known today, the technology of OLEDs has definitely been under the spotlight. Initially, the EL observed from organic single crystals was not energy efficient and required a large voltage to drive the devices. In 1987, Tang and Van Slyke developed light-emitting devices based on amorphous organic thin films and achieved a quantum efficiency of 1% under an electrical bias of less than 10 V. In 1990, OLEDs incorporating conjugated polymers were also reported by Professor Friend at Cavendish Laboratory. Since then, relevant technologies – including new materials, device structures, and device engineering approaches – evolved rapidly, gradually establishing a new industry.

As organic-based devices have matured from scientific concepts in the laboratory to applications in the real market, there is a requirement to understand the unique properties of OSCs and determine the opportunities that this new generation of electronic materials might offer. In this article, we discuss the electronic structures of OSCs and several fundamental charge storage scenarios in OSCs. We also review the concept of doping in OSCs. We conclude with a brief overview of interesting device applications, including electrophotographic devices, thin film transistors, and light-emitting transistors.

Electronic Structures

OSCs are usually categorized into two main groups, depending on the molecular weights of their organic components: conjugated polymers (Fig. 1) and small molecules (Fig. 2). Polymers are constituted by repeated structural units (monomers) connected by covalent bonds. Because the number of repeating units usually cannot be controlled precisely, they are prepared with a distribution of molecular weights. On the other hand, small molecules have precise and much smaller molecular weights. The other distinction between the two OSC categories is in their methods of fabrication. Most conjugated polymers are soluble in organic solvents and can be processed using various solution-processing approaches. In contrast, small molecules are usually deposited through thermal evaporation under high vacuum – a deposition method that allows good control over the thickness, morphology, and other properties of the organic films. Accordingly, very thin (even down to a few nanometers), high-quality films of small molecules can be obtained quite readily. The chemical structures of the small molecules can be also tailored so that they become soluble in organic solvents, facilitating the use of solution fabrication processes. For example, pentacene (Fig. 2(d)) can be deposited only through thermal evaporation, whereas 6,13-bis[(triisopropylsilyl)ethynyl]pentacene (TIPS-pentacene) (Fig. 2(f)) features side chains that improve its solubility, simplify its processing while maintaining high crystallinity.

To understand the electronic structures of OSCs, we begin with the atomic orbitals (AOs) of carbon, the most important element of any organic materials. A carbon atom has six electrons; its electronic configuration is $(1s)^2(2s)^2(2p)^2$. It can be bonded to other atoms using various hybridization orbitals, including sp , sp^2 , and sp^3 hybrid orbitals (Fig. 3). For example, one s and two p orbitals are superposed to form three sp^2 hybrid orbitals; the orbitals are distributed in the same plane with an angle of 120 degree between them. In a simple model molecule, ethylene, each carbon atom offers three sp^2 hybrid orbitals to bond with other atoms (Fig. 4). The $1s$ orbital of a hydrogen atom overlaps with one of the sp^2 hybrid orbitals to form a molecular orbital (MO),

Fig. 1 Chemical structures of polymer-based OSCs: (a) poly[1-methoxy-4-(2-ethylhexyloxy)-*p*-phenylene vinylene] (MEH-PPV), (b) poly(9,9-dioctylfluorene) (PFO), (c) poly(3-hexylthiophene-2,5-diyl) (P3HT), (d) poly[2,5-bis(3-hexadecylthiophen-2-yl)thieno[3,2-*b*]thiophene] (PBTBT), and (e) poly[3-(4-octylphenyl)thiophene] (POPT).

a so-called σ -orbital; the resulting bonding is a σ -bond. The two carbon atoms are also bonded through sp^2 hybrid orbitals. Each carbon atom, however, retains one p atomic orbital, aligned orthogonal to the plane of the sp^2 hybrid orbitals. The two p_z atomic orbitals overlap side-by-side with the electron density distributed above and below the internuclear axis, forming a different type of MO called a π -orbital. Note that the π -electron cloud is delocalized between the two carbon atoms. Consequently, the carbon atoms are bonded by two bonds: a σ -bond and a π -bond; this arrangement is termed a “double bond.” In view of the electron wave functions, the overlapping of two AOs produces two MOs: a bonding state and an anti-bonding state, after constructive and destructive interference, respectively. Because destructive interference results in lower electron density between the atoms, the energy of the anti-bonding state is higher than that of the bonding state. For π -orbitals, the bonding and anti-bonding states are denoted as π - and π^* -MOs, respectively.

Benzene, a larger molecule (**Fig. 5**), has six carbon atoms that are also bonded using sp^2 hybrid orbitals. Similarly, the six p_z AOs that remain form six π -bonding MOs: three bonding and three anti-bonding orbitals. As a consequence of interference among the six p_z orbitals, the lower bonding and upper anti-bonding states are degenerate (**Fig. 5(b)**). Six p_z electrons occupy the three bonding states in a neutral benzene molecule. Similar to ethylene, the π -electron cloud is delocalized over the six carbon atoms. In other words, the electrons can move from one carbon atom to another; such a delocalized structure is said to feature “conjugation.”

The MO of highest energy that electrons occupy is known as the highest occupied molecular orbital (HOMO). Meanwhile, the lowest unoccupied molecular orbital (LUMO) is the MO of lowest energy that electrons do not occupy. The difference in energy between the HOMO and LUMO is the energy required to excite an electron in the molecule. In benzene, for example, **Fig. 5(b)**, the upper bonding MOs (π_2, π_3) are the HOMOs and the lower anti-bonding MOs (π_4^*, π_5^*) are the LUMOs. For OSCs, because the energy splitting of π -bonds is usually smaller than that of σ -bonds, electronic processes (e.g., photon absorption and emission) occur energetically favorably on π -orbitals. Similarly, the charges injected from the metal contacts of organic electronic devices would tend to occupy π -MOs. In other words, the electronic functions of OSCs originate from the smaller and favorable energy levels of the frontier orbitals of the π -electron system; the σ -electrons are hardly excited because much higher energy is required for electronic transitions between σ -orbitals. Furthermore, the HOMO–LUMO energy gap decreases upon increasing the size of the π -conjugation system, because of the greater extent of π -electron delocalization.

Trans-polyacetylene was the first conducting polymer to be discovered (Fig. 6). For a single chain of neutral polyacetylene, the π -band, which can be considered to be composed of an almost infinite number of p_z orbitals, would be half-filled, resulting theoretically in metallic behavior (Fig. 6(a)). Experimental results have strongly indicated, however, that polyacetylene is a semiconductor having an energy gap of approximately 1.5 eV. In reality, the one-dimensional (1D) “metal” is unstable and the structure tends to distort, as displayed in Fig. 6(b). Accordingly, the main chain of polyacetylene actually has alternately long and short bonds. The so-called Peierls distortion converts the repeating unit of *trans*-polyacetylene to *trans*- $(-\text{HC}=\text{CH}-)_n$, instead of *trans*- $(\text{CH})_n$. As displayed in Fig. 6(g), dimerization of the molecule opens an energy band gap. The π -band is fully occupied and the upper π^* -band is empty; this band structure is similar to that of a typical inorganic semiconductor, which features a full-filled valence band and an empty conduction band. While a 1D π -electron metal is not stable, higher-dimensional π -electron systems are not subject to such Peierls instability. For example, carbon nanotubes and graphene can be metallic or semi-metallic.

Solitons, Polarons, and Bipolarons

The electronic structure of a polymer can be described using the Su-Schrieffer-Heeger (SSH) model, based on a quasi-one-dimensional tight-binding model. It assumes that the π -electrons are strongly coupled to the polymer backbone through the electron-phonon interactions. Charge storage occurs through formation of solitons, polarons, and bipolarons. Solitons are structural defects on the polymer chains. As illustrated in Fig. 6(b) and (c), polyacetylene has two resonance forms. The soliton is a domain boundary of these two degenerate resonance configurations (Fig. 6(d)); the domain wall can actually extend over several carbon atoms (Fig. 6(e)). A soliton may be neutral or carry a charge. The energy of the soliton lies between the π - π^* gap, because of its nonbonding nature. This defect state is mobile because the system energy does not depend on the position of the soliton. For non-degenerate ground-state polymers – for example, poly(phenylene vinylene) (PPV, Fig. 7(a)) and polyparaphenylene (PPP, Fig. 7(b)) – in which the interchange of single and double bonds leads to changes in energy, the solitons cannot be stable because the structure is not symmetric. Instead, double defects are required for such non-degenerate polymers. Such double defects are called polarons; they can be considered as a bound state of a charged soliton and a neutral soliton (Fig. 7(c)). Consequently, its energy levels hybridize the two states, which are split into a bonding, less energetic level and an anti-bonding, more energetic one (Fig. 7(d)). The two energy levels can be occupied by zero, one, or two electrons, resulting in the formation of positive or negative polarons. A bipolaron is a bound state of two charged solitons of equal charge; it also consists of a split pair of energy levels between the energy gap. Furthermore, solitons, polarons, and bipolarons are coupled with structural relaxation, implying strong electron-phonon interactions of the charge storage in conjugation polymers. In other words, the charges are surrounded by lattice distortions that can stabilize the system.

Excitons

Excitons are states of electronic excitations in OSCs. An exciton is a particle composed of an electron/hole pair bounded by coulombic force. The total charge of an exciton is zero. An exciton is, however, capable to move through the organic materials carrying the excitation energy. There are three types of excitons (Fig. 8): Frenkel, Wannier-Mott, and charge-transfer (CT) excitons. The main difference among them is the binding energy and/or the distance between the electron/hole pair. When the radius of the electron/hole pair is comparable with the size of a single molecule or the crystalline constant (a_L), the exciton is of Frenkel type. The small radius also implies a strong coulombic interaction. In other words, it is very difficult to overcome the binding energy and dissociate the exciton into free charges. If the radius of the exciton is much larger than a_L , it is a Wannier-Mott exciton. Therefore, the binding energy of this type of exciton is small. The intermediate case, in which the exciton extends over several molecular units, it is termed a CT exciton. The Wannier-Mott exciton is the most common one found in inorganic semiconductors. Usually it can

Fig. 6 (a–e) Polyacetylene: (a) undimerized structure; (b, c) two resonance forms resulting from Peierls effects; (d) soliton in *trans*-polyacetylene; (e) domain wall extension of the soliton. (f, g) Electronic band dispersion $E(k)$ plotted with respect to k for (f) non-dimerized and (g) dimerized systems. E_F is the Fermi energy; a gap appears in the dimerized system, the so-called “Peierls gap.”

be detected only at low temperature, because the thermal energy at room temperature is sufficiently high to overcome its binding energy. In OSCs, most excitons are Frenkel-type because of their strong binding energy, which originates from the low dielectric constants of organic materials and their relatively localized electronic clouds. A typical binding energy for excitons in OSCs is approximately 0.5 eV.

The generation of excitons is a very important process in organic optoelectronic devices. In OLEDs, the recombination of electrons and holes results in excitons that subsequently decay to produce EL. In organic photovoltaic devices (e.g., organic solar cells), photon absorption generates the excitons, which move freely within the semiconductors, due to the strong binding energy, but are subject to effective charge dissociation at the interface between strong organic electron-donors and organic electron-acceptors. Such exciton dissociation generates free charges, eventually leading to a photocurrent after the charges have been collected by the electrodes.

Because of the strong binding energy, the directions of spin of the excitons are not likely to change readily when generated in common OSCs. Therefore, the excitons can be categorized into two different types depending on their combinations of spin directions. As displayed in Fig. 9(a), the total spin angular momentum of a molecule in the ground state is a sum of the two spin vectors, equal to zero because of the opposite spin directions. In other words, the overall spin quantum number (S) is zero

$$S = |s_1 + s_2| = |(+1/2) + (-1/2)| = 0 \quad (1)$$

Fig. 7 Chemical structure of (a) poly(phenylene vinylene) (PPV) and (b) polyparaphenylene (PPP). (c) Schematic representation of a negative polaron in PPP. (d) Band diagram of various polarons.

Fig. 8 Schematic representation of three different types of excitons in solid state materials; a_L is the lattice constant.

where s_1 and s_2 are the spin quantum numbers of the individual electron. If one electron is excited to the π -orbital, the resulting exciton is called a singlet because no net spin angular momentum exists in the molecule (Fig. 9(b)). On the other hand, if the two spin vectors have the same direction, the total spin angular momentum is now equal to 1, as revealed in the following equation

$$S = |s_1 + s_2| = |(+1/2) + (+1/2)| = 1 \quad (2)$$

Note that if s_1 and s_2 were both equal to $-1/2$, the sum would remain the same. Accordingly, the excited state (exciton) now exhibits a net angular momentum. Assuming the presence of a magnetic field, the energy of the exciton could be split into three different energy levels. Therefore, it is called a triplet (Fig. 9(c)).

Fig. 9(d) displays possible decay processes of a typical organic molecule, where S_0 , S_1 , and T_1 represent the ground state, first singlet state, and first triplet state, respectively; k_{nr} and k'_{nr} are the rate constants of non-radiative decay processes and k_r and k'_r are the rate constants of radiative decay processes. The singlet exciton can flip its spin direction and transform into a triplet exciton

Fig. 9 Schematic representation of electron spins in the (a) ground state, (b) singlet exciton, and (c) triplet exciton of an organic molecule. (d) Excitation and possible decay processes in an OSC.

through a process called inter-system crossing (ISC); its rate constant is k_{isc} . As indicated in Fig. 9(d), the relaxation of a singlet exciton (S_1) to the ground state (S_0) is possible because the spin angular momentum is conserved. In quantum mechanics, such a transition is allowed; its radiative decay may lead to a highly efficient emission, called fluorescence (k_r). On the other hand, the transition of a triplet exciton to its ground state is forbidden. Consequently, the efficiency of the radiative decay is very low and, for most organic molecules, can be observed only at a very low temperature. The emission of triplet excitons is called phosphorescence (k_r').

Concept of Doping and p- and n-Type OSCs

Like inorganic semiconductors, OSCs can also be classified as p- and n-type semiconductors. The doping concept and process are, however, substantially different from those of inorganic materials, even though the same terminology of “doping” is used. For example, the inorganic semiconductor silicon is doped through ion implantation, in which impurities (phosphorus (P) or boron (B) atoms) are introduced. These foreign atoms substitute some of the silicon atoms and lead to new energetic levels in the band gap. Silicon becomes an n- or p-type semiconductor after the introduction of P or B atoms, respectively.

On the other hand, many different methods can be used to “dope” OSCs, including chemical doping, electrochemical doping, photo-doping, and charge injection from metal contacts. Chemical doping involves CT redox chemistry, as illustrated in the following examples for polymers

From a chemical point of view, p- and n-type doping is analogous to electrochemical oxidation and reduction, respectively. The doping process generates charge carriers in the OSCs. The electrical conductivity increases upon increasing the doping level and can reach a level comparable with that of a metal at a very high doping concentration. The drawback of this chemical method is that the doping level is hard to control, especially for intermediate doping levels. Fortunately, electrochemical doping can solve this problem. An electrode supplies redox charges to the semiconductor, and ions simultaneously diffuse in or out of the polymer chains from the electrolyte to compensate the charge mismatch. Through control of the voltage of the electrode, the doping level can be determined precisely. Electrochemical doping can be illustrated using the following equations:

The third method, photo-doping, is a process in which photon absorption generates an electron/hole pair, which could lead to locally oxidized (p-type doping) and nearby reduced (n-type doping) states of the material. The unique mechanism is illustrated by the following equation:

After photon absorption, recombination to the ground state can be either radiative or nonradiative. The value of γ in the equation depends on the excitation rate in competition with the recombination rate.

The last scenario involves charge injection from metallic contacts into the OSCs. Holes and electrons are introduced into the π - and π^* -bands, respectively, as illustrated by the following equations:

Eq. (8) describes the injection of a hole into the filled π -band, corresponding to an oxidation reaction (removal of an electron). Eq. (9) describes the injection of an electron into an empty π^* -band, analogous to a reduction reaction. The major distinction of doping through charge injection from other doping processes (e.g., chemical doping) is the absence of counter ions to compensate the charges. Therefore, the doping process is only temporary; the states are relatively unstable. On the other hand, for chemical or electrochemical doping, the doping is permanent, unless the carriers are removed by an “undoping” process. As for photo-doping, the resulting photoconductivity is transient and limited by recombination and decay processes.

Even though OSCs can indeed be “doped” as described above and become p- or n-type semiconductors, many reports define OSCs as p- or n-type by judging whether they are good conductors for electrons or holes. For instance, pentacene is usually referred to as an excellent p-type semiconductor (Fig. 2(d)) because it exhibits a very high hole mobility. TPD (Fig. 2(d)) is often employed as a hole-transporting material in OLEDs. As a result, TPD is also considered a p-type OSC because it transports holes effectively and because holes are injected readily from the metal electrodes. Note that these OSCs are not intentionally doped and they are usually purified to as high a degree as possible to remove impurities before they are processed for device fabrication. Therefore, we cannot assume extra energy levels appear near the HOMOs, as they do for inorganic semiconductors. Another way of defining OSCs is to determine whether they function as electron donors (p-type) or electron acceptors (n-type) during device operation. For example, fullerene derivatives (Fig. 2(e)) are defined as n-type OSCs because they accept electrons upon photoexcitation and transport the photogenerated electrons in organic solar cells. Meanwhile, many conjugated polymers blended with fullerene derivatives are considered as p-type OSCs because they donate electrons upon photoexcitation in solar cells.

Device Applications

In this section, we review some of the most important organic electronic devices, including electrophotographic devices, OLEDs, organic thin-film transistors (OTFTs), and organic light-emitting transistors (OLETs). For practical applications, organic photoconductors were the first technology to use OSCs as a key component in commercially available products; they are often employed in offices in copy machines and laser printers (Fig. 10). In such an electrophotographic device, the image of a document is transferred to a photoconductive plate (photoreceptor), previously charged with static electricity, through a set of optical components. Because only parts of the photoconductive plate are discharged, as a result of its high photoconductivity, upon exposure to light, an image duplicates the original document on the surface of the photoconductive plate. The next development step involves the placement of the electrostatically charged toner particles over the partially charged surface; some of the particles are adhered to the image by the electric field. An electrostatic field then transfers the image composed of toner particles to a sheet of paper. Finally, the image is fixed through pressure and heating. After swiping out the toner particles (clean) and exposing to light to remove the remaining static electricity (erase), the photoconductive plate is ready for the next copy process.

The simplest device structure of an OLED is displayed in Fig. 11(a). It typically consists of two organic layers: an electron-transport layer (ETL) and a hole-transport layer (HTL). This design obviates the need to find an OSC possessing balanced injection and transport between electrons and holes. Unlike an individual single crystal (e.g., anthracene) that allows only effective hole injection, the bilayer structure facilitates hole injection from an indium tin oxide (ITO) electrode and electron injection from a metal alloy (MgAg) electrode. The charge balance can be further finely tuned through control over the thicknesses of the HTLs and ETLs. The excitons formed after recombination of the injected electrons and holes relax to the ground states, resulting in photon emission. Because the ITO anode is transparent, a strong green emission is observed through the ITO side of this device.

In solid state organic materials, only very weak van der Waals forces exist between the molecules. Many experimental results have indicated, however, that π -electrons can be transported effectively within OSCs. Organic field effect transistors (OFETs) provide a useful platform for examining the charge transport properties of OSCs. Transistors are fundamental building blocks in modern electrical circuits; they function as either signal amplifiers or on/off switches. The phenomenon of the conductivity of a semiconductor being modulated by applying an electric field normal to its surface is called the “field effect.” Most OFETs are OTFTs, implying that the active (semiconducting) layer is nearly two-dimensional. Fig. 11(b–d) presents the three common device structures of OTFTs; Fig. 11(e) illustrates the operation mechanism. The charge carriers travel in a channel at the dielectric–OSC

Fig. 10 Working principle of an electrophotographic device: (1) charge, (2) expose, (3) develop, (4) transfer, (5) fix, (6) clean, and (7) erase. interface. The source and drain electrodes provide contacts to the OSCs, and can inject and collect, respectively, the charges in the channel. The conductance of the channel can be modulated by a third gate electrode, which is separated by a layer of gate insulator. In a p-channel OTFT, for example, a negative voltage is applied to the gate (V_G), inducing holes in the channel through field effects. A negative bias is also applied between the source and drain electrodes (V_D), resulting in a driving force to flow the field-induced holes from the source to drain electrodes. The device behaves as a resistor, with the drain current (I_D) increasing linearly with respect to the increasing value of V_D . From the relationship between I_D and V_D (Fig. 11(f)), this operation region is called the linear region. While a substantial value of V_D is supplied, the magnitude of the field inducing the charges is partially canceled near the drain. When the effective voltage is lower than the threshold voltage (V_t), the concentration of induced charges drops to almost zero, forming a high resistance regime in the channel close to the drain end. The channel now pinches at one side and the value of I_D starts to saturate. This phenomenon is known as "pinch-off" and this operation region is the saturation region

Fig. 11 (a) Device structure of a typical organic light-emitting diode (OLED); the layers of Alq_3 and diamine are the electron-transport layer (ETL) and hole-transport layer (HTL), respectively. Common structures of organic thin-film transistors (OTFTs): (b) top-contact, bottom-gate, (c) bottom-contact, bottom-gate, and (d) bottom-contact, top-gate. (e) Illustration of the operating mechanism of a typical OTFT. (f) Output characteristics (I_D – V_D) of a typical OTFT. ITO, indium tin oxide.

(Fig. 11(f)). Notably, the magnitude of the saturation current depends on the applied gate voltage. For n-channel OTFTs, the electrical behavior is similar, but the current–voltage curves are located in the first quadrant, instead of the third. The charge carriers are now electrons.

In the linear region, the drain current is described by:

$$I_D = C_{\text{ox}} \mu (W/L) [(V_G - V_{\text{th}}) V_D - (1/2) V_D^2] \quad (9)$$

where C_{ox} is the capacitance per unit area of the dielectric layer, μ is the mobility of the OSC, and W and L are the channel length and width, respectively. In the saturation region, the value of I_D can be expressed as

$$I_D = C_{\text{ox}} \mu (W/2L) (V_G - V_{\text{th}})^2 \quad (10)$$

Therefore, fitting the curves with the above equations can allow determination of the mobilities of the OSCs in either the linear or saturation regions. The other important parameter for evaluating the performance of an OTFT is the on/off ratio, defined as $I_{\text{on}}/I_{\text{off}}$, where I_{on} and I_{off} are the drain currents when the channel is turn on and off, respectively. A noticeable leakage current usually exists because charges can leak through the gate and/or because some charges are stored within the semiconductors. For state-of-the-art OTFTs, the mobility can readily reach up to $1 \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$. Mobilities greater than $10 \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$ have also been demonstrated for solution-processed OTFTs. For example, a highly aligned metastable structure of 2,7-diocetyl[1]benzothieno [3,2-*b*][1]benzothiophene (C8-BTBT), grown from a blended solution of C8-BTBT and polystyrene, has displayed a mobility of $43 \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$ ($25 \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$ on average), suggesting great potential for future electronic applications.

Because OLEDs are typically two-terminal devices, field-effect transistors are essential to control their luminescence levels and to switch individual OLED pixels when they serve as the elements of active-matrix display panels. In contrast, no transistors are needed when OLETs are employed for similar applications; a single OLET can perform both light-generation and electrical switching functionalities. For an unipolar OTFT, only a single type of charge carrier, electron or hole, is injected and transported along the conducting channel. Two carriers, however, are required to form excitons for light emission in OLETs. Therefore, an ideal OLET is an ambipolar device, although unipolar OLETs have also been reported. Light emission in unipolar OLETs occurs close to one of the electrodes, and the excitons are readily quenched by the metals, potentially decreasing the luminescence efficiencies.

Fig. 12 (a) Schematic representation of a typical organic light-emitting transistor (OLET) device structure and its working principle. (b) Device structure of the first ambipolar OLET; the Au and Ca metal sources are positioned off-center, opposite each other, leading to two electrodes for hole and electron injection, respectively; the chemical structure of MDMO-PPV is also depicted. Spatial control of the recombination zone in an ambipolar light-emitting organic transistor. *Nature Materials* 5, 69–74 with permission from Nature Publishing Group, Copyright (2007).

Fig. 12(a) displays the structure of a typical OLET having a bottom contact geometry; it is similar to that of a conventional OTFT. In other words, other structures, like the two other geometries in **Fig. 11**, are also possible choices. The source and drain electrodes are hole-injecting and electron-injecting electrodes, and the OSC should be emissive. Upon application of a reasonable gate bias (V_G), holes and electrons are injected from the source and drain contacts, respectively. The two opposite charges form excitons in the channel and, subsequently, they decay radiatively to produce light.

Ideal performance of an ambipolar device is, in practice, very difficult to achieve. First, the source and drain should be capable for injecting both holes and electrons efficiently. The OSC should also exhibit balanced hole and electron mobilities. In 2006, Zaumseil *et al.* reported the first ambipolar OLETs incorporating poly(2-methoxy-5-(3,7-dimethyloctyloxy)-*p*-phenylene-vinylene) (MDMO-PPV), a conjugated polymer displaying high photoluminescence efficiency (**Fig. 12(b)**). On the dielectric surface, they deposited a layer of crosslinked benzocyclobutene derivative (BCB) as a buffer dielectric to prevent the trapping of electrons at the dielectric–semiconductor interface. This approach is one of the keys to significantly improve electron (n-channel) transport on oxide dielectric surfaces. Au and Ca electrodes were then deposited for effective hole and electron injection, respectively. The use of Au electrodes only for both contacts would have led to high electron injection barrier at one side. Similarly, the use of Ca electrodes only would have led to a high hole injection barrier at one of the contacts. **Fig. 12(c)** illustrates the light emission from the OLET, and the movement of the light emitting zone between the two electrodes. In fact, no light emission was observed when the value of $|V_D|$ was below a certain threshold, because of limited electron injection. A narrow line of light appeared once the value of $|V_D|$ exceeded the threshold voltage. The light emission line moved toward the Au electrode upon increasing the value of $|V_D|$. The transfer characteristics of the device (**Fig. 12(d)**) revealed ambipolar behavior; the minimum point, at a value of V_G of approximately -20 V, indicates the transition from the electron- to hole-dominated current in the OLET. The output characteristics in **Fig. 12(e)** also reveal ambipolar currents. High-performance OLETs can also be fabricated by using mixed p- and n-type OSCs as the semiconducting layer. This approach can be accomplished through a bilayer structure, or co-deposition of hole and electron

transporting materials. More recent results have indicated that OLETs can outperform equivalent light-emitting diodes when using a trilayer semiconducting heterostructure.

Summary

The properties of OSCs are much different from those of inorganic semiconductors in many aspects. For example, π -electrons are responsible for the charge transport in OSCs, and the concept of doping is fundamentally different. Nevertheless, OSCs are very attractive for use in electronic devices because they are formed from inexpensive starting materials and have many useful properties, including solution-processability and flexibility. These unique properties offer many possibilities for various applications. For example, high-performance inorganic light-emitting diodes are usually fabricated through delicate crystal growth, and large-area devices are very difficult to implement. In contrast, OLEDs are readily pixelated and, therefore, can be used for flat-panel displays. We must emphasize, however, that organic electronic devices are not designed intentionally to compete with those containing inorganic counterparts. Rather, we believe that there will be many new applications in which inorganic semiconductors will not be useful; therefore, the exploration of organic devices should continue in the future.

OLED Architectures

Organic light-emitting diode (OLED) is a thin film electroluminescent device that emits electromagnetic radiation from organic materials sandwiched between two electrodes to an external electric field. Since the first observation on the organic electroluminescence in 1963, Tang *et al.* made a great progress in efficiency and lifetime using a double layer structure based on small molecules in 1987. Friend *et al.* first reported polymer light-emitting devices in 1990. Baldo *et al.* made a quantum leap in efficiency of OLED using a phosphorescent molecule in 1998.

A simple OLED structure is illustrated in Fig. 1. Organic thin films are situated between the anode and cathode. At least, one of both electrodes should be optically transparent. When a sufficient forward bias is applied to the anode, electrons, and holes are injected into the organic electron and hole transport layers (HTLs) from the cathode and the anode, respectively. The injected carriers transport through the respective carrier transport layers by the internal electric field toward the electrode of opposite polarity, recombining to form excitons in the emission layer. The radiative decay of these excitons generates photons in the visible range that are extracted out of the device.

Carrier injection is improved by lowering the potential barrier height at the electrode/organic interface, which can be approximately estimated by the difference between the work function of electrode and the highest occupied (or lowest unoccupied) molecular orbital (HOMO or LUMO) energy level. ITO is widely used as a transparent anode material because it is electrically conductive and its work function is relatively high (4.5–5.0 eV). ITO surface is treated with oxygen plasma or ozone in order to increase the work function and to remove surface contaminants. Low work function metals such as Mg, Ca, Mg:Ag, or LiF/Al are used as cathode materials. The light emission processes in OLEDs provide several features such as wide viewing angle, fast response time, and current driving of luminance. OLEDs can be fabricated on many kinds of substrates including large area glasses, silicon wafers, plastic films, metal foils, and textiles. This high degree of freedom in selecting substrates makes OLEDs very promising for future optoelectronic applications.

Various functional organic layers are used to improve the efficiency and lifetime in modern OLED architectures. Typical layers are hole injection layer (HIL), HTL, electron block layer (EBL), hole block layer (HBL), electron transport layer (ETL), and electron injection layer (EIL). EBL and HBL confine the recombination and emission processes to the emission layer (EML) composed of host and guest molecules. The host molecules can be mixed with two or three kinds of molecules to control the recombination and emission processes.

Small Molecule and Polymer OLEDs

OLEDs can be prepared using small molecules or polymers. Thin film of small molecules is usually deposited by thermal evaporation in high or ultrahigh vacuum (typically 10^{-6} – 10^{-7} Torr). The thermal evaporation of small molecules allows for easy deposition of multilayer devices with sophisticated architectures that precisely control all the emission processes from carrier injection to photon emission. Small molecules often have a thermal decomposition temperature much higher than the sublimation temperature so that the materials can be purified by repeated sublimation in vacuum or inert gas. High purity materials are essential in achieving high efficiency and long lifetime devices. Polymers cannot be deposited by thermal evaporation because their decomposition temperature is generally lower than their sublimation temperature. Polymer films are prepared by solution processing such as inkjet printing and spin coating. Hence, the polymer devices have advantages in simple and large area fabrication.

Fig. 1 Device structure of organic light-emitting diode (OLED) with triple organic layers.

Carrier Injection and Materials

Organic materials are regarded as insulator because they generally have very high resistance at low electric field. It means that a strong electric field is required to inject carriers from the electrodes to the LUMO or HOMO levels of organic layers. Charge carriers can be injected into the organic layers via Schottky or tunnel emission as shown in Fig. 2. Electrons or holes acquire sufficient energy at high temperature. When the energy of charge carriers is higher than the potential barrier at the interface, the carriers are thermally excited over the barrier into the organic layer. This phenomenon is called Schottky or thermionic emission. If the barrier is thin enough, electrons tunnel into the organic layer through the barrier. This mechanism is called field emission and it is expressed by Fowler–Nordheim equation assuming triangular shape of energy barrier. In both processes, small barrier height is important in improving carrier injection so that the organic materials with shallow HOMO and deep LUMO levels are preferred as the hole and electron injection layers, respectively.

Fig. 3 shows the organic materials for the HIL. Triphenylamine derivatives are widely used as a HIL material. Typical examples are 4,4',4''-tris[phenyl(*m*-tolyl)amino]triphenylamine (*m*-MTDATA) (*m*-MTDATA) and 4,4',4''-tris[2-naphthyl(phenyl)amino]triphenylamine (2-TNATA) (2-TNATA). copper phthalocyanine (CuPc) is also frequently used as a HIL material. HOMO levels of these materials are less than 5.2 eV. Hole injection can also be improved by using a material with a very deep LUMO level, where the holes are directly injected into the LUMO level rather than the HOMO level. For example, dipyrzino[2,3-f:2',3'-h]quinoxaline-2,3,6,7,10,11-hexacarbonitrile (HAT-CN) has a LUMO level of 5.5–6.0 eV. poly(3,4-ethylenedioxythiophene)-poly(styrenesulfonate) (PEDOT:PSS) is widely used as a hole injecting polymer layer. This conducting polymer has a work function of about 5.2 eV. Metal oxides such as MoO₃, WO₃ are often used as inorganic buffer layer for hole injection.

The selection of electron injecting material is somewhat complicated. A low work function metal results in a small barrier for electron injection. However, they are susceptible to atmospheric oxidation and corrosion. They easily react with air, water, and organic materials. More stable metals such as Al are widely used in electronics. However, they have too high work functions to efficiently inject electrons. Therefore, very thin electron injection buffer layer is inserted between ETL and Al cathode. Alkali metal halides and metal oxides are widely used as an electron injection buffer. For example, LiF/Al is most commonly used for the cathode. Lithium quinolate (Liq) is also widely used as a small molecule EIL for Al cathode. Low binding energy between lithium and hydroxyquinoline ligand liberates lithium in the Liq complex during deposition of Liq or cathode. The interface dipole layer can be formed by charge transfer, surface rearrangement, and chemical reaction at the organic/electrode interface. The dipole layer results in the vacuum level shift at the interface so that the injection barrier is different from the simple expectation based on the work function and the HOMO or LUMO level. The sign of vacuum level shift is generally negative, attributing to the downward shift of organic energy levels. Large amount of shift is often observed at the metal/organic interface.

Carrier Transport and Materials

When the number of injected charges is higher than the equilibrium charge density in organic material, the excess charges form a space charge inducing an electric field inside the organic layer. That is, local polarization layer is formed near the electrode, which limits the charge injection from the electrode. This polarized layer is called space-charge layer. Current flow is limited by the rate at which carriers drift out of the space-charge layer, so it is called space-charge-limited current (SCLC). As the organic materials generally contain defects and impurities acting as charge carrier traps, the charge carrier transport is also limited by the number of traps. In both cases of trap-limited and space-charge-limited conduction, the current is controlled by the mobility of charge carriers. Organic molecular crystals such as anthracene exhibit band-like charge carrier transport because the charge carriers are highly delocalized. Thus, the charge carrier mobility reaches to about 1 cm²/Vs. However, in the amorphous organic materials that are generally used in OLEDs, the charge carriers are highly localized due to weak intermolecular interaction and strong local polarization. Here, hopping process from one molecule to a neighboring molecule dominates the charge carrier transport. The resulting charge carrier mobility is low (10⁻⁷–10⁻² cm²/Vs) in amorphous organic materials.

Fig. 2 Injection mechanisms of electrons from the metal into the organic layer under an applied voltage: (a) Schottky emission and (b) tunnel emission.

Fig. 3 Organic materials for the hole injection layer (HIL): (a) copper phthalocyanine (CuPc), (b) 4,4',4''-tris[phenyl(*m*-tolyl)amino]triphenylamine (*m*-MTDATA), (c) 4,4',4''-tris[2-naphthyl(phenyl)amino]triphenylamine (2-TNATA), (d) dipyrzino[2,3-*f*:2',3'-*h*]quinoxaline-2,3,6,7,10,11-hexacarbonitrile (HAT-CN), and (e) poly(3,4-ethylenedioxythiophene)-poly(styrenesulfonate) (PEDOT:PSS).

HTL provides conductive pathway for the injected holes to migrate into the EML. The HOMO level of HTL material is designed to be slightly shallower than that of EML material for improving the charge flow into the EML with minimal hole accumulation at the HTL/EML interface. Another function of HTL is to act as electron or exciton block layer that prevents the transfer of electrons or excitons in EML to the adjacent organic or anode layer. For this purpose, the HTL material should have a shallow LUMO level and wide energy gap. Fig. 4 shows various HTL materials. Typical examples are aromatic amine-based materials such as 4,4'-cyclohexylidenebis[*N,N*-bis(4-methylphenyl) benzenamine] (TAPC), *N,N'*-bis(3-methylphenyl)-*N,N'*-diphenylbenzidine (TPD), and *N,N'*-Di(1-naphthyl)-*N,N'*-diphenyl-(1,1'-biphenyl)-4,4'-diamine (NPD). They have shallow HOMO levels of 5.4–5.8 eV and shallow LUMO levels of 2.4–2.7 eV. They have a small energy for hole creation and the resulting radical cation is stable. They have relatively high hole mobility of 10^{-4} – 10^{-3} cm²/Vs. However, they are easily crystallized at high temperature due to their low glass transition temperatures (T_g) of 65–96°C. Carbazole-based *tris*(4-carbazoyl-9-ylphenyl)amine (TCTA) is also widely used as HTL material. TCTA has a high T_g of 151°C and its hole mobility is about 10^{-5} cm²/Vs. Polymers such as poly(9-vinylcarbazole) (PVK) and poly[(9,9-dioctylfluorenyl-2,7-diyl)-*co*-(4,4'-(*N*-(4-*sec*-butylphenyl)diphenylamine))] (TFB) are also widely used as HTL materials for solution-processed OLEDs.

ETL material should have good electron injection property, high electron mobility, high hole and exciton blocking ability. There are much smaller number of ETL materials compared with the HTL materials. The electron mobility of ETL materials is typically lower than the hole mobility of HTL materials. In operating OLEDs, it is difficult to achieve the chemical stability in ETL materials. Imidazole, siloles, boranes, and phosphine oxide, and metal complexes are used as an ETL material. Fig. 5 shows various ETL materials. *tris*(8-hydroxyquinoline) aluminum (Alq₃) is well-known electron-transporting material. The LUMO level (about 3.1 eV) of Alq₃ is sufficient to inject electrons whereas its HOMO level (<6.0 eV) is too shallow to block holes. 2,2',2''-(1,3,5-benzinetriyl)-*tris*(1-phenyl-1-*H*-benzimidazole) (TPBi) is an important ETL material for high efficiency OLEDs. The electron mobility of TPBi is 10^{-6} – 10^{-5} cm²/Vs. TPBi has large energy gap and its LUMO level is 2.7 eV while its HOMO level is 6.2–6.7 eV. 3-(biphenyl-4-yl)-5-(4-*tert*-butylphenyl)-4-phenyl-4 *H*-1,2,4-triazole (TAZ) and BCP are wide energy gap ETL material. Pyridine-containing 2,9-dimethyl-4,7-diphenyl-1,10-phenanthroline (BCP), (e) 1,3,5-*tris*(3-pyridyl-3-phenyl)benzene (TmPyPB) has a good electron-transporting ability, exhibiting high electron mobility of about 10^{-3} cm²/Vs. HOMO and LUMO levels of TmPyPB are 2.7 and 6.7 eV, respectively. Boron-containing 3TPYMB is also typically used as wide gap ETL material. ETL materials with wide energy gap and deep HOMO level such as TAZ, BCP, TPBi, and TmPyPB act as hole or exciton block layer. Various benzothiadiazole, pyridine, and oxadiazole polymers are generally used as an ETL material for solution-processed OLEDs.

Fig. 4 Organic materials for the hole transport layer (HTL): (a) 4,4'-cyclohexylidenebis[*N,N*-bis(4-methylphenyl) benzenamine] (TAPC), (b) *N,N*-bis(3-methylphenyl)-*N,N*-diphenylbenzidine (TPD), (c) *N,N*-Di(1-naphthyl)-*N,N*-diphenyl-(1,1'-biphenyl)-4,4'-diamine (NPD), (d) *tris*(4-carbazoyl-9-ylphenyl)amine (TCTA), (e) poly(9-vinylcarbazole) (PVK), and (f) poly[(9,9-dioctylfluorenyl-2,7-diyl)-*co*-(4,4'-(*N*-(4-sec-butylphenyl) diphenylamine))] (TFB).

Doped Transport Layer

OLEDs generally require high electric field to inject charge carriers and to drive the injected carriers into the emission region because of contact barriers at the interface and low carrier mobility of organic materials. High operating voltage exceeding thermodynamic limit is typically required to drive an OLED at high luminance level. Consequently, doped transport layer is frequently used for minimizing the voltage drop in the transport layer and improving the charge carrier injection from the contacts into the neighboring organic transport materials. Hole transport or injection layer can be doped with the electron accepting atoms or molecules that releases the mobile holes in the layer (p-type doping). **Fig. 6** shows the various dopant molecules for the doped transport layer. For example, if *m*-MTDATA HIL is doped with 2,3,5,6-tetrafluoro-7,7,8,8-tetracyanoquinodimethane (F4-TCNQ) molecules, electron transfer occurs from *m*-MDATA to F4-TCNQ as the electron affinity of F4-TCNQ is comparable to the ionization energy of *m*-MTDATA. It leads to negative charged F4-TCNQ molecules and positive charged *m*-MTDADA molecules, i.e., holes in the *m*-MTDATA layer that can move relatively freely throughout the *m*-MTDATA layer. F4-TCNQ molecule thus improves the electrical conductivity of the organic layer, eventually resulting in low voltage drop. HAT-CN is also widely used as a p-type dopant. The LUMO level of HAT-CN (5.7 eV) is very similar with those of typical HTL materials, thus the extra holes can be generated in the HTL by transferring electrons from HTL to HAT-CN molecules. MoO₃ is another effective p-type dopant in improving the injection efficiency and reducing ohmic losses in the transport layers. Other materials such as metals (Au, Pt), gases (Cl, Br, I), and small molecules (1,3,4,5,7,8-hexafluorotetracyanonaphthoquinodimethane – F6-TNAP) can be used as p-type dopants. Similarly, electron injection and transport can be improved by n-type dopants that donate electrons to the neighboring ETL molecules. Organic molecules (Liq, pyronine B – PyB chloride), inorganic materials (Cs₂CO₃), low work metals (Li, Cs) can modify the interface electronic structure, enhancing the conductivity of ETLs. The doped transport layer is typically separated by thin undoped organic layer from the emission region because the p-type and n-type dopants tend to provide nonradiative exciton recombination centers.

Exciton Formation and Decay

When electrons and holes recombine on organic molecules, two kinds of excitons, singlet and triplet excitons, are generated. Singlet excitons have spin antisymmetry states and their transitions to ground state are quantum mechanically allowed, giving rise to fluorescence as shown in **Fig. 7**. Triplet states with spin even symmetry lead to phosphorescence. Radiative transition rate of

Fig. 6 Organic materials for the doped transport layer: (a) 2,3,5,6-tetrafluoro-7,7,8,8-tetracyanoquinodimethane (F4-TCNQ), (b) 1,3,4,5,7,8-hexafluorotetracyanonaphthoquinodimethane (F6-TNAP), and (c) pyronine B (PyB) chloride.

singlet exciton is fast (< 10 ns), whereas the decay rate of triplet exciton is slow ($100 \mu\text{s}$ – 10 s) because it is a disallowed transition. Statistically 25% singlet and 75% triplet excitons are generated in the OLED due to the random nature of spin orientation when the carriers are injected into the organic materials from the electrodes. Therefore, the internal quantum efficiency (IQE) (photons/electrons) of fluorescent OLED is limited to 25%. In some fluorescent conjugated polymer or small molecules, the formation fraction of singlet excitons is higher than 25%. Triplet excitons can be converted to singlet excitons via reverse intersystem crossing (ISC) or triplet-triplet fusion in some fluorescent materials. In these cases, the IQE higher than 25% can be achieved in fluorescent OLEDs. In general, it is difficult to observe phosphorescence from fluorescent materials because the

Fig. 7 Energy diagram of singlet and triplet excited states relative to the ground state, fluorescence, phosphorescence, and intersystem crossing (ISC).

Fig. 8 Energy transfer processes from the host to the guest molecules: (a) Förster energy transfer and (b) dexter energy transfer.

radiative decay rate of triplets is much slower than that of the competing nonradiative decay process. However, phosphorescent molecules containing heavy metals such as iridium or platinum exhibit strong radiative transition from triplet excited states to ground states and fast ISC from singlets to triplet states, leading to 100% IQE device. Significant fraction of light generated by exciton decay is absorbed by surface plasmons and waveguide modes. Only about 20% of the light, i.e., roughly estimated by $0.5n^2$ where n is the refractive index of organic emitter, is coupled out of the device. Thus, the maximum achievable external quantum efficiency (EQE) is limited to 20% in OLEDs. However, high efficiency device with 20–40% EQE can be also obtained by outcoupling efficiency improvement techniques such as microlens array and horizontal dipole orientation.

Host–Guest System

Emission layer is composed of host and guest molecules in OLEDs (Fig. 8), where at least one electroluminescent emissive material is doped into the charge transporting host material. The host–guest system is an effective way to achieve high efficiency in small molecule OLEDs because most of emitters exhibit significant concentration quenching. That is, low photoluminescence

Fig. 10 Host materials for the blue fluorescent guest molecule. (a) 9,10-di(2-naphthyl)anthracene (ADN) and (b) 4,4'-*bis*(2,2-diphenylvinyl)-1,1'-biphenyl (DPVBi).

quantum yield (PLQY) is obtained in solid state even though the PLQY is about unity in gas phase or solution state. In polymer OLEDs, the EML material is often composed of a single polymer comprising multiple monomer units that provide emissive and charge transporting properties. However, the host–guest system is popular in both small molecule and polymer devices. The system also takes advantageous features of easy color tuning and operational stability. The dopant concentration in the host–guest system should be sufficiently low for avoiding nonradiative aggregate traps.

Excitons in the emission layer can be generated on the conductive host molecules. The energy of excited host molecules can be transferred to the guest molecules by Förster or Dexter mechanism. Förster energy transfer is a long range (up to about 10 nm) dipole–dipole coupling of host donor and guest acceptor molecules. This process contributes to the emission process in fluorescent OLEDs because of its singlet–singlet transfer nature. Dexter energy transfer is a short range (typically about 1 nm), intermolecular electron exchange process between donor and neighboring acceptor sites. Dexter transfer involves the triplet–triplet transfer process in phosphorescent OLEDs. Another exciton formation process is a direct recombination of electrons and holes on the guest molecules. It involves trapping of charge carriers and consequent recombination on the guest molecules.

4-(dicyanomethylene)-2-methyl-6-(4-dimethylaminostyryl)-4 *H*-pyran (DCM) and 4-(dicyanomethylene)-2-*tert*-butyl-6-(1,1,7,7-tetramethyljulolidin-4-yl-vinyl)-4 *H*-pyran (DCJTB) are widely used as fluorescent guest molecules as shown in Fig. 9. Coumarin and quinacridones are generally used as green fluorescent emitters. Distyrylarylene derivatives such as 4,4'-*bis*(9-ethyl-3-carbazovinylenyl)-1,1'-biphenyl (BCzVBi) are widely used as efficient fluorescent blue dopants. Alq₃ is the most popular electron-transporting host material for the fluorescent dopants. Fig. 10 shows the typical blue fluorescent guest molecules. 9,10-di(2-naphthyl)anthracene (ADN) and 4,4'-*bis*(2,2-diphenylvinyl)-1,1'-biphenyl (DPVBi) are thermally stable and good phase-compatible large bandgap host for blue fluorescent guest molecules. Iridium complexes such as Ir(piq)₃, Ir(ppy)₃, Irpic are typically doped into the wide energy gap host materials having high triplet energy levels in phosphorescent OLEDs.

Degradation of OLEDs

The luminance decreases with operating time as a result of physical, morphological, chemical degradation in OLEDs. The half-lifetime (T₅₀ or LT₅₀) is defined as the time the luminance drops to 50% of its initial value at the constant current density. Similarly, T₇₀ and T₉₇ refer to the time the luminance drops to 70% and 97% of its initial value, respectively. Typically, the lifetime becomes shorter at higher initial luminance value. The OLED luminance is approximately proportional to current density over a substantial range. Hence, the lifetime decreases in proportion to 1/(current density)^{*n*}, where *n* is acceleration factor of 1.2–1.9. The continuous drop of luminance under the constant current means the continuous decrease of device efficiency. This luminance degradation can be attributed to many causes such as electrochemical/photochemical reaction, crystallization, and impurities. Another common degradation phenomenon is the formation and growth of small and non-emissive regions which is called dark spots. High purity organic materials, high vacuum processes, and thorough device encapsulations are essential for long lifetime OLEDs.

Fig. 11 Schematic pixel structures for organic light-emitting diode (OLED) displays: (a) passive matrix OLED (PMOLED) pixel and (b) active matrix OLED (AMOLED) pixel and equivalent circuit.

OLED Applications

The major applications of OLEDs are displays and lightings. OLEDs can be pixel elements in the passive matrix (PM) and active matrix (AM) displays. Vertically oriented data lines are crossed by the horizontally oriented scan bus lines in passive matrix OLED (PMOLED) displays (Fig. 11). OLED pixels are located at the crossing points. OLED pixels are fabricated by solution printing or evaporation process. PMOLED displays are limited to the low resolution and small size applications. On the other hand, active matrix OLED (AMOLED) displays are widely used for the high resolution, large size applications. AMOLED display contains thin film transistors (TFTs) for providing a constant current to an OLED pixel. Polycrystalline silicon and oxide TFTs are preferred to drive OLED pixels due to their high field effect mobility and current stability. Color pixels are fabricated by the several patterning techniques such as shadow mask process, transfer from donor substrates, and solution printing. Another method of using color filter and white OLED is widely used to fabricate high resolution and large area AMOLED displays. White OLED structure for displays is very similar with that for lightings. White OLED can be realized by various structures such as multi-emission layers, stacked device, and down-conversion method. Although the display techniques are mostly applicable in lighting applications, the light sources having a high color rendering index value are preferred for the reasonable color reproduction of the illuminated objects. Therefore, the white OLED for lightings has an emission spectrum of multiple wavelength peaks.

OLEDs also offer new possibilities not accessible in other device technologies. OLEDs can be prepared on various kinds of flexible and stretchable substrates. OLEDs can provide bendable, foldable, stretchable, and rollable displays or lightings. Transparent or mirror-type displays and lightings are also possible with OLEDs. They provide widow information displays, head-mounted displays, digital speed meters, and so on. The OLED technology will open up the numerous new fields of novel applications.

Introduction

As early as 1960s, Pope observed an electroluminescence (EL) phenomenon from organic semiconductor, where he used a single crystal of anthracene as EL material. The driving voltage was around 400 V and the luminance was very low. Vincett brought a major step-forward in organic EL in 1982, who applied a vacuum-deposited anthracene film as the emissive layer (EML) and the driving voltages dropped to below 30 V. However, these discoveries had not drawn many attentions until Tang and VanSlyke reported a double layer heterojunction organic light-emitting diode (OLED) in 1987. The device was composed of a vacuum thermal evaporated aromatic diamine layer for hole transporting, and a tris(8-hydroxyquinoline) aluminum (Alq3) layer for electron transporting and emission. This was the first time that an organic electroluminescent device could reach a high brightness ($> 1000 \text{ cd/m}^2$) with a relatively low operating voltage ($< 10 \text{ V}$) and an external quantum efficiency (EQE) about 1%, demonstrating its exciting prospect for applications in display and lighting. Since then, OLED has attracted tremendous interests and been developed rapidly. Up to now, small size OLED displays have been widely adopted in high-end smart phones, digital cameras, mp3 players, and so on; large size OLED TVs have also entered the market. With further development of OLED, more and more OLED displays will be around us and energy saving OLED lighting will definitely shine our daily life as well.

As of a novel flat panel display technology, OLED has its remarkable advantages of wide viewing angle, high contrast ratio, fast response, large color gamut, and low power consumption, and considered as the next generation of display competing with liquid crystal display (LCD). Furthermore, because of high efficiency, large area, light and thin factors, flexibility, OLED is also an ideal diffusive light source, showing a great potential in environmental friendly lighting applications.

A simple OLED structure consists of a thin organic electroluminescent film, sandwiched between two electrodes. When an external bias is applied on the device, holes and electrons are injected from the anode and the cathode into the organic semiconductor layer, respectively, then migrate in the organic layer to the opposite side. Subsequently, they meet in the EML and recombine to form excitons. Finally, the excitons radiatively decay to the ground states and emit light. However, to improve the charge carrier injection and transport and to confine excitons within EML to achieve high performance, multilayer structure is commonly adopted in advanced OLED. A typical high efficiency OLED consists of five organic layers (Fig. 1): hole injection layer (HIL), hole transport layer (HTL), EML, electron transport layer (ETL) and electron injection layer (EIL), where the HTL is often used as electron blocking layer (EBL), while ETL is used as hole blocking layer (HBL).

The OLED development focuses mainly on the materials and structures. Soon after Tang's first OLED report on small molecules, in 1990, Richard Friend *et al.* successfully discovered an OLED using solvable spin-coated polymer as EML, which is usually called as polymer light-emitting diode (PLED). In their publication, a single layer of poly(p-phenylenevinylene) (PPV), sandwiched between indium tin oxide (ITO) and Al electrodes, emitted green light under applied voltages. The relatively high efficiency and low turn-on voltage promised for a large-area, low-cost solution processable commercial application. However, all these small molecule and polymer materials are fluorescent, whose emission is from singlet excited state. The electrons in organic materials are

Fig. 1 Typical multilayer organic light-emitting diode (OLED) structure. EIL, electron injection layer; EML, emissive layer; ETL, electron transport layer; HIL, hole injection layer; HTL, hole transport layer.

Fig. 2 Fluorescence (F) process. ISC, intersystem crossing.

mostly paired up with opposite electron spin orientations because of the Pauli Exclusion Principle. When receiving enough energy such as from light, one of the paired electrons can be excited from ground state to excited states. These two electrons have either the antisymmetric or symmetric spin orientation. Each electron spin is denoted as “ s ”, which equals to either $+1/2$ or $-1/2$. The spin multiplicity (total spin number, S), calculated by $S=2\sum s+1$, is either 1 for singlet if the pair of electrons are spin-antisymmetric or 3 for triplet if the pair of electrons are spin-symmetric. If an organic material is excited from the ground state, the excited state usually remains as singlet due to the Wigner–Witmer selection rule in quantum mechanics for the electronic transition process. Similarly, the transition from the triplet excited state ($T1$) to ground state ($S0$) is prohibited, i.e., the phosphorescence is not observable at room temperature for normal organic electroluminescent materials. In the OLED, the excitons are generated by injected holes and electrons from the anode and the cathode, respectively, which have their own spin orientations. Therefore, the electrically generated excitons can be either singlets or triplets. According to the statistic calculation of quantum mechanics, there will be 3 triplet excitons for every singlet exciton formed. Since radiative decay from triplet excited state to singlet ground state is spin-forbidden, only a quarter of electrically generated excitons, singlets, contribute to the light emission, which limits the internal quantum efficiency of OLED at 25%, as shown in Fig. 2.

To achieve a real high efficiency, it is necessary to harvest these non-radiative (NR) triplet excitons. One strategy is to make the radiative decay possible from triplet state $T1$ to ground state $S0$ by incorporating heavy metals in the molecules to increase spin-orbit coupling, which are called phosphorescent materials. Another strategy is to make the reverse intersystem crossing (RISC) process possible by narrowing the gap between the singlet and triplet excited states. By using these two methods, all electrically generated singlets and triplets can contribute to the light emission, and the internal quantum efficiency can be up to 100% theoretically, which is four times as high as conventional fluorescence.

In 1998, Thompson and Forrest groups boosted OLED internal quantum efficiency limit from 25 to 100% by using phosphorescent electroluminescent materials. Heavy metal atoms were widely used in phosphorescent materials to mix the triplet and the singlet excited states to make the radiative decay possible from triplet state to ground state. Recently, Addachi group from Kyushu University realized 100% internal quantum efficiency via thermally activated delayed fluorescence (TADF), without using heavy metal chelate. It is another breakthrough in the development of organic electroluminescent materials. If we call fluorescent materials as the first generation, high efficiency phosphorescent materials as the second generation, then TADF materials are considered as the third generation.

Phosphorescent EL

Although the OLED had been extensively studied since the first practical OLED was invented by Kodak, a breakthrough of its development is the discovery of electro-phosphorescence by Forrest *et al.* Compared with fluorescent OLED using only singlet excitons for light emission, phosphorescent OLED can utilize both singlet and triplet excitons, which boosts the internal quantum efficiency (IQE) of OLED by a factor of 4 theoretically. Hence, phosphorescence has attracted tremendous research interests in both academia and industry for its significant performance potential. In fact, highly efficient and long living red and green phosphorescent electroluminescent materials have already been employed in commercial OLED displays. Compared with the great achievements in red and green phosphorescent materials, although the EQE of blue phosphorescent OLED has already exceeded 20%, lacking of deep color and poor lifetime still restrain its commercialization.

Fig. 3 Phosphorescence (P) process. ISC, intersystem crossing.

The typical lifetime of triplet excited state of organic material is usually longer than millisecond (ms), which is long enough for releasing its energy via NR decay channels such as the thermal vibration motion. There is one way to enable phosphorescence from organic materials is to suppress the thermal vibration motion by lowering temperatures down to liquid nitrogen temperature (77K). However, it is surely not practical for OLEDs, which usually operate at room temperature. A practical and effective way is to reduce the lifetime of triplet excited state so that the transition process from T1 to S0 can compete with the NR thermal vibration motion.

To enhance the phosphorescence, the most effective way is to use heavy metal atom in organic molecule, which enhances spin-orbit coupling, the interaction between spin magnetic moment and orbital magnetic moment. The strength of such coupling is proportional to the proton number in atomic nucleus, which is in turn related to the electromagnetic field generated by atomic electrons circling around. This is called as “heavy atom effect”. The distinguish between triplet and singlet state becomes diminished when spin-orbit coupling constant is large. The selection rule is losing its restriction and radiative decay from the triplet excited state to singlet ground state becomes feasible, and the triplet state lifetime is shortening, faster than molecular thermal vibration motion (**Fig. 3**). Up to now, the heavy atoms used in phosphorescent materials are all transition metals, such as Ru, Re, Os, Ir, Pt, Au, and Hg. Among them, most phosphorescent materials focus on those group VIII B elements, Os, Ir, and Pt. Especially, Ir-containing phosphorescent materials attract the most attentions.

The presence of a heavy metal atom in complexes increases singlet–triplet mixing and adds excited states to the electronic spectrum. In addition to states localized on the organic groups (ligands), the metal atom can participate in an excited state formed by the transfer of an electron from the metal to a ligand, known as metal–ligand charge transfer (MLCT) state. The MLCT state has a larger overlap with the heavy metal atom than the ligand excited states. Therefore, the spin-orbit coupling is higher, and the mixing between singlets and triplets is greater. Consequently, the radiative decay from the MLCT triplet state to ground state is more feasible. The phosphorescence often occurs from both MLCT and ligand excited states, and the relative importance of the MLCT and ligand components depends on their relative energies. If the ligand has a significantly lower triplet energy, the MLCT component will be very small, and the phosphorescence is mainly from the ligand triplet state. In this case, the triplet experiences less spin-orbit coupling induced by the central heavy metal atom, and consequently, its lifetime may not be reduced greatly. Triplet–triplet annihilation (TTA) is more pronounced with long triplet lifetime, and the OLEDs based on such materials may experience poor efficiency at large current densities due to strong efficiency roll-off. Thus, a high efficiency phosphorescent material should preferably have a triplet lifetime of less than $\sim 10 \mu\text{s}$, by enhancing the singlet–triplet mixing, which can be realized by ensuring that the energy of $^3\text{MLCT}$ triplet state is lower than that of ligand triplet state.

The first phosphorescent material employed in OLED was a red phosphorescent dye based on heavy metal Pt, called 2,3,7,8,12,13,17,18-octaethyl-21 H,23 H-porphine platinum(II) (PtOEP) (**Fig. 4**). The external quantum efficiency (EQE) reaches a maximum value of 4% with saturated red emission of (0.7, 0.3), which was not extremely high, relative to high efficiency fluorescent red emitter. However, PtOEP still attracted enough attention due to its phosphorescence nature. Firstly, PtOEP has an absorption peak at around 540 nm, and its fluorescence emission peak is at longer wavelength around 580 nm. In contrast, the observed EL peak is at 650 nm with a very nice narrow red emission band, which is much longer than the fluorescence emission of PtOEP. Furthermore, the lifetime of the emission at $\sim 650 \text{ nm}$ in solution was measured about $\sim 50 \mu\text{s}$, which is significantly longer than typical fluorescence lifetime of 0.1 $\sim$ 10 ns. All these spectroscopic data infer that the EL emission at 650 nm is

Fig. 4 Chemical structures of several typical phosphorescent materials.

phosphorescence rather than fluorescence. However, the PtOEP phosphorescent OLED shows serious efficiency roll-off, a typical EL behavior for phosphorescent OLEDs at elevated current density, which is mainly ascribed to their relatively long triplet lifetime. Furthermore, the flat square planar structure of Pt complexes often causes molecular π - π stacking that quenches the emission readily, leading to poor efficiencies in the devices.

Iridium is another mostly investigated heavy metal atom in phosphorescent materials. The $5d^6$ orbitals of Ir^{3+} provide a flexible platform for $^3\text{MLCT}$ phosphorescence. These complexes possess a chemically stable octahedral symmetry, with three bidentate ligands complexed to the central Ir atom. $\text{Ir}(\text{piq})_3$ (tris(1-phenylisoquinoline)iridium(III)) and $(\text{piq})_2\text{Ir}(\text{acac})$ (bis(1-phenylisoquinoline) (acetylacetonate)iridium(III)) are two typical red phosphorescent emitters based on Iridium (Fig. 4). The common feature of these two Ir complexes is the cyclometalate ligand 1-phenylisoquinoline (piq). In fact, cyclometalate ligand piq is very powerful for red phosphorescence. Most of the red phosphorescent materials developed later are based on derivatives of piq ligand.

If the ligands are changed to ones with higher triplet energies, the phosphorescence emission can be shifted to the shorter wavelength. For example, the ligand 2-phenylpyridine (ppy) is the parent structure for many other cyclometalation ligand of green phosphorescent materials, such as $\text{Ir}(\text{ppy})_3$ (tris(2-phenylpyridine)iridium(III)) and $(\text{ppy})_2\text{Ir}(\text{acac})$ (Bis[2-(2-pyridinyl-N)phenyl-C](acetylacetonato)iridium(III)) (Fig. 4). The ancillary ligand acac has a weaker ligand-field strength than ppy, leading to smaller d-orbitals splitting, which results in smaller energy of MLCT. Therefore, the emission peak wavelength of $(\text{ppy})_2\text{Ir}(\text{acac})$ is longer than that of $\text{Ir}(\text{ppy})_3$ (525 vs. 514 nm). The photophysical properties of $\text{Ir}(\text{ppy})_3$ and $(\text{ppy})_2\text{Ir}(\text{acac})$ are quite similar, although $\text{Ir}(\text{ppy})_3$ is homoleptic and $(\text{ppy})_2\text{Ir}(\text{acac})$ is heteroleptic. The phosphorescence quantum yield of $\text{Ir}(\text{ppy})_3$ is 0.40 and that of $(\text{ppy})_2\text{Ir}(\text{acac})$ is 0.34. The triplet lifetime of $\text{Ir}(\text{ppy})_3$ is 1.9 μs and that of $(\text{ppy})_2\text{Ir}(\text{acac})$ is 1.6 μs . The color coordinates of $\text{Ir}(\text{ppy})_3$ are (0.27, 0.63), whereas those of $(\text{ppy})_2\text{Ir}(\text{acac})$ are (0.31, 0.64). Such differences are not large, but very similar trend have been observed for other homoleptic and heteroleptic coordination complexes as well. In terms of molecular dipole moment, facial homoleptic coordination complexes are smaller than heteroleptic coordination complexes, which in turn are smaller than meridional homoleptic coordination complexes. And it is indicated by the experimental data that the molecular dipole will quench phosphorescence of the material.

Alternatively, if the ligand is made strongly electron accepting, then $^3\text{MLCT}$ emission may be blue shifted. The most famous blue phosphorescent materials are heteroleptic bis[2-(4,6-difluorophenyl)pyridinato-C2,N](picolinato)iridium(III) (FIrpic) and bis (2,4-difluorophenylpyridinato)-tetrakis(1-pyrazolyl)borate iridium(III) (FIr6) using fluoro-substituted phenylpyridine ligands

and an anionic 2-picolinic acid or poly(pyrazolyl)borate as an auxiliary ligand, respectively (Fig. 4). However, these emissions are either greenish-blue (0.17, 0.34) or sky-blue (0.16, 0.26), far from a saturated blue color as the National Television Standards Committee (NTSC) standard of (0.14, 0.08).

As the first blue phosphorescent material, FIrpic has two emission peaks at 470, 494 nm with phosphorescence quantum yield of 50–60%. The strong vibration peak at longer wavelength of main emission peak makes the color actually cyan containing a lot of green emission. With improved blue color, FIr6 has a shorter emission wavelength (λ_{max} at 457, 485 nm) and a higher phosphorescence quantum yield (96%) than those of FIrpic, but its device stability was poorer. Since the emission is mainly from the $\pi\pi^*$ state of cyclometalated ligands mixing with d-orbital of heavy transition metal via MLCT, such emission state due to the mixing of d-orbital is often inadequate, particularly for the short wavelength blue phosphorescence. Consequently, such phosphorescence usually has a longer triplet lifetime, closer to pure organic species (organic compound without containing heavy atom). Triplet state lifetime of microsecond range is required for fast emissive decay process and high phosphorescence quantum yield is desirable to achieve theoretical maximum EQE over 20%. It has been known that Ir-based organometallic compounds show short excited state lifetime due to singlet–triplet mixing and easy control of emission spectra by managing the chemical structure of ligands.

FIrpic has two fluorines on the phenyl unit to shift the highest occupied molecular orbital (HOMO) level downward for high triplet energy. The triplet energy is increased by the electron withdrawing fluorine and a bulky picolinic acid ancillary ligand. Although the emission spectrum of FIrpic is blue-shifted, it exhibits only sky blue color with y-coordinate over 0.30. The spectrum is further blue-shifted by changing the ancillary ligand from picolate (pic) to bulky tetrakis(1-pyrazolyl)borate ligand in FIr6. The FIr6 has bulky tetrakis(1-pyrazolyl)borate ligand to reduce the conjugation of the main ligand through steric hindrance. The peak wavelength of the FIr6 is shifted to 458 nm compared with 470 nm of FIrpic.

Besides platinum and iridium, europium (Eu) is also employed as the central metal to develop phosphorescent emitters. For example, Zheng *et al.* obtains Eu(TFacac)₃phen using 1,1,1-trifluoroacetylacetone as ligand, and Male *et al.* demonstrates Eu (TTFA)₃phen using tris-(thiophenyltrifluoromethylacetylacetone)(phenanthroline) as the ligand. The EL emission from Eu complexes is extremely sharp since the emission is from the f–f transition of Eu atom.

Os is another heavy metal atom often used in phosphorescent materials, and the emission color can be tuned by changing the ligand. Jiang *et al.* have designed a series of Os complexes. The phosphorescence lifetime is 0.6–1.9 μs , and the EL emission peak is from 620 to 650 nm, with color coordinates around (0.65, 0.33). For example, when (fptz)₂Os(PPh₂Me)₂ was doped into tris[4,9-phenylfluoren-9-ylphenyl]amine (TFPA), the device exhibits red EL having EQE as high as 18% (power efficiency ~ 25 lm/W). It is quite remarkable that the device has minor efficiency roll-off, which is mainly attributed to the short phosphorescence lifetime of ~ 0.7 μs . On the other hand, symmetrical structure induces small net dipole moment and reduce dipole–dipole interaction and quench emission.

As of relatively long phosphorescence lifetime, the phosphorescent emitter materials usually need to be doped into suitable host materials to avoid severe TTA. Besides some common rules to be followed, such as excellent film-forming property, good thermal and electrochemical stability, high glass transition temperature (T_g), there are still some special criteria to meet for host materials of phosphorescent emitters. Firstly, the host material should possess appropriate the HOMO and the lowest unoccupied molecular orbital (LUMO) levels to ensure effective hole and electron injection; secondly, the host material should have higher triplet energy than the phosphorescent emitter to prevent reverse energy transfer; Finally, the host material should possess high hole or electron transport property to reduce the operating voltages. Recently, bipolar host materials, capable of transporting both holes and electrons, have drawn more attentions. It is confirmed that employing bipolar host materials can not only reduce the operating voltages but also improve the device stabilities.

Advanced Delayed Fluorescence

After nearly 20 years development, all red, green and blue phosphorescent OLEDs have achieved extremely high EQE over 30%. However, these phosphorescent emissive materials contain heavy metals such as iridium and platinum, which are rather expensive and resource limited. To overcome this issue, a lot of studies focus on delayed fluorescent materials, which do not use heavy metals and can convert triplet excitons to singlet excitons through RISC. There are mainly two methods to achieve efficient RISC: TTA and TADF. More and more ultra-high efficiencies of fluorescent OLEDs exceeding 10%, far beyond the theoretical limitation of fluorescent emitters, have been reported recently, attracting wide research interests in both academic institutions and industry (Figs. 5 and 6).

In 2009, Kodak demonstrated some high EQE OLED devices using a fluorescent material 4,4'-bis[4-(di-p-tolylamino)styryl]biphenyl doped in 9,10-bis(2-naphthyl)-2-phenylanthracene (PADN) as EML, which are attributed to TTA contribution. Based on the assumption that spin statistics dictate 20% probability of generating a singlet exciton through TTA, they proposed a formula to estimate the maximum EQE of such system: $0.2 \times (25\% + 0.2 \times 75\%) = 8\%$. Soon later they obtained an EQE of $> 11\%$ at 3 V using rubrene as emitter. This value is far beyond the theoretical limit of the fluorescent emitter imposed by spin statistics, and cannot be satisfactorily explained by previous equation. They surmise that the fluorescent OLED devices are capable of using a considerably larger fraction of triplet states than it was previously believed. With the appropriate emissive material and host material, every two triplet excitons can form one singlet exciton to contribute to the light emission, i.e., the upper limit for the singlet excited state yield in the TTA process is 0.5. Therefore the maximum internal quantum efficiency of fluorescent OLEDs is to be $25\% + 0.5 \times 75\% = 62.5\%$. The estimated maximum EQE of the fluorescent OLEDs should be revised to at least $0.2 \times 62.5\% = 12.5\%$ after considering a light out-coupling efficiency of $\sim 20\%$ in the device. However, in order to promote the nonlinear up-conversion TTA process, high driving voltages or concentrated sensitizers are generally essential, accompanied by proportionally increased device efficiency roll-off.

Fig. 5 Triplet-triplet annihilation (TTA) process. ISC, intersystem crossing.

Fig. 6 Thermally activated delayed fluorescence (TADF) process. ISC, intersystem crossing; RISC, reverse intersystem crossing.

A more efficient way to harvest triplet excitons is via the direct RISC process from T1 to S1. According to Hund's rule, the energy of T1 is always lower than S1, therefore such RISC process must be stimulated or activated by external energy. If the energy difference between T1 and S1 (ΔE_{ST}) is small enough, the thermal activation of the molecules can overcome the barrier and commit the endothermic RISC process. The triplet excitons at T1 are back-transferred to S1, followed by radiative decay to the ground state S0, called TADF. There are two distinct unimolecular mechanisms involved in TADF: the prompt fluorescence (PF) from the direct electrical excited singlet S1, and the delayed fluorescence (DF) from the back-transferred singlet S1. Apparently, PF and DF have different luminescent lifetimes, which can be distinguished from the transient photoluminescence spectroscopy. And their individual fluorescence efficiency can also be calculated by integrating the intensity of each component.

In these processes, the efficient RISC from T1 to S1 is the key to harvest triplet excitons to enhance the DF. However, when the RISC process is enhanced by reducing the singlet-triplet energy splitting ΔE_{ST} , the intersystem crossing (ISC) process from S1 to T1 is also enhanced. Moreover, the RISC rate ($\sim 10^6 \text{ s}^{-1}$) is lower than the ISC rate in TADF molecules generally. In the end, there is a balance of exciton distribution between S1 and T1 states in TADF molecules. Consequently, ΔE_{ST} , rate constant of ISC and RISC are the key parameters to design efficient TADF materials.

In traditional fluorescent and phosphorescent materials, S1 energy is considerably higher than T1, and RISC hardly occurs. To facilitate RISC, a small ΔE_{ST} is particularly important. At S1 or T1 state, the unpaired two electrons are mainly distributed on the frontier orbitals of the HOMO and the LUMO, respectively. To obtain small ΔE_{ST} in the molecules, a spatial wave function separation of HOMO and LUMO need to be adopted. The general strategy is to introduce a large steric hindrance structure or a donor–acceptor system with twist/spiro/bulky connection, which can reduce the overlap between the HOMO and LUMO.

RISC process is an endothermic transition, hence it is temperature sensitive, and high temperature facilitates it. At low temperature (<100K), the fluorescence efficiency of TADF molecules are significantly suppressed and is strongly dependent on photoexcitation intensity, which are considered as characteristic features of TADF emitters.

At the early stage, such TADF materials always exhibit low fluorescence efficiencies, making it really difficult to verify the effectiveness for EML in OLED. It was not until 2009 that Adachi group at Kyushu University first introduced a series of Sn(IV) fluoride-porphyrin complexes with small ΔE_{ST} around 0.4 eV. It is demonstrated that the photoluminescence efficiency of such TADF material can be increased from ~1 to 3% with an increase in temperature due to RISC. However, the activation energy of the RISC (ΔE_{ST}) was still rather high at 0.24 eV, leading to inefficient RISC, and the overall EL efficiency is still very low.

Donor–acceptor systems with pronounced intramolecular charge transfer (CT) characteristics are very suitable to realize small ΔE_{ST} through separated HOMO in donor groups and LUMO in acceptor groups for TADF emission. A steric hindrance, such as twist, bulky, or spirojunction, incorporated between the donor and acceptor groups can further effectively separates the spatial overlaps between HOMO and LUMO. For example, a typical molecule 2-biphenyl-4,6-bis(1,2-phenylindolo[2,3-a]carbazol-11-yl)-1,3,5-triazine (PIC-TRZ) has ΔE_{ST} of only 0.11 eV, which realizes a significant contribution of 30% RISC efficiency under both photoluminescence and EL processes.

Another strategy proposed again by Adachi group to realize high RISC efficiency is via exciplex of electron-donating and electron-accepting molecules, also called as intermolecular donor–acceptor system. The electron transition from the LUMO of an acceptor to the HOMO of a donor is in a large electron–hole separation distance for exciplex emission. It is possible that the hole and electron wavefunctions are spatially separated and electronic exchange energy is very small compared to that of intramolecular excited states, resulting in the triplet levels being very close to the singlet levels, i.e., a small ΔE_{ST} for efficient TADF emission via RISC. However, the limited overlap of hole and electron wavefunctions generally results in very low fluorescence efficiency of exciplex according to the Franck–Condon principle. For strong TADF emission in the exciplex, the donor and acceptor molecules should have high triplet energy levels to confine the triplet exciplex state to prevent the quenching of the triplet state via the triplet energy back transfer to the donor or acceptor. Furthermore, such intramolecular donor–acceptor system should have not only high RISC efficiency but also high fluorescence efficiency. For example, an exciplex system of 4,4',4''-tris[3-methylphenyl(phenyl)amino]triphenylamine (m-MTDATA) as a donor and tris-[3-(3-pyridyl)mesityl]borane (3TPYMB) as acceptor has a high RISC efficiency of 86.5%. Using this emission system, the OLED achieves a maximum EQE of 5.4%, even with the rather low photoluminescence efficiency of 26%, showing a significant contribution of efficient RISC.

Within just several years' development, the EQE of TADF OLED is already over 21%, and further increased to 30% in a suitable cohost system. The device stability is significantly improved as well, with lifetimes of 2800 h at an initial luminance of 1000 cd/m², and of over 10,000 h at 500 cd/m². To take advantage of the triplet harvesting property, TADF molecules can act as host materials or singlet exciton sensitizers to harvest triplet excitons in OLEDs for fluorescent emitters. The devices show a significantly increased EQE and an enhanced device operational stability.

Although TADF materials have the potential to harvest ~100% excitons, the mechanism of TADF still requires further clarification. The efficiency roll-off is quite serious for most TADF emitter based OLED, which could be attributed to pronounced triplet–triplet or singlet–triplet quenching because of slow RISC process. It is necessary to further improve the performance of TADF materials to meet the requirements of real application. Novel device configurations should be developed according to the molecular features of TADF materials, which will promote the overall device performances for advanced optoelectronic applications.

Organic Light-Emitting Diodes/Light Extraction

Jiun-Haw Lee, National Taiwan University, Taipei City, Taiwan

Introduction

Organic light-emitting diode (OLED) consists of organic thin-film stacks with different functions, sandwiched by two electrodes. When the electrical voltage applied to the OLED, electrons and holes are injected from cathode and anode, respectively, into the organic layers. Usually, there are several layers such as hole-injection layer (HIL) and hole-transporting layer (HTL) to carry holes, as well as electron-injection layer (EIL) and electron-transporting layer (ETL) to carry electrons. Electrons and holes recombine in the emitting layer (EML) and form excitons. Excitons relax the energy radiatively to generate photons. There are several optical losses when the light propagates from the OLED to the air.

Due to the difference of refractive index (n) between the organic material (typically $n \sim 1.6$ – 2.0) and the air ($n = 1$), part of photons emitted from the EML are trapped due to total internal reflection (TIR). Typically, the OLED was fabricated on the glass substrate ($n = 1.5$). And a transparent anode (indium tin oxide (ITO), $n = 1.8$ – 2.0) and a reflective cathode (Al) are used. Optical wave tends to propagate at the medium with higher refractive index. Hence, part of light is trapped inside the ITO/organic layers, which is called “waveguiding mode.” And the light inside the glass substrate is called “substrate mode,” to separate the TIR effects at different interfaces.

Note that the carrier mobility of the organic materials for the OLED application are pretty low (typically $< 10^{-2} \text{ cm}^2/\text{Vs}$), and hence total film thickness of the thin-film stacks in an OLED is typically less than 300 nm, which is needed to operate such a device with a reasonable driving voltage ($< 10 \text{ V}$). Such a thickness is comparable to the visible wavelength which results in an interference effect. Typically, we can consider the OLED structure (from anode to cathode) as a “microcavity.” For the case with ITO anode, reflection mainly comes from the reflective cathode (such as Al) and it is called “weak cavity.” On the other hand, a semitransparent anode (such as thin metal) can be employed to replace ITO, which is formed a “strong cavity” with reflective metal cathode. By suitable tuning of the organic layer thicknesses, optical interference effect can be optimized for achieving higher extraction efficiency.

Due to the thin organic layers, the emission dipole is physically close (typically $< 100 \text{ nm}$) to the metal electrode, which results in plasmonic loss. That is, the emission dipole excites the surface plasmon polariton (SPP), which relaxes the energy non-radiatively. A minor, but nonnegligible loss is the material coming from the organic materials and the electrodes. Fig. 1 shows the external quantum efficiency (EQE) versus the ETL thickness. The oscillatory behavior of the outcoupled mode results from the microcavity effect with ETL thickness modulation, and the substrate mode shows similar trend. Surface plasmon mode decreases with increasing the ETL thickness, because the distance between emission dipole and metal cathode increases. However, on the other hand, the substrate mode increases with thicker ETL because it supports more optical modes.

In the following, we will introduce various schemes for improving the light extraction in an OLED, starting from the enhancement of substrate mode. By applying some structures to destroy the TIR at the (glass) substrate and the air, extraction efficiency can be significantly improved. Note that OLED can be used for lighting and display applications. Image quality is an important parameter for a display, which may decrease due to these structures, and careful design should be made. Besides, enhancement ratio of the outside (substrate) mode cannot fully decoupled with the internal (waveguiding and plasmonic) modes,

Fig. 1 Electron-transporting layer (ETL) thickness vs. distribution of different modes (outcoupled, substrate, waveguided, surface plasmons...) in an organic light-emitting diode (OLED). Black dots shows the measurement results. Maximum external quantum efficiency (EQE) (outcoupled mode) is 21% with ETL = 250 nm. Reproduced from Meerheim, R., Furno, M., Hofmann, S., Lüssem, B., Leo, K., 2010. Quantification of energy loss mechanisms in organic light-emitting diodes. *Applied Physics Letters* 97, 253305. Copyright (2010) with permission from American Institute of Physics.

which needs to be considered simultaneously. And we will move to the discussions of the internal modes. Again, at the ITO/organic and (glass) substrate interfaces, we can do some modulations of refractive index and structures for reducing the TIR. To reduce the plasmonic loss, a straightforward method is to keep the emission dipole away from the metal surface. And an alternative is to introduce nanostructure to couple the SPP back to the air mode.

Light Extraction of the Substrate Mode

To extract the light rays in the planar glass substrate, a straightforward method is to use a hemisphere lens structure, which has been used in semiconductor light-emitting diodes (LEDs).

Note there is a basic difference between semiconductor LED and OLED. LED was cut into a small piece, called “LED die” with the dimension $\sim 1\text{ mm} \times 1\text{ mm}$ for the following lens-like encapsulation process. On the other hand, a unique advantage for the OLED is the large-sized fabrication with the flat emission feature. For an OLED lighting panel (such as $10\text{ cm} \times 10\text{ cm}$), a hemisphere macro lens with radius much larger than 10 cm is not practical. Instead, miniaturized microlens is an alternative to extract the substrate mode. One may use a microlens array film (MAF) attached on the glass substrate to improve the OLED efficiency. Fig. 2(a) shows the scanning electron microscope (SEM) picture of MAF. In Fig. 2(b), MAF was applied on the top of OLED, and a brighter region was clearly seen. EQE was improved by 50% from 9.5 to 14.5%. The function of the lens structure is to redirect the light beams out of the OLED, which can be also accomplished by scattering medium. By incorporation of the material with different refractive index into the matrix film, it can be applied to the OLED which improved the light extraction with the flat out-surface, which is important for display application with touch-panel function. As shown in Fig. 2(c), a polyimide (PI) film (high-index matrix) with air voids ($n=1$) increased the EQE by 65%.

The basic idea of microlens structure for increasing light extraction of the OLED is to couple out the light at the substrate at larger incident angle. Fig. 3(a) shows the lit-on picture of an OLED pixel with the size of $100\text{ }\mu\text{m} \times 100\text{ }\mu\text{m}$. When applying MAF (with the pitch of $50\text{ }\mu\text{m}$) on the OLED as shown in Fig. 3(b), photons were extracted from the surrounding of the pixel region with larger incident angle (larger than critical angle between glass substrate and the air) which increased the light outcoupling. At the same time, note that there were some dark regions at the area where the emission area and the microlenses overlapped. Because the photons with smaller incident angle can couple out of the OLED without microlenses, the incorporation of microstructure on the pixel region actually decreased the outcoupled photons at this region. Hence, a concept of patterned microlens array was proposed. By removing the pixel on the top of the pixel region, light extraction at this region was maintained, while increasing the EQE from the contribution of surrounding areas, as shown in Fig. 3(c).

For using OLED in display application, not only light extraction, but also image quality should be taken into consideration. As shown in Fig. 3(b), light extraction from the region outside the pixel implied image blurring when using as an OLED display and it decreased the image quality. Fig. 4(a) shows the Lena image on the OLED display, and Fig. 4(d) shows the enlarged picture of the left eye region. Fig. 4(b) and (e) shows the image taken with MAF attachment. Although the luminance increased by 23%, the image quality index was decreased to 74%. Fig. 4(c) and (f) are the image with patterned-MAF. One can see that the image is better with patterned-MAF, with the image quality index of 94%. Besides, the luminance of the OLED display increased by 52%.

Light Extraction of the Waveguiding Mode

To extract the waveguiding mode, it is straightforward to use some structure inside the glass substrate, close to the OLED device. Fig. 5(a) shows a low-index structure which was inserted between the ITO substrate and the organic layers. The effective refractive

index of the waveguiding mode is decreased, and photons trapped in the waveguiding mode (light rays A and B in Fig. 5(a) with larger incident angle) can be effectively coupled out. By applying such low-index grid (LIG) in an OLED, 32% enhancement in EQE was observed. By using LIG and microlenses simultaneously, 130% improvement in EQE was achieved. However, the loss of contact area between ITO and organic layer reduced the luminance. Hence, one may insert such a grid structure beneath the ITO layer, as shown in Fig. 5(b). With sequential processes of deposition, etching, and planarization, embedded structure on the top of glass substrate was fabricated for extracting the waveguiding mode. Again, EQE was enhanced from 15 to 40% when using the grid structure to couple out the waveguiding mode, combined with the immersion of the OLED and photodetector inside the index-matching oil to extract all the glass substrate mode.

As discussed before, glass substrate mode and waveguiding mode both come from the TIR, with the refractive index of 1.5 and ~ 1.6 –2.0, respectively. By using a glass substrate with high refractive index ($n=1.8$), the waveguiding mode no longer exists. As

shown in Fig. 6(a), one can see that when using a high-index substrate, there is no TIR at the OLED device and glass substrate. Then, with the incorporation of macro lens or patterned surface (such as microlenses), all the contributions from waveguiding and substrate modes can be extracted, as shown in Fig. 6(b). EQE=54% can be achieved when ETL=235 nm, as shown in Fig. 6(c).

Thinking from the other side, it is possible to reduce the effective refractive index of the organic materials in the OLED device for reducing the waveguiding mode. As shown in Fig. 7(a), by decreasing the refractive indexes of the HTL and ETL from 2.0 to 1.4, the EQE can be improved from 20 to 40%. One may also use a complex anode structure $\text{Ta}_2\text{O}_5/\text{Au}$ on the flexible substrate ($n=1.6$) to couple out the waveguiding light into the substrate mode. Then, with the use of the lens structure, 63% EQE was achieved.

Light Extraction of the Plasmonic Mode

Let us go back to the microcavity effect in an OLED in **Fig. 1**. For the bottom emission OLED on the glass substrate with ITO anode, the distance of the emission dipole to the reflective cathode is crucial to the light extraction efficiency. And hence modulation of ETL thickness changes the efficiency more effectively than that of HTL thickness. As shown in **Fig. 8(a)**, when varying the thickness of HTL (CBP, 4,4'-bis(carbazol-9-yl)biphenyl), the current efficiency changed between ~ 50 and ~ 65 cd/A. On the other hand, current efficiency changed from < 10 cd/A to ~ 80 cd/A with increasing the ETL (TPBi, 2,2',2''-(1,3,5-benzinetriyl)-tris(1-phenyl-1-H-benzimidazole)) thickness, in **Fig. 8(b)**. Besides, one can also notice that with increasing the ETL thickness, the efficiency can be higher than the first peak which was due to the reduction of plasmonic loss, as shown in **Fig. 1**. **Fig. 8(c)** shows the power efficiency versus luminance for different OLEDs. Device L1 is a common OLED structure on glass substrate. With the incorporation of half-sphere macro lens, power efficiency over 50 lm/W can be achieved. By applying a high-index substrate for coupling out the substrate mode, the efficiency can be boosted up over 80 lm/W, in device HI-1. For devices HI-2 and HI-3, thick ETL was employed, which resulted in a much higher power efficiency > 150 lm/W and > 110 lm/W, respectively.

Because the plasmonic loss mainly came from the metal electrode, it is possible to reduce this mode by using transparent conductive oxides as both the anode and cathode materials. **Fig. 9(a)** shows the device structure. ITO and indium zinc oxide (IZO) was used as the cathode and anode, respectively. Light emission from both sides and it is called transparent OLED. With the incorporation of micro- and macrostructures for extracting the substrate mode, EQE was increased from 18.1 to 47.3% and 62.9%, respectively, due to the reduction of plasmonic and substrate modes.

The origin of the non-radiative behavior of the plasmonic mode because the dispersion curve (w - k) of surface plasmon mode has no intersection with the air light cone, as shown in **Fig. 10(a)**. However, with the introduction of the periodic nanostructure such as grating, it is possible to provide an extra in-plane wave-vector which can convert the plasmonic mode radiatively. Note that the nanostructure extracts not only the plasmonic mode, but also the waveguiding mode. To distinguish these two effects, one can use polarization dependent measurement. Emission from the surface plasmonic mode is only p-polarized. On the other hand, enhanced emission from s-polarization resulted from the outcoupling of the waveguiding mode by the nanostructure grating. Hence, a polarizer can be put in front of the detector for separating these two effects. As shown in **Fig. 10(c)** and **(d)**, p- and s-polarized emission at different viewing angles were obtained, which came from the light extraction of plasmonic and waveguiding mode, respectively.

Although the uniform nanostructure provides an efficient way to extract the plasmonic and waveguiding mode, one can note that wavelength dependence is pretty strong, which means the color of this OLED is varied from different viewing angles and it is not suitable for display and lighting applications. A quasi-periodic structure was proposed by buckling fabrication. Due to different thermal expansion coefficient between poly(dimethylsiloxane) (PDMS) and Al, a quasi-periodic structure can be obtained, as shown in **Fig. 11**. With one-, two-, and three-times buckling, the structure with longer period (saying 900 nm) can be enhanced, with the major peak at 410 nm. 2.2- and 2.9-times improvement in power efficiency was achieved with two- and three-time buckling structure on an OLED without significantly changing the emission profile.

Thinking from the molecule viewpoint, it acts like an oscillation dipole for generating electromagnetic wave, as shown in **(Fig. 12a)**. Here, the upper medium is metal, and surface plasmon was excited due to the electrical dipole. Depending on the Θ value, one can divide the contribution from vertical ($\Theta = 0$ degree) and horizontal ($\Theta = 90$ degree) dipoles. Note that SP mode was excited by TM waves, and hence radiation of horizontal dipoles coupled much less into plasmonic mode compared

Fig. 10 Dispersion relation and device structure of a (a) planar and (b) grating structure. (c) and (d) shows the photoluminescence (PL) spectra at different viewing angles of p- and s-polarization. to vertical dipole. By suitable choosing the organic material, it is possible to “align” the organic emitter horizontally and achieve the high EQE. Ratio between horizontal and vertical dipoles can be obtained from photoluminescence (PL) intensity at different viewing angles, as shown in Fig. 12(b). Black and yellow dashed lines show the cases with pure horizontal and isotropic dipole emission, respectively. With higher horizontal dipole ratio (93% for Pt(fppz)₂, Pt(II) bis(3-(trifluoromethyl)-5-(2-pyridyl)-pyrazolate)), the EQE can be as high as 38.8%, as shown in Fig. 12(c). Note that it was a planar structure without any lens structure. Substrate was a typical glass. And the thin-film thickness from the emitter to the metal electrode was less than 100 nm. Hence, such a high EQE came from the reduction of plasmonic mode due to the alignment of horizontal dipole.

Summary

Here, we introduced the problem of light extraction in an OLED which limits the outcoupling efficiency $\sim 20\%$ in a conventional bottom emission configuration, mainly due to TIR and plasmonic loss. Various methods were introduced to improve the light extraction, with different structures and refractive index modulation. For the recent stage, experimental and simulation results show that $\text{EQE} = \sim 60\%$ is achievable, and further improvement is still on-going.

Introduction

Photovoltaic, which directly harvest energy from sunlight into electricity, is being increasingly recognized as an important component for future global energy production. Organic semiconductor and particularly conjugated polymers-based solar cells (OPVs) have attracted world-wide attention in the past decade, because of their distinct features such as low cost production, lightweight, flexibility, electronic functional versatility from chemical synthesis, roll-to-roll compatible large area fabrication, (semi)transparency and potentially environmental friendly in fabrication, etc. The performance of OPV has been greatly improved in last decade, now reaching over 12% as shown in [Fig. 1\(a\)](#) (Source: National Renewable Energy Laboratory (NREL)). These achievements come from comprehensive research – from materials discovery, nanostructure morphology control in photon absorbing active layer, to interface materials innovation and device architecture engineering, device physics, to fabrication technologies. Strictly speaking, OPV can be divided into polymer and small molecule type. This article only focus on polymer solar cells and use the term OPV to represent them.

Polymer OPVs are based on organic conjugated polymers, which are carbon-based materials whose backbones are comprised of alternating C–C and C=C bonds (carbon–carbon triple bonds may also be possible in rare cases), shown in [Fig. 1\(b\)](#). In the alternating C–C and C=C bonds molecular structure, through sp^2 hybridization, it leads to a linear series of overlapping p_z orbitals, and creates a conjugated chain of delocalized electron density. The π electron delocalization along the conjugated backbone – i.e., the interaction of the π electrons – is responsible for their semiconducting properties. As the conjugation length (or the electron delocalization length) increases, the intrinsic material energy levels becomes closely spaced, and similar to inorganic semiconductors, a quasi “band” structure will form in organic semiconductors, including conjugated polymers. In organic semiconductors, the lowest unoccupied molecular orbital (LUMO) is equivalent to the conduction band minimum (CBM) in inorganic semiconductors, while the highest occupied molecular orbital (HOMO) is equivalent to the valence band maximum (VBM) in inorganic semiconductors ([Fig. 1\(c\)](#)). The primary photoexcitation in the organic semiconductors are bounded Frenkel excitons (electron–hole pair), which is very different from the free electrons/holes in crystalline inorganic semiconductors. The excitons have a typical lifetime of ~ 100 ps to 1 ns, decay either radiatively or non-radiatively. These differences make the working mechanism in organic polymer solar cells very different from the inorganic solar cells.

The high performance polymer solar cells are now dominated by BHJ structure, with conjugated polymer as electron donors, mixed with fullerene or nonfullerene electron acceptors.

This article aims at a concise review of polymer organics solar cell (OSC) development, and discuss the possible strategy for future improvement in polymer solar cell.

Basic Principles of OSC

The main structure of OPV is an organic material(s)-based active layer(s) sandwiched between a cathode and an anode. The active layers consist of material with low ionization potential (IP) as electron donor and material with high electron affinity (EA) as electron acceptor material. Various materials are used as either donor or acceptor including polymer, fullerene derivatives and small molecules. Furthermore, donor material is hole rich which ideally make ohmic contact with anode, whereas acceptor material contact with the cathode.

In the simplest picture of organic solar cell operation principle, the process of the photon-to-electron conversion can be divided into four basic steps ([Fig. 2\(a\)](#)) each with efficiencies – photon absorption (η_A), exciton diffusion (η_{ED}), charge carrier transfer (η_{CT}), and charge carrier collection (η_{CC}). The detail of every step is discussed as below.

1. Photon absorption

The organic material semiconductor only absorbs photon that higher or equal to its bandgap. As consequence, only material with low bandgap is suitable for active layer. In this step, photon was absorbed then electrons in donor (/acceptor) material are

Fig. 1 (a) Efficiency-chart of best solar cell summarized by National Renewable Energy Laboratory (<https://www.nrel.gov/pv/assets/images/efficiency-chart.png>); (b) alternating C–C and C=C bonds in conjugated polymer backbone; (c) energy diagram in organic semiconductors via π electron delocalization – π conjugation. HOMO, highest occupied molecular orbital; LUMO, lowest unoccupied molecular orbital.

excited to the LUMO level and created holes in the HOMO level. These electron and hole pair are bound together by attractive coulomb interaction and are called excitons. Furthermore, the absorption efficiency (η_A) of active layer is determined by the absorption spectra of the organic material, their thickness, as well as the device architecture.

2. Exciton diffusion

The generated excitons in photon absorption process move via diffusion. This exciton should transport to the donor–acceptor interface within its lifetime to convert to charge carrier. The morphology plays significant role on exciton diffusion (η_{ED}).

3. Charge transfer

The room temperature thermal energy of 26 meV is an order smaller than the binding energy of tightly bound Frenkel excitons in organic semiconductors. Therefore to generate “free” electron and hole polarons as charge carriers, an exciton needs to reach the donor–acceptor interface where the molecular energy level difference will provide the driving force for exciton dissociation into a geminate pair first and overcome the monomolecular process called geminate recombination. Only after this process that free charge carriers can be generated which ultimately contribute to photocurrent.

4. Charge collection

From the D/A interface, the free charge carrier needs be transported (hole in donor, electron in acceptor material) to the organic/electrode interfaces. Again nano-morphology in BHJ configuration is critical. After the charge carriers transport to the active layer/electrode interface, they can finally be extracted from the device in order to yield photocurrent. Buffer layers (hole transport layer (HTL) and electron transport layer (ETL)) are usually necessary and critical to aid hole or electron collection by reducing the energy barriers required to transport carriers and increasing the built in electric field to help electron collections.

Fig. 2 (a) Simplified schematic mechanism of photocurrent generation in organic solar cells which consist of four sequence steps photon absorption (η_A), exciton diffusion (η_{ED}), charge transfer (η_{CT}), and charge collection (η_{CC}); (b) J - V characteristic curve of solar cell under illumination; (c) standard terrestrial AM1.5G solar spectrum (irradiance) and a typical external quantum efficiency (EQE) spectrum of polymer solar cell. HTL, hole transport layer; HOMO, highest occupied molecular orbital; ITO, indium-tin-oxide; LUMO, lowest unoccupied molecular orbital.

The overall quantum efficiency (a function of wavelength) can be calculated by following equation:

$$\eta_{EQE}(\lambda) = \eta_A(\lambda)\eta_{ED}(\lambda)\eta_{CT}(\lambda)\eta_{CC}(\lambda) \quad (1)$$

Beyond the simple model, one should realize that there are different electronic states in OPV devices – excitons, the charge transfer (CT) states/excitons, the mobile polaron transport states and localized trap states – each play a crucial role in the device operation. In particular, the CT state is an intermediate state between exciton and “free” polaron state. It comprises an electron and hole on either side of the BHJ interface, the electron and hole separation reduces the Coulomb interaction. The CT state is tightly connected with the V_{oc} limit of the solar cell.

Characterization of OSC

The J - V characteristics of a solar cell under illumination are shown in Fig. 2(b). There are three important parameters that combined to give the power conversion efficiency (PCE): short-circuit current density J_{sc} , open circuit voltage V_{oc} , and fill factor (FF).

1. Short circuit current density

Short circuit current density, J_{sc} , is defined as the current when the solar cell has no external load. The J_{sc} represents the number of charge carrier that generated in active layer can collected at electrode at short circuit condition. However, not all incident light is absorbed in active layer and not all generated carriers can reach the electrodes. The magnitude of the J_{sc} depends on the absorption spectrum of the material, the morphology, and the mobility of charge carrier in the material. The high photocurrent can be achieved by selecting material with absorption spectra that overlap the photon flux density.

The J_{sc} also depends on solar spectrum. The extraterrestrial solar spectrum resembles that of a blackbody at 5760K. For terrestrial solar cell application, the standard solar spectrum is AM1.5G, where the sunlight goes through 1.5 times the atmosphere, or incide from an elevation angle of 42 degree, and the label G means the spectrum includes both direct light and diffused light as there is scattering by the atmosphere. Fig. 2(c) shows the standard terrestrial AM1.5G solar spectrum (irradiance) and a typical external quantum efficiency (EQE) spectrum of polymer solar cell. In principle, the integration of the EQE with solar irradiance should be equal to the J_{sc} .

2. Open circuit voltage (V_{oc})

Besides J_{sc} , another key parameter that determine the efficiency of PSC is the open-circuit voltage V_{oc} , which represents the maximum voltage a solar cell can provide to an external circuit. Light harvesting materials employed in OPVs have an optical bandgap of around 1.3–2.1 eV and yet the V_{oc} barely exceeds 1.0 V, i.e., significant loss of photon's original energy. In organic solar cell, the V_{oc} mainly proportional to the energy level difference between HOMO level of donor and LUMO level of acceptor, and more detailed analysis will involve the CT states tightly linked to these levels. As consequence, the selection of the

donor material and acceptor will largely determine and limit the V_{OC} value. In addition, secondary parameters affecting the V_{OC} include recombination, temperature (and thus temperature dependent mobility), work function of electrode, and morphology of active layer.

For a long period of time, fullerene derivatives such as PC₆₁BM and [6,6]-phenyl-C71-butyric acid methyl ester (PC₇₁BM) are dominating acceptor materials in OPV research. In the BHJ system with fullerene derivatives acceptors, as the acceptor LUMO level is fixed, significant efforts were given to donor materials. To enhance the J_{SC} , lower bandgap polymers are the choice, and at the same time, to avoid the typical photovoltage loss, the low bandgap polymers have to have deep HOMO level.

3. FF

FF is the ratio of the maximum power to the open and short circuit values (J_{SC} times V_{OC}) which represents the difference between a real solar cell and the ideal condition. FF shows the dependence of the photocurrent output on the internal field of device, and it's related to the series resistance (R_s) and parallel resistance (R_p). While lower R_s normally results in the higher FF value, FF is much more complex, and potential dependent recombination has to be investigated.

4. Maximum power point

The performance of a solar cell is evaluated from an experimentally measured current–voltage characteristic curve. Maximum power point (MPP) is the point on the J – V curve that the area of resulting rectangle is largest. The MPP represent the maximum of power that can be generated by a solar cell.

5. PCE

The PCE is define as the efficiency of the solar cell and it can be calculated as the maximum output power divided by the input power. The PCE can be calculated as follows:

$$\text{PCE (\%)} = \frac{P_{\text{maz}}}{P_{\text{in}}} = \frac{FE \times J_{SC} \times V_{OC}}{PP_{\text{in}}} \quad (2)$$

The current in the solar cell at any voltage is most readily understood as the sum of the dark current $J_D(V)$ and the photocurrent $J_P(V)$, where they have opposite sign in PV region.

$$J(V) = J_D(V) + J_P(V) \quad (3)$$

From $J(V_{OC})=0$, we know the carrier excitation rate is balanced by an equal carrier recombination rate. The photon generation rate G under 1-sun illumination in a typical organic cell is about 10^{22} cm^{-3} , and the recombination lifetime τ is about 10^{-6} s , thus the carrier concentration $N_C=G\tau$ is about 10^{16} cm^{-3} .

The dark forward current in solar cells obey the diode equation,

$$J_D(V) = J_0 \exp \left[\left[\frac{e(V - R_s J_D)}{nkT} \right] - 1 \right] + \frac{V - R_s J_D}{R_p} \quad (4)$$

where n is the ideality factor, R_p is the parallel shunt resistance, and R_s is the series resistance. The J_0 is related to the barrier height and decreases with larger built-in potential V_{BI} . The ideality factor n is typically in the range 1.3–2 in good organic cells. In classic semiconductor theory, $n=1$ is associated with band-to-band recombination, while $n=2$ is associated with recombination through trap states by the Shockley–Read–Hall mechanism. Modeling shows that the intermediate values arise from recombination through band tails states, possibly in combination with deeper states.

OPV Device Structures

The organic polymer solar cell structure evolution is mainly for improve the interface between donor and acceptor materials, and also the polarity of the device. The development of device structure historically starts from single layer structure, to double layer structure, and bulk heterojunction (BHJ). The structure of the device discussed in sequence.

1. Single polymer layer device

The single polymer layer OPV is the simplest structure. Polyacetylene (PA) were used in single layer organic solar cell that producing V_{OC} 0.3 V and PCE 0.3%. And poly(3-nethyl-thiophene) film sandwiched between aluminum and platinum had external quantum of 0.17% and V_{OC} of 0.4 V and FF 30%.

Organic polymers intrinsically have large exciton binding energy. Using external electrical potential alone is very hard to provide excitation dissociation, and thus the photocurrent will be very low. It has to be extremely thin to dissociate exciton, but this leads to very low light absorption – a dilemma to conquer.

2. Bilayer polymer/acceptor structure.

In bilayer heterojunction (also known as planar heterojunction) solar cell device, film of a polymer as the electron donor (p-type), and a film of electron acceptor (n-type) are deposited on top, as shown in Fig. 3. The selected active layer should realize an offset in HOMO and LUMO energy level at the donor–acceptor (D/A) interface to drive exciton dissociation by CT. In the first successful of two layer organic photovoltaic device by Tang *et al.* a copper phthalocyanine (CuPC) as donor material and a perylene tetracarboxylic derivative as acceptor material were vacuum deposited to make active layer and achieved

Fig. 3 Polymer solar cell in (a) bilayer structure and (b) bulk heterojunction (BHJ) structure (reproduced from Ganesamoorthy, R., Sathiyar, G., Sakthivel, P., 2017. *Solar Energy Materials & Solar Cells* 161, 102–148); schematic morphology in polymer solar cell (c) pure bilayer structure, (d) “uniform” BHJ structure with very small phase separation domain size, and (e) BHJ with moderately phase separation domain size (reproduced from Maqsood, I., Cundy, L.D., Biesevker, M., *et al.*, 2013. Monte Carlo simulation of Förster resonance energy transfer in 3D nanoscale organic bulk heterojunction morphologies. *Journal of Physical Chemistry C* 117 (41), 21086–21095). ITO, indium-tin-oxide.

efficiency around 1%. However, the drawback of bilayer structure is that the layer thickness is limited to the exciton diffusion length. Also, the bilayer structure is limited by small donor–acceptor interface area.

Since the lifetime of the exciton in most polymer films is short, the diffusion lengths are limited to less than 20 nm, which is shorter than the optical absorption pass length (~ 100 – 200 nm). Therefore only a limited part of exciton can diffuse to the interface in bilayer heterojunction. If the polymer is very thick, the excitons cannot reach the donor acceptor interface then recombine. In order to realize efficient photon conversion, this architecture must strike a balance between the relative long optical absorption length ($L_A \sim 50$ nm) and shorter characteristics length scale for exciton diffusion ($L_D \sim 10$ nm).

In evaporated small molecule solar cell, the complicated layered solar structure can be realized. IMEC group developed bilayer nonfullerene solar cell with PCE more than 6% using α -6T as donor and SubNc as acceptor. The device performance is better than using fullerene as acceptor due to broaden the absorption spectrum. The multilayer planar heterojunction to led PCE up to over 8%. The multiplayer structure, however, is difficult to realize in solution process OPV.

3. BHJ polymer solar cell structure.

Bilayer structure problem can be addressed by BHJ structure. In the BHJ device a blend or mixture of donor and acceptor molecules were used to form a bi-continual layer as shown in **Fig. 3(b)**. Bicontinuous three dimensional interpenetrating network yielded an increased D–A interface, which is the necessary criteria for the effective exciton dissociation.

The first BHJ concept was introduced by Hiramoto *et al.* in evaporated small molecule through co-deposited of phthalocyanine (Pc) and perylene derivatives (PTC) as interlayer between Pc and PTC. The photocurrent enhanced due to a large number of molecular contact while in the bilayer the donor and acceptor are completely separated. The much more attractive solution processed BHJ organic polymer solar cell was realized by Heeger’s group using polymer–fullerene and Friend’s group in polymer–polymer blend in 1995. The BHJ concept has significantly increased the number of interfacial area of donor and acceptor phase.

Strategy to Improve BHJ Device Performance

The high performance polymer solar cell is dominated by BHJ structure. We review the progress in three key research areas: morphology, active materials, and interface and structural engineering.

BHJ Morphology Control Through Process Engineering

Bicontinuous interpenetrating active layer morphology is a pre-requisition for high organic solar cell performance. The morphology controlling is affected by many factors including crystallinity, molecular arrangement, and drying rate. In bilayer structure, interfacial area between donor and acceptor is on the planar surface (Fig. 3(c)), thus exciton dissociation efficiency into free carrier is very low. The “uniform” BHJ structure has very large donor–acceptor interface area, but the morphology become more important. As shown in Fig. 3(d), the small domain phase separation of BHJ provides a large number D–A interface, but it is not providing continuous pathway. As consequence, large number of charge generation produced but electron and hole trapped in the active layer then recombine, and cannot effectively generate J_{sc} . The right BHJ morphology will look like the excessively D–A interface in Fig. 3(e) – it has the right balance of D/A interface (for efficient exciton dissociation) and nanoscale bicontinuous pathway to enable the separated electron and hole polarons reaching the electrodes.

The reported effective approaches in tuning morphologies of the active layer in OPVs including solvent annealing (SA), thermal annealing, solvent additives, solvent (vapor) annealing, and solvent mixtures, which would be presented in the following section.

Thermal Annealing

Thermal annealing is an effective method to improve PCE discovered in the early years of OPV, when the workhorse material changed from poly[2-methoxy,5-(2'-ethyl-hexyloxy)-p-phenylene vinylene] (MEH-PPV) to soluble polythiophenes, especially regioregular poly(3-hexylthiophene) (RR-P3HT), which has lower bandgap of 1.9 eV. The PCE of P3HT: fulleropyridine was enhanced by 3–4-fold with mild thermal treatment (50°C for 30 min); thermal annealing temperature, annealing time, and annealing sequence – either before (preannealing) or after (postannealing) electrode deposition, all play role in determining the performance of classical P3HT:phenyl-C61-butyric acid methyl ester (PCBM) solar cells.

The absorption of the P3HT in the P3HT:PCBM active layer, when processed in typical fast spin-coating approach, is very different from that of the pristine P3HT film. It's generally observed the P3HT absorption red shifted after thermal annealing, indicating the enhanced (or partially recovered) polymer crystallinity. Grazing incidence X-ray scattering (GIXS) become a powerful approach to investigate the polymer blend. GIXS technique gives clearly evidence of the π – π stacking orientation (orientated parallel to the substrate in P3HT:PCBM case), and enhanced crystallinity after thermal annealing above transition glass temperature (T_g). Upon thermal annealing, the PCBM molecules can freely diffuse out of these mixed regions to aggregate into PCBM cluster while enhancing P3HT crystallinity. The PCBM diffusion may induce simultaneously more ordered packing of P3HT and form bicontinuous morphology (Fig. 4(a)). In semi crystalline polythiophenes, high charge mobility occurs along the polymer main chain and parallel to the π – π stacking direction of the thiophenes rings. The increased crystallization via thermal annealing also reduces density of the defects at the interface and in the bulk. Thermal annealing is effective beyond P3HT:PCBM. Annealing at 100°C for 20 min improves PBDTS-DTBT (as donor) and nonfullerene ITIC (as acceptor) solar cell from 7.80 to 9.09%. Increased interchain packing with significantly intensified face-on π – π stacking indicates enhanced exciton dissociation and charge transport, thus results in enhanced current density and FF.

Solvent (Vapor) Annealing

SA is another method to control morphology of the active layer by slowing down the evaporation rate of the solvent, which slows the film formation/drying process. In P3HT:PC₆₁BM system using high boiling point solvent ODCB, the slow solvent removing process provide the polythiophene chains enough time to demonstrate the self-organization capability embedded in the regioregular design of the polymer. The SA approach results in a much increased hole mobility and balanced charge transport, which lead to a more than doubled PCE of 4.4%. The thermal annealing and SA approaches improves the morphology in different way in P3HT system. Regioregular P3HT itself has excellent absorption up to 650 nm and the π – π stacking of polymer chains ensured high mobility. However the long wavelength absorption is severely suppressed with the present of acceptor PCBM when the solvent was removed quickly in traditional way. The thermal annealing approach can partially recover the polymer ordering and absorption. The SA takes another route by preserving the high degree of ordering rooted in the self-organization during the initial film formation period instead. Fig. 4(b) shows the GIXS results of the RR-P3HT:PCBM film with and without SA. This shows the polymer chain packing is dominated by edge-on orientation, and the SA not only leads to higher crystallinity, but also smaller mainchain spacing (a -axis). Phase image of atomic force microscopy (AFM) shows very clear polymer fibril structure with ~20–30 nm fiber diameter (Fig. 4(c)).

Dynamically, during the SA process, the BHJ blend was found swollen by solvent, which allowed PCBM acceptor to diffuse out of P3HT domains. This also improves mobility of fullerene, increases the crystallinity of P3HT, and improves phase separation between domains.

Mixed-solvent and vapor annealing can be combined to improve polymer crystallinity and inhibit intercalation into polymer side chains, shown in a poly[N-9'-heptadecanyle-2,7-carbazole-alt-5,5'-(4',7'-di-2-thienyl-2',1',3'-benzothiadiazole)] (PCDTBT): PC₇₀BM blend system. After solvent vapor annealing in mixed solvent tetrahydrofuran (THF) and carbon disulfide (CS₂), the out-of-plane GIXS results show that PCDTBT crystals with larger size and higher crystallinity were formed due to enhanced π – π interaction of polymer chain as shown in Fig. 4(d). Moreover, the PC₇₀BM molecules diffused out of polymer chain and formed

Effects of additives on the morphology of solution phase aggregates formed by active layer components of high-efficiency organic solar cells. *Journal of the American Chemical Society* 133, 20661–20663); and (g) the GIXS data of PBDTTT polymer film, showing the face-on orientation of the polymer chain.

large aggregates due to the THF component, which induced phase separation. In addition, owing to the existence of the CS₂ vapor component, the migration ability of PCDTBT chains was improved, which enhanced its self-organization ability and facilitated the formation of nanofibrils (Fig. 4(e)).

Solvent Additive

The addition of small amount solvent additive during film casting is a simple and effective strategy to control morphology of polymer solar cell in many OPV systems.

The addition small amount of 1,8-octanedithiol (ODT) in poly[2,6-(4,4-bis-(2-ethylhexyl)-4H-cyclopenta[2,1-b;3,4-b']dithiophene)-alt-4,7-(2,1,3-benzothiadiazole)] (PCPDTTT):PCBM system effectively improve PCE from 2.8 to 5.5%. It's an important and surprising discovery. Alkanedithiol additives do not react with either the polymer or the fullerene and removed

while film drying. The alkanedithiol selectively dissolves the PCBM, but not the donor polymer. The differential solubility and boiling point provide powerful tool to achieve better ordering of donor polymer and control the phase separation. Devices without ODT addition has predominately amorphous structure, while addition 3 wt% of ODT resulted in the nucleation of crystalline PCPDTBT. Time resolved in situ wide angle (WA) GIXS experiments revealed that small amount of ODT simultaneously reduces the nucleation barrier for polymer crystallization, which facilitated reorientation and crystal growth during a prolonged film drying process.

DIO (1,8-diiodooctane) additive in main solvent chlorobenzene (CB) improves the PCE of PTB7:PC₇₁BM polymer solar cell from 3.92 to 7.40%. It was found that the dramatic enhancement of the device performance due to the change in the morphology more uniform, showing good miscibility between PTB7 and PC₇₁BM and form interpenetration networks. The DIO-processed blend films results more homogenous phase separation distance of 20–40 nm. The finer domain size is beneficial for charge separation and transport which enhancing FF. X-ray scattering technique shows that without DIO, the large PC₇₁BM aggregates hinder PC₇₁BM intercalation into the PTB7 network during film formation. DIO selectively dissolves PC₇₁BM aggregates, facilitates integration of PC₇₁BM into PTB7 domain and optimizing both domain sizes with improved donor/acceptor interface (Fig. 4(f)).

1-Chloronaphthalene (CN), diphenyl ether (DPE), 1-phenylnaphthalene (PN), 1-naphthalenethiol (SH-NA), diiodohexane (DIH) are also examples of effective additives in polymer solar cell. In fact, PN additive has enabled 11.7% PCE in OPV cell, which promotes face-on polymer backbone orientation, reduces domain size, and increases domain purity. While solvent additives show great performance in efficiency enhancement, one must try to avoid the possible drawbacks. Additives are typically high boiling point. They need to be fully removed, otherwise the film will be too weak mechanically to be used in production, and there are evidences that the remaining additives like DIO accelerates photodegradation of the active layer due to nano-morphology change. This actually leads to a new research direction of high boiling point additive free OPV toward high performance. Mixed solvent of common major organic solvents in OPV such as DCB, CB, CF, etc. sometimes can give better performance in solar cell. This approach actually already exists for over a decade. It is also a straight forward way of control the solvent remove rate.

Active Materials in Polymer Solar Cells

Polymer Active Materials

Polymer active materials are at the core of the polymer solar cell technology. The optimal morphology formation in the device is highly material system dependent. A brief review of some of the key polymer solar cells will be presented below. For detail OPV materials development, there are many excellent review publications on the topic.

One of the earliest PSCs polymers is MEH-PPV, Fig. 5(b)), and excellent representative PPV derivative, which is also a good light emitting polymer. MEH-PPV was further improved into poly(2-methoxy-5-(3',7'-dimethyl-octyloxy))-*p*-phenylene vinylene (MDMO-PPV) (or OC₁C₁₀-PPV) through side chain modification, and efficiency up to 3.5% was realized in MDMO-PPV:PC₇₁BM. This is the best before the society figured our ways to conquer the morphology problem in regioregular RR-P3HT:PCBM in ~ 2005, a decade after the invention of RR-P3HT. Since then, the pace of OPV progress became much faster, and many excellent materials were invented for OPV.

Model polymer RR-P3HT has bandgap of ~ 1.9 eV, which only allowed about 30% of photon was absorbed. Compared to the silicon band of 1.1 eV and absorption up to 77% of the sunlight, lower bandgap material is a continuously pursuing target of the OPV society. Hsu *et al.* reviewed the low bandgap polymer design strategy for OPV shown in Fig. 5(a), which still largely holds.

RR-P3HT (Fig. 5(c)) is an excellent example of the first strategy – stereo regularity induced interchain coupling. The interchain π - π interaction leads to increased ordering and crystallinity in the materials and red shift in absorption. Beyond RR-P3HT, several very effective synthetic strategies have been developed – (1) using alternating electron-rich (donor) and electron-deficient (acceptor) units in the backbone to form the D-A copolymers; (2) tuning the aromaticity and bond length alternation (BLA), which stabilize the lower bandgap quinoid resonance structure over aromatic structure; (3) incorporate strong electron withdrawing substitutes such as carbonyl group or fluorine atoms; (4) incorporating chemically rigid (e.g., larger planarity) unit. Thousands of new compounds have been designed and synthesized for OPV applications. Here are some representative OPV materials in the last decade.

Electron-donating carbazole unit and electron-withdrawing benzothiadiazole (BT) unit-based polymer (PCDTBT) with 1.88 eV bandgap and low lying HOMO (5.5 eV) shows promising PCE of 3.6%, which was later improved to ~ 7% level. Cyclopenta[2,1-b;3,4-b']dithiophene (CPDT) and dithieno[3,2-b:2',3'-d]silole (DTS) units with stronger electron-donating properties were copolymerized with BT unit, and two much lower bandgap polymers (Fig. 5(d)) – PCPDTBT (response up to 850 nm) and poly[(4,4'-bis(2-ethylhexyl)dithieno[3,2-b:2',3'-d]silole)-2,6-diyl-alt-(2,1,3-benzothiadiazole)-4,7-diyl] (PSBTBT) (response up to 820 nm) were formed due to the strong intramolecular donor-acceptor interactions. The substitution of C-atom to heavier Si-atom in PSBTBT started the heavy atom substitution approach in the OPV field. The C-Si bond is longer than the C-C bond and less steric hindrance is created in the DTS core by the side chains, leading to a better π - π stacking and enhanced crystallinity. Follow-up work shows replacing Si atom with even heavier Ge atom in carbazole unit can further improve the performance, due to the improved molecular ordering.

A beautiful example of using larger planar unit to improve carrier transport and thus OPV performance is the benzo[1,2-b;4,5-b']dithiophene (BDT) unit. When copolymerized with thieno[3,4-b]thiophene (TT) series of building blocks, star polymers

Fig. 5 (a) Design principles for energy level and bandgap tuning in conjugated polymers (reproduced from Cheng, Y.-J., Yang, S.-H., Hsu, C.-S., 2009. Synthesis of conjugated polymers for organic solar cell applications. *Chemical Reviews* 109 (11), 5868–5923); molecular structures of representative donor polymers; (b) poly[2-methoxy,5-(2'-ethyl-hexyloxy)-p-phenylene vinylene] (MEH-PPV); (c) regioregular poly(3-hexylthiophene) (RR-P3HT); (d) poly[2,6-(4,4-bis-(2-ethylhexyl)-4H-cyclopenta[2,1-b;3,4-b'] dithiophene)-alt-4,7-(2,1,3-benzothiadiazole)] (PCPDTBT) and poly[(4,4'-bis(2-ethylhexyl) dithieno[3,2-b:2',3'-d] silole)-2,6-diyl-alt-(2,1,3-benzothiadiazole)-4,7-diyl] (PSBTBT); (e) PTB-7; (f) poly(2,6'-4,8-di(5-ethylhexylthienyl) benzo[1,2-b;3,4-b]dithiophene-alt-5-dibutyltolyl-3,6-bis(5-bromothiophen-2-yl)pyrrolo[3,4-c]pyrrole-1,4-dione) (PBDDT-DPP) and poly(2,6'-4,8-di(5-ethylhexylthienyl)benzo[1,2-b;3,4-b]dithiophene-alt-2,5-bis(2-butyltolyl)-3,6-bis(selenophene-2-yl)pyrrolo[3,4-c]pyrrole-1,4-dione) (PBDDT-SeDPP) (g) PDTP-DFBT molecular structures of representative acceptors; (h) PC₆₁BM; (i) Bis-PC₇₁BM; (j) IC₆₁BA and (k) IT-M. HOMO, highest occupied molecular orbital; LUMO, lowest unoccupied molecular orbital.

PTBx, also called PBDT-TT (**Fig. 5(e)**) series of polymers were formed. Further materials improvements include adding a fluorine atom on the TT unit to lower the HOMO level, side chain engineering to tune the solubility, crystallinity, etc. This series of star polymers set the 7, 8, and 9% PCEs milestones of OPV, and still are among the best. It is also a great example that all four synthetic strategies have been used jointly to get the best result. Another example is a high V_{oc} polymer PBDT-TPD formed by copolymerizing BDT unit with strong electron accepting thieno[3,4-c]pyrrole-4,6-dione (TPD) unit.

Diketopyrrolopyrrole (DPP) unit is a strong electron-withdrawing unit, and shows its effectiveness of low bandgap OPV polymer below 1.5 eV. poly(2,6'-4,8-di(5-ethylhexylthienyl) benzo[1,2-b;3,4-b]dithiophene-alt-5-dibutyloctyl-3,6-bis(5-bromothiophen-2-yl)pyrrolo[3,4-c]pyrrole-1,4-dione) (PBDTT-DPP) polymers, a series of D-A copolymers with BDT and DPP unit, show small bandgap of ~ 1.46 eV, deep HOMO level, and high charge carrier mobility. The reduction of the bandgap and the enhancement of the charge transport properties of PBDTT-DPP can be accomplished by substituting the sulfur atoms on the DPP unit with selenium atoms. The resulted poly{2,6'-4,8-di(5-ethylhexylthienyl)benzo[1,2-b;3,4-b]dithiophene-alt-2,5-bis(2-butyloctyl)-3,6-bis(selenophene-2-yl)pyrrolo[3,4-c]pyrrole-1,4-dione} (PBDTT-SeDPP) ($E_g \sim 1.38$ eV, Fig. 5(f)) polymer gives single junction devices with PCEs of 7.2%.

Adding two fluorine atom on BT unit leads to strong electron deficient unit difluoro-benzothiadiazole (DFBT) unit. Copolymerized with less electron donating BDT unit (through side chain substitution with alkyl group), PBDT-DTffBT polymer of 1.7 eV bandgap gives higher V_{oc} and PCE. Asymmetric electron rich dithieno[3,2-b:2',3'-d]pyran (DTP) unit shows even stronger electron-donating property than BDT unit, and when copolymerized with electron deficient DFBT unit, a regiorandom polymer (PDTP-DFBT) with bandgap 1.38 eV was formed. Even with this low bandgap, high V_{oc} of 0.69V, EQE over 60 and 8.0% PCE single junction device was achieved. In polymer PffBT4T, where DFBT was copolymerized with four thiophene rings, the side chains on two of the thiophene rings were found very critical for the intermolecular interaction between different polymer chains and polymer-fullerene interaction. Generally, larger side chains improve the solubility of polymer by reducing π - π interchain interaction. However, longer alkyl chains were found to be detrimental to the domain size and domain purity. This is a great example of side chain engineering in polymer design. Record 11.7% PCE was achieved in PffBT4T- C_{80} :PCBM system, assisted by the sophisticated morphology control.

Acceptor Materials in OPV

Donor polymer and the acceptor together determine the device performance. The donor polymers are dominantly designed to be compatible with the fullerene derivatives ($PC_{61}BM$ (Fig. 5(h)) or $PC_{71}BM$) for a long time.

Fullerene bisadducts based on $PC_{61}BM$ (Bis- $PC_{61}BM$, Fig. 5(i)) has ~ 0.1 eV higher LUMO than that of PCBM, and gives higher V_{oc} and PCE in P33HT system. Indene- C_{60} or Indene- C_{60} bisadduct ($IC_{60}BA$ (Fig. 5(j)) or $IC_{70}BA$), via a simple one-pot reaction of indene and fullerene molecules, can achieve higher V_{oc} by over 0.2V, and PCE up to 7.4% in P3HT:ICBA system, which is due to the higher LUMO (by about 0.2 eV).

In addition, n-type polymer-based electron acceptors have also been explored such as F8TBT, CN-PPV and perylene diimide (PDI)-DTT. PDI-based acceptor perylene bisimide (PBI) has lead to 8.4% PCE polymer solar cell. Small molecule nonfullerene acceptor is a new star in the OPV research in the past a few years. Indacenodithieno[3,2-b]thiophene-based nonfullerene acceptor (ITIC), and methyl-modified nonfullerene acceptor (IT-M, Fig. 5(k)) are great examples. Poly[(2,6-(4,8-bis(5-(2-ethylhexyl)thiophen-2-yl) benzo[1,2-b:4,5-b']dithiophene))-co-(1,3-di(5-thiophene-2-yl)-5,7-bis(2-ethylhexyl) benzo[1,2-c:4,5-c']dithiophene-4,8-dione)] (PBDB-T):IT-M polymer cell reached 11.6% efficiency, while adding Bis-PCBM leads to ternary OPV with 12.2% efficiency – a record, from much preferred nonfullerene acceptor.

Interface and Architectural Engineering

The active materials and the BHJ morphology determines how efficient the active layer harvest solar irradiation, exciton conversion into free carrier, and the free carrier transport to the organic/electrodes interface. The organic/electrode contacts of OPV device determines the charge carrier extraction efficiency into the external circuit. An Ohmic electrical contact is highly desired, as a barrier height of few tens of millielectron volt can result in significant charge accumulation and thus inferior photovoltaic performance. This is true for both the anode and cathode sides of contacts for efficient charge extraction with high selectivity.

In the simplest sandwich OPV structure described by the rigid band metal-semiconductor-metal model, the difference of work function between the anode and cathode provides the driving force for the charge transport and extraction process. Sufficient metal electrodes work function difference is required for the efficient and selective charge collection in the device. Pure metal electrodes, however, are not desired, as the metal surfaces have a high density of defects causing surface recombination or strong surface dipoles at metal/organic interfaces that may harm selective charge extraction.

HTLs

Transparent conductive indium-tin-oxide (ITO) with a high work function of ~ 4.7 eV is the most widely used transparent electrode in organic electronics. Naturally a solution processible, water-based p-type interface layer poly(3,4-ethylenedioxythiophene):poly(styrene sulfonate) (PEDOT:PSS) (work function ~ 5.0 eV) was applied to form the ohmic contact with both the ITO and the organic photoactive layer for effective charge collection. Other functions including smoothing the ITO surface and removing potential pinholes, which improves the yield of the device fabrication. The PEDOT:PSS's organic, water absorbing and acidic nature are not preferred for device long-term stability.

p-Type transition metal oxide – NiOx is a wide bandgap (direct bandgap, $E_g \sim 3.7$ eV), transparent semiconductor with weak absorption bands due to d-d transitions of $3d^8$ electron configuration. Both vacuum sputtered and solution processed forms of

NiOx have been demonstrated to be effective HTL materials. With O₂-plasma treatment, the WF of NiOx can be increased from 4.7 to 5.3 eV, indicating a doping effect, and very suitable for HTL application. P-type copper oxides CuOx, and binary copper oxide such as CuGaOx, CuCrOx are also recently emerging as effective HTL materials. The binary copper oxide has larger bandgap of over 3 eV – is more suitable for window layer, as compared with visible absorbing pure CuOx.

V₂O₅, MoO₃, WO₃ and recently CrOx, are also experimental proven to be effective HTL materials in OPV. Surprisingly, it is demonstrated with direct and inverse photoemission spectroscopy measurements that Cr₂O₃, MoO₃, WO₃, and V₂O₅ are n-type materials exhibiting very deep lying electronic states. Ultrahigh vacuum (UHV) prepared MoO₃ by evaporation possesses a 6.86 eV Fermi level, a 6.70 eV EA and 9.68 eV IP. Evaporated transition metal oxides – WO₃ and V₂O₅ with even higher WFs of a ~6.7 eV, and ~7.0 eV, respectively. The fact that they function as HTL may be associated with the multivalence state of metal cation. It worth mentioning that the very different work function from UHV and normal high vacuum evaporation is due to the existence of oxygen in the evaporation case.

Graphene oxide (GO), also water soluble, can also function as HTL in OPVs. In addition to find the interface materials with right work function, the solution processability is a much preferred research topic.

ETLs

Low work function metals are very sensitive to oxygen and moisture – good for device efficiency, but very poor stability and cost perspective. N-type transition metal oxides, such as ZnO and TiOx, are proven ETLs in both OLEDs and OPV devices. They have good stability, proper work function, smooth film morphology and solution processability. TiOx and ZnO were also shown to function as a hole blocking layer and optical spacer to modulate the optical field inside thin device to enhance absorption, and thus may help efficiency.

Many compounds with low work-function metal such as Cs₂CO₃, CsF, LiF, Ca(acac)₂, etc., which have been proven to be effective ETL in OLED research, are also useful in OPV. Another class of ETL are polyelectrolyte, either conjugated (such as poly [(9,9-bis(3'-(N,N-dimethylamino)propyl)-2,7-fluorene)-alt-2,7-(9,9-dicetylfluorene)] (PFN) or nonconjugated (e.g., ethoxylated polyethylenimine (PEIE)), can enhance the electron extraction significantly in the OPV devices.

Combining the different ETLs has shown surprising performance improvement. Anatase TiOx with Cs₂CO₃ leads to Cs-doping of TiOx, and this leads more reliable electron buffer material for OPV and OLED, and it removes the UV photo-catalytic degradation disadvantage of TiOx alone in the device. ZnO and PFN double layer ETL was also shown to be of enhanced efficiency in OPV device.

Inverted OPV Device

Some ETL materials can convert the given high work function ITO transparent electrode into low work function contact. This provides the versatility in device polarity. Fig. 6(a) shows the 2006 UCLA work on the formation of inverted OPV by using Cs₂CO₃ ETL to convert ITO into low work function contact, and use transition metal oxide (V₂O₅) as HTL.

Different forms of TiOx, ZnO (sol-gel, nanoparticle), PFN, etc. were also shown to be able to enable low WF contact on transparent electrode. Ultraviolet photoemission spectroscopy gives clear evidence of the large WF reduction after these ETL applied on ITO, for example. ETLs like LiF does not have such effect. On the other side, MoOx is the most popular HTL used in inverted polymer solar cell.

Fig. 6(b) shows the device structure, the molecular structure of PFN ETL, and active layer polymer PTB7 in the over 9% PCE inverted polymer solar cell. Fig. 6(c) is the energy diagram of the inverted OPV device.

Tandem OPV Devices

Single junction solar cell has its theoretical limit. Shockley and Queisser proposed detailed balance model to predict the efficiency limit for p-n junction solar cells. The biggest two major losses under the S-Q assumptions (Fig. 7(a)) are (1) below bandgap loss – photons with energy higher than bandgap of absorbers can be completely absorbed, while photons below the bandgap just pass through without any absorption; (2) the thermalization loss – photons of higher energy than the bandgap energy will thermally relax, and the excess energy loses. While lower bandgap materials absorb more sunlight, and potentially higher photocurrent, the larger bandgap materials will win in the photovoltage side. Therefore a delicate balance exists in the theoretically optimization of bandgap, and ~1.4 eV is the optimal bandgap of solar cell material under terrestrial illumination, with theoretical limit of ~31%. The most effective way in overcoming S-Q limit is the multijunction or tandem structure, which consists of several semiconductors with different and complement bandgaps to have better coverage of the solar spectrum. The carefully designed system will use the solar photons much more effectively by reducing the thermal loss. For example, theoretically three-junction solar cell design raises the ceiling to ~50%.

For disordered solar cell system with lower efficiency like OPV, the tandem structure is a clear go for higher efficiency. The preferred way is the solution process tandem solar cell, as it has the potential of higher efficiency without losing the low-cost edge. The structure of tandem solar cell is more complex. Besides the two photoactive subcells, the interconnection layer connecting the two subcells is very important. In inorganic multijunction solar cells, the interconnection layer is heavily doped p-n

Fig. 6 (a) The formation of inverted organic conjugated polymers-based solar cells (OPVs) by switching position of electron transport layer (ETL) and hole transport layer (HTL); (b) device structure of inverted OPV using poly[(9,9-bis(3'-(*N,N*-dimethylamino)propyl)-2,7-fluorene)-alt-2,7-(9,9-dicyclopentafluorene)] (PFN) as ETL and PTB7 as active polymer; (c) energy diagram of the inverted OPV device. ($p^+ + n^+ +$) tunneling junction, which has the opposite direction than that of the two subcells to produce photovoltage of the same direction.

In organic polymer solar cell, the extensive interface engineering research provide many high quality p-type and n-type interface layers to choose. In polymer tandem solar cells, the interfacial layers should also provide physical protection to the underlying subcells. Here we only provide a brief introduction on the topic.

In the beginning, the simple way of making tandem device was using semitransparent solar cell, which differ from the normal solar cell by a thin layer of thermally evaporated metal as semitransparent electrode. Tandem solar cell by stacking two or more semitransparent solar cells (allow one to be normal nontransparent cell) has four terminals, and can be connected either in series or in parallel. The configuration has clear disadvantage in optical loss, materials (substrate/TCO) cost, and was used mainly for proof of concept. Early efforts typically use subcells with same active materials, for example, P3HT:PC₆₁BM, PCDTBT:PC₆₁BM, and the efficiency was not really improved. Monolithic integrated tandem solar cell on one substrate is the more preferred way.

Heterogeneous polymer tandem solar cells with complemented spectrum coverage is the main stream research direction. In principle the complemented spectrum coverage is required for the current matching of two subcells, the high and low bandgap combination also leave the opportunity of reducing thermalization loss.

The two most important components in heterogeneous tandem polymer cells are (1) the spectrum complemented active layers in two subcells, and (2) the interconnection layer. In the spectrum complemented active layer, the classical, process well controlled P3HT is a model high bandgap polymer subcell. The 1.9 eV bandgap is similar to the high bandgap component in inorganic multijunction solar cell. It's thus a long time trend in tandem OPV field to pursue high performance polymer at ~1.4 eV bandgap, which is lower than the optimal bandgap in OPV research. In interconnection layer, there are also two major device architectures just like in single junction OPV device, i.e., conventional tandem and inverted tandem OPV device (Fig. 7(b)). A few milestones in the tandem OPV devices are the following.

Fig. 7 (a) Loss mechanism and efficiency limitation of single junction solar cell as a function of semiconductor bandgap (reproduced from Hirst L.C., Ekins-Daukes N.J., 2011. Fundamental losses in solar cells. *Progress in Photovoltaics: Research and Applications* 19, 286–293); (b) diagram of conventional tandem and inverted tandem organic conjugated polymers-based solar cell (OPV) devices; (c) device structure of, and (d) wide and low bandgap polymers in the 10.6% certified tandem OPV device ((c) and (d) reproduced from You, J., Dou, L., Yoshimura, K., 2013. *Nature Communications* 4, 1446); (e) molecule structures and device structure of a homogeneous tandem OPV device (reproduced from You, J., Chen, C.-C., Hong, Z., *et al.*, 2013. 10.2% Power conversion efficiency polymer tandem solar cells consisting of two identical sub-cells. *Advanced Materials* 25, 3973–3978); and (f) picture of an all solution process visibly transparent OPV device. ITO, indium-tin-oxide.

Conventional tandem polymer solar cell – UCSB group reported solution processed TiO₂(n-type)/PEDOT:PSS (p-type) as interconnecting layer, and subcells are based on (1) low bandgap PCPDTBT:PC₆₁BM front cell, and (2) wide bandgap P3HT and PC₇₁BM rear cell. With the front and rear cell of 3.0% and 4.7% efficiency, respectively, a 6.5% tandem device was achieved. Improving both cells to P3HT:ICBA and PSBTBT:PCBM, and traducing MoO₃ into interconnection layer, UCLA improved the tandem efficiency to 7%. Another popular interconnection layer is based on ZnO(n)/pH-neutral PEDOT:PSS (p) from a Netherland group.

Inverted tandem polymer solar cells – UCLA used low bandgap polymer PBDTT-DPP (~ 1.44 eV bandgap):PC₇₁BM as rear cell and P3HT:ICBA as front cell, modified PEDOT:PSS/ZnO as interconnection layer, 8.62% NREL certified tandem efficiency was achieved. Further reducing the bandgap of LBG polymer by replacing S to heavier atom Se, polymer PBDTT-SeDPP has bandgap of 1.38eV. The better spectrum complementation and higher hole mobility lead to 9.5% tandem PCE. PDTP-DFBT:PC₇₁BM as LBG subcell gives even better performance, and the first double digit certified tandem polymer solar cell PCE of 10.6% (Fig. 7(c) and (d)).

Homogeneous tandem solar cell, in which the subcells adopt the same active materials, is not supposed to reduce thermalization loss in principle. But homogeneous tandem polymer solar cells were shown to be able to enhanced the solar cell efficiency

over single junction cell. For example, tandem cell with two identical PDTP-DFBT:PC₇₁BM subcells showed a PCE enhancement of over 25% – from 8 to 10.2% (Fig. 7(e)). It is worth mentioning that when the HOMO level of polymer is deeper, such as PDTP-DFBT, PEDOT:PSS will not be able to provide good enough energy alignment and hole transport function. Higher work function material MoO₃ was used to form a three layer MoO₃/PEDOT:PSS/ZnO interconnection layer for this efficient homogeneous tandem cell. Tandem cell with two identical PTB7-Th:PC₇₁BM subcells showed a PCE enhancement from ~9% to over 11%. The enhancement originates from the weakness of typical polymer solar cell materials (even champion materials like PDTP-DFBT and PTB7-Th) – the limited thickness for optimal device due to the low carrier mobility. Therefore using two thinner subcells to form tandem cell can overcome the limitation and achieve higher performance.

Triple junction tandem polymer solar cell was also successfully demonstrated. Based on the 10.6% heterogeneous tandem cell, a midbandgap PTB7-Th:PCBM cell was added into the device, and the efficiency was enhanced to 11.6%. The higher work function component in interconnection layer was further improved from thermally evaporated MoO₃ into solution processed WO₃. The success of the all solution processed triple junction polymer solar cell represents an important technology progress.

The donor-acceptor type low bandgap polymers, when goes below 1.4 eV bandgap, many have the absorption spectrum that absorb in UV and near infrared (NIR), but very low absorption in visible range. This makes possible high performance visibly transparent solar cells. Fig. 7(f) shows such a cell, where the top transparent electrode is from silver nanowire ink, and the whole process is free from vacuum. Other transparent electrode techniques include thin metal layer(s), dielectric/metal/dielectric multilayer, carbon nanotube, conducting polymer, polymer-CNT, polymer-metal nanowire composites etc. Transparent tandem solar cell can be used to tune the color, and achieve higher efficiency. Currently 7% transparent tandem solar cell has been realized with relatively high visible transparency. This shows how versatile the technology is, and broad applications the technology can offer.

Polymer solar cell research is very active with continuous discoveries and breakthroughs coming out. Future new polymer donor and acceptor materials, deep understanding and control of morphology, device structure innovations will continue improve OPV performance, establish it as a nontoxic, low cost, flexible and transparent form factor clean energy solution for novel PV applications.

Dye-Sensitized Solar Cells

Lu-Yin Lin, National Taipei University of Technology (Taipei Tech), Taipei, Taiwan

History

The concept of dye-sensitized solar cells (DSSCs) based on a TiO_2 thin film originated from the year of 1972 (Fujishima and Honda, 1972). By constructing a chlorophyll-sensitized zinc oxide electrode, the photons were converted into electricity via the charge injection from the excited dye molecules into a wide band gap semiconductor for the first time (Tributsch, 1972). Numerous researchers started to study zinc oxide-based DSSCs since then. However, the relevant solar-to-electricity conversion efficiency is poor, probably due to flat surface of the semiconductor to provide only monolayer adsorption of the sensitizer. A breakthrough development was realized in the year of 1991 by Grätzel and his coworkers at the Laboratory of Photonic and Interfaces in the École Polytechnique Fédérale de Lausanne in Switzerland. They introduced nanoporous TiO_2 electrodes with rough surface to increase the light harvesting efficiency and successfully achieved a solar-to-electricity conversion efficiency (η) of 7% (O'Regan and Gratzel, 1991). Afterwards DSSCs experience a rapid growth since 2009, as shown in the annual publication number summarized in Fig. 1. In the year of 2011, a recorded η value of 12.3% was obtained for the DSSC composed of a zinc porphyrin dye (YD2-o-C8) co-sensitized with another organic dye (Y123) (Fig. 2), and $\text{Co}^{(\text{II/III})}$ tris(bipyridyl)-based redox electrolyte (Yella *et al.*, 2011). In the year of 2014, a DSSC coupled with a zinc porphyrin dye and $\text{Co}^{(\text{II/III})}$ tris(bipyridine)-based redox electrolyte achieved an impressive η value of 13.00% (Mathew *et al.*, 2014). Right after this achievement, a recorded η value of 14.30% was attained for a DSSC composed of the metal-free organic co-sensitizers and the redox electrolyte based on $\text{Co}^{(\text{II/III})}$ tris(phenanthroline) in the year of 2015 (Kakiage *et al.*, 2015). These breakthroughs inspire the researchers to pursue economical photovoltaic devices based on DSSCs more eagerly for the years to come.

Mechanism and Parameters

When the light illuminated the DSSC, the incident photons are absorbed by sensitizers adsorbed on the semiconductor surface. The sensitizers are excited from the ground state (S) to the excited state (S^*). Then the excited electrons would inject into the conduction band of the semiconductor, generating the oxidation of the sensitizer (S^+). These processes can be represented as Eqs. (1) and (2).

The injected electrons in the conduction band of the semiconductor would transport toward the conducting substrate, and then the electrons would reach the counter electrode (CE). Then the oxidized photosensitizer (S^+) would accept the electrons transported from the I^- ion redox mediator, and then be regenerated to the ground state (S), as shown in Eq. (3).

Simultaneously the I^- would be oxidized to I_3^- and diffuse toward the CE. Finally, it is reduced to I^- at the CE, as shown in Eq. (4).

The energy level diagram of a DSSC and the electron transfer routes are shown in Fig. 3.

Like other solar cells, the performance of the DSSC can be evaluated by using the open-circuit voltage (V_{OC}), the short-circuit current density (J_{SC}), the fill factor (FF), the solar-to-electricity conversion efficiency (η), the incident photon-to-current conversion efficiency (IPCE), and the charge transfer resistances measured by using the electrochemical impedance spectroscopy (EIS).

V_{OC} is determined by the difference in energy of the electron at the semiconductor and the CE for a typical photoelectrochemical cell, or the difference in energy level of the quasi-Fermi level of the semiconductor under illumination and the Nernst potential of the electrolyte solution. V_{OC} is measured with no current flow and is the maximum voltage which the DSSC can provide to an external circuit. Eq. (5) shows the relation of photovoltaic parameters to V_{OC} for regenerative photoelectrochemical systems.

$$V_{\text{OC}} = V_{\text{T}} \ln \left(1 + \frac{J_{\text{SC}}}{J_0} \right) \quad (5)$$

where V_{T} is the thermal voltage and J_0 is the reverse saturation current density.

J_{SC} is the maximum output current of a DSSC and is measured under illumination at the zero voltage across the cell. The magnitude of J_{SC} is determined by the product of the optical absorption efficiency, charge collection, and the solar irradiance,

Fig. 1 Number of publications on the subject of dye-sensitized solar cells (DSSCs) from 1991 to December 2016. *Source:* Scopus.

Fig. 2 The chemical structures of YD2-o-C8 and Y123 dyes.

integrated over the whole wavelengths of the incident light spectrum, as shown in Eq. (6).

$$J_{SC} = \int (1 - 10^{-Abs(\lambda)}) \times IQE(\lambda) \times e \times \Phi(\lambda) d\lambda \quad (6)$$

Fig. 3 The energy level diagram of a dye-sensitized solar cell (DSSC) and the illustration of the electron transfer routes in the DSSC.

where $\text{Abs}(\lambda)$ is the absorbance of the sensitizer as a function of the wavelength λ , e is the elementary electron charge, and $\Phi(\lambda)$ is the standard AM 1.5 irradiance spectrum. $\text{IQE}(\lambda)$ is the internal quantum efficiency for the hot electron injection, dye regeneration, and then charge collection.

FF is defined as the ratio of the maximum power output ($P_{\max}$) from a DSSC to the product of V_{OC} and J_{SC} . The fill factor can be calculated by using Eq. (7).

$$\text{FF} = \frac{P_{\max}}{V_{\text{OC}} \times J_{\text{SC}}} = \frac{V_{\max} \times J_{\max}}{V_{\text{OC}} \times J_{\text{SC}}} \quad (7)$$

where $V_{\max}$ and $J_{\max}$ respectively represent the photovoltage and photocurrent density corresponding to $P_{\max}$.

η depends on the total light intensity, the intensity spectral distribution, and the DSSC temperature. The η of a DSSC is calculated as the ratio between the maximum generated power ($P_{\max}$) and the incident power (P_{in}). The incident power is equal to the irradiance of the AM1.5 spectrum normalized to 1000 W/m^2 . Hence, the η of a DSSC can be determined by the V_{OC} , J_{SC} , FF, and P_{in} as shown in Eq. (8) as follows.

$$\eta = \frac{P_{\max}}{P_{\text{in}}} \times 100\% = \frac{V_{\text{OC}} \times J_{\text{SC}} \times \text{FF}}{P_{\text{in}}} \times 100\% \quad (8)$$

A typical current density–voltage curve is shown in Fig. 4 with the V_{OC} , J_{SC} and $P_{\max}$ indicated in the figure.

IPCE is defined as the ratio of the number of photo-generated electrons ($N_{\text{electrons}}$) flowing in the external circuit to the number of incident photons (N_{photons}) with a given wavelength, as shown in Eq. (9).

$$\text{IPCE}(\lambda) = \frac{N_{\text{electrons}}}{N_{\text{photons}}} \quad (9)$$

IPCE is also referred to as the external quantum efficiency (EQE). IPCE or EQE value is most often expressed as the percentage of the absorbed incident photons and the converted electrons as a function of the wavelength. The internal quantum efficiency (IQE) is also reported which represents the number of absorbed photons converted to electrons and indicates that how efficient the numbers of absorbed photons are converted into current. The IPCE value can also be calculated using Eqs. (10) and (11) as follows.

$$\text{IPCE}(\lambda) = \text{LHE}(\lambda) \times \text{IQE}(\lambda) \quad (10)$$

$$\text{LHE}(\lambda) = 1 - 10^{-\text{Abs}(\lambda)} \quad (11)$$

where $\text{LHE}(\lambda)$ is the light-harvesting efficiency.

Thus, the J_{SC} can also be represented as Eq. (12) as follows.

$$J_{\text{SC}} = \int \text{IPCE}(\lambda) \times e \times \Phi(\lambda) d\lambda \quad (12)$$

where e is the elementary charge and $\Phi(\lambda)$ is the photon flux.

It is important and useful to examine the $\text{IPCE}(\lambda)$ value not only in getting further information of $\text{IQE}(\lambda)$ or other parameters, but also in examining the validity of the measured photocurrent. If the measured J_{SC} value showed a discrepancy from the integral IPCE results in Eq. (12), there would be a spectral mismatch or variance between the solar simulator and the true solar emission.

Fig. 4 A typical current density–voltage (J – V) curve with the V_{OC} , J_{SC} , and P_{max} indicated.

The steady state J – V measurements can only provide limited information about the electron transport and recombination rates. Hence, a dynamic technique like the EIS is required to study the charge transfer kinetics and therefore to get the information about the resistance and capacitance of different components in DSSCs. The primary investigated resistance at the interfaces of DSSCs from the charge transfer processes are the series resistance (R_s), the recombination resistance at the semiconductor/dye/electrolyte interface (R_{ct1}), the electron transfer resistance in the CE (R_{ct2}), and the diffusion resistance of the electrolyte causes (Z_w), which can be fitted from the Nyquist plot measured using the EIS technique. **Fig. 5** shows a typical Nyquist plot for a DSSC, in which the corresponding portions for fitting to get various resistances are also labeled in this figure.

Constructions

A DSSC is composed of a photoanode, a CE, and in-between embedded an electrolyte.

Photoanode

The photoanode is one of the important components of DSSC because of its functions in adsorbing dye molecules and transferring electrons. A high electron transport rate is required to reduce electron–hole recombination rate and enhance the conversion efficiency. The photoanode is consisted of a conducting substrate, a semiconductor layer deposited on the top of the substrate, and a sensitizer adsorbed on the semiconductor layer.

Conducting substrates

The selection of suitable conducting substrates is the key factor to determine the cost and the fabrication process of DSSCs, and therefore to influence the cell performance and long-term stability. Traditionally, transparent conducting oxide (TCO) glasses were utilized as the substrate of DSSCs, for example, fluorine-doped tin oxide ($\text{SnO}_2\text{:F}$) (FTO), tin-doped indium oxide ($\text{In}_2\text{O}_3\text{:Sn}$) (ITO), and aluminum-doped zinc oxide (ZnO:Al) (AZO) glasses. Despite of their good stability against oxygen and water, the shortages of high cost, fragility, rigidity, and shape limitations restrict their practical applications. In addition, the roll-to-roll production process cannot be used for this system. Therefore, flexible substrates with light weight and easy transportation properties have become an alternative choice.

One kind of the flexible substrates is conducting plastics, for example, ITO coated polyethyleneterephthalate (ITO/PET) and ITO coated polyethylenenaphthalate (ITO/PEN). The critical challenge for conducting plastics lies in the low temperature preparation of TiO_2 layer since their maximum endurable temperature is around 150°C . Normally the TiO_2 layer is sintered at higher temperature of around 400 – 500°C to get good electrical contact among particles. Additionally, the typical TiO_2 paste contains organic binder and viscous solvents which should be removed in a high temperature sintering process. Mechanical compression of nanocrystalline semiconductor powder and hydrothermal synthesis of metal oxide nanocrystals have been proposed to avoid applying the high temperature sintering process. Other kind of the flexible substrates is metal foils, which possess inherent high conductivity, light scattering, and high-temperature sintering abilities, for example, stainless steel (StSt), titanium foils, and zinc foils. Among them, the best is the Ti foil-based DSSC because of its characteristics of higher conductivity and superior corrosion resistance resulted from the existence of a passive film of TiO_2 on the surface of a Ti foil. However, there remain two major challenges to overcome for metal-based DSSCs. First, metal substrates are non-transparent and the pertinent DSSCs have to be illuminated from the back side, i.e., the Pt CE side. A loss of about 25% incident solar energy is encountered because the Pt CE partially reflects light and iodine in the electrolyte absorbs photons in the near UV region. Secondly, there would be serious formation of metal oxides after sintering, leading to the increase in the interfacial resistance and therefore the cell performance is reduced.

Fig. 5 A typical Nyquist plot for a dye-sensitized solar cell (DSSC).

Semiconductor layers

The semiconductor layer is a junction with a large contact area between two continuous networks for dye adsorption and allows electron transferring through the DSSC.

Mesoporous oxides are the most commonly used materials as the semiconductor layer, including TiO₂, ZnO, SnO₂, and Nb₂O₅. **Table 1** lists the photovoltaic performance for the DSSCs using different semiconductors on the photoanode. The nanocrystalline TiO₂ is the most applied material because of its cheap, abundant, and nontoxic characteristics. The band gap of anatase TiO₂ is 3.2 eV at an absorption edge of 388 nm and that of rutile TiO₂ is 3.0 eV at an absorption edge of 413 nm. The crystalline of TiO₂ is classified into anatase, brookite, and rutile. The illustration for the crystal structures of TiO₂ is shown in **Fig. 6** (Zhang *et al.*, 2014). Anatase and rutile phases are the main TiO₂ crystallines but the brookite TiO₂ is rarely existed, which remains stable only at the temperature higher than 600°C. Moreover, rutile TiO₂ absorbs 4% of incident light in the near-UV region, resulting in generation of holes which would reduce the long-term stability of DSSCs (Yuvapragasam *et al.*, 2015). Therefore, anatase TiO₂ is most suitable as the semiconductor layer on the photoanode of DSSCs. The high dielectric constant of TiO₂ ($\epsilon = 80$

Copyright (2011) by Elsevier.

for anatase) provides good electrostatic shielding of the injected electron from the oxidized dye molecule, thus preventing the electrons from recombination before the reduction of the dye molecule by the electrolyte. High refractive index of TiO_2 ($n=2.5$ for anatase) results in efficient diffuse scattering of light inside the porous photoanode and hence significantly enhances the light absorption.

Most photoanodes of DSSCs were based on a nanocrystalline TiO_2 film with a particle size of about 20 nm. However, the performance of the pertinent DSSCs was limited by its slow electron transport, which is in the range of a few milliseconds. The random distribution of the TiO_2 particles and the associated structural disorder of the film lead to an enhancement on the dye-injected free electrons scattering, and thereby to a reduction of electron mobility. Therefore, altering the morphology and structure of the TiO_2 film is one of the strategies for improving the efficiency of a DSSC. Several nanotubular architectures have been investigated for potential enhancement of electron percolation pathways as well as for improved ion diffusion at the semiconductor/electrolyte interface. Ordered and strongly interconnected nanoscale architecture of a TiO_2 film enables a great improvement in the electron transport in the film, for example, a vertically oriented array of one-dimensional (1D) TNTs (**Fig. 7**), which have been proved to exhibit better electron transport and therefore to reduce the loss of electrons by recombination (Lin *et al.*, 2011).

Sensitizers

The sensitizer carries out the light harvesting function and influences the electron transfer processes occurring at the semiconductor/dye/electrolyte interfaces. An efficient sensitizer has a broad and strong absorption, excellent chemical stability,

reduction potential sufficiently higher than the conduction band edge of the semiconductor, and an oxidation potential sufficiently lower than the redox potential of the electrolyte. The primary classifications of sensitizers are metal-based sensitizers and metal-free organic sensitizers.

The metal-based sensitizers comprising the chromophores of ruthenium complexes have been widely studied for DSSCs, which can achieve solar-to-electricity conversion efficiencies of around 11% under AM1.5 conditions, due to the favorable photoelectrochemical properties as well as the excellent chemical stability and intense light absorption over a wide visible range. Several efficient Ru-based complex photosensitizers were developed by Grätzel *et al.* The first famous Ru-based complex photosensitizer is *cis*-bis(isothiocyanato)bis-(4,40-dicarboxylic acid-2,20-bipyridine) Ru (II), denoted as N3 or red dye (Nazeeruddin *et al.*, 1993). Afterwards, the other two efficient dyes were synthesized by the same group. One is the black dye or denoted as N749 dye with the formula of tris(isothiocyanato)-2,20,2''-terpyridyl-4,40,4''-tricarboxylate Ru(II) complex, and the other is denoted as N719 dye, with the formula of di(tetrabutylammonium)*cis*-bis(isothiocyanato)bis-(4-carboxylic acid-40-carboxylate-2,20-bipyridine)Ru(II). The structures for these efficient sensitizers are shown in Fig. 8. Table 2 gives a partial list of the photovoltaic parameters for the DSSCs using Ru-based complex photodyes as the sensitizer. The disadvantage of the ruthenium complex dyes is that they contain a

heavy metal which is expensive and harmful to the environment. Therefore, the metal-free organic dyes have been proposed as an alternative for DSSCs.

There are some advantages for the metal-free organic dyes to be used in DSSCs. First, the metal-free organic dyes are relatively inexpensive, since they can be easily synthesized and their resources are more abundant than that of the noble metals. Secondly, the extinction coefficients and the absorption coefficients of organic dyes are relatively higher than those of the noble metal-based ones. Organic dyes based on porphyrin, perylene, cyanine, xanthenes, merocyanine, coumarin, hemicyanine, indoline, diketopyrrolopyrrole, and ethylenedioxythiophene have been widely investigated for DSSCs due to their phototherapeutic and photochemical applications. **Table 3** is a partial list of the photovoltaic parameters for the metal-free organic dye-based DSSCs repeated in literatures.

Electrolytes

Electrolyte is one of the crucial parts overtaking the dye regeneration after electron injection and the electron transfer between the photoanode and the CE. The electrolyte can be classified into liquid electrolyte, quasi-solid-state electrolyte, and solid-state electrolyte.

The liquid electrolyte is composed of redox couples, additives, and solvents. The redox couple is in charge of transferring charges between the photoanode and the CE, as well as the dye regeneration. The redox couple possesses a redox potential less negative than the oxidized level of the sensitizer. Also, fast electron transfer kinetics at the CE, slow electron recombination kinetics at the sensitizer, small absorption in the visible region, as well as the noncorrosive, reasonable stability, and good diffusion properties are indispensable factors for the redox couples. The redox couple of lithium iodide/iodine was first used in DSSC by Hagfeldt and coauthors in an organic liquid electrolyte (Hagfeldt and Graetzel, 1995). However, the I_3^- is extremely corrosive toward metals such as copper or silver, and a significant part of visible light would be absorbed by the I^-/I_3^- based electrolyte. Hence, many other redox couples were proposed to replace this redox couple nowadays, for example, cobalt complexes and inorganic redox couples such as Br^-/Br_3^- , $SCN^-/(SCN)_2$, $SeCN^-/(SeCN)_2$, and S^{2-}/S , or other organic compounds. A recorded η of 12.3% was attained for the DSSC with $Co^{(II/III)}$ tris(bipyridyl)-based redox couple (**Fig. 9**) in its electrolyte. **Table 4** is a partial list of the photovoltaic parameters for the DSSCs using different redox couples in the liquid electrolytes. On the other hand, the additives were used in the electrolyte to enhance the photovoltaic performances. Specific cations like guanidium or alkali cations are typically used to increase the photocurrent density. The cations in the electrolyte would adsorb on the surface of the semiconductor layer to render the conduction band of the semiconductor shift toward more positive potentials, thus affecting the electron injection dynamics of the dye molecules in the excited state. Also, nitrogen-containing heterocyclic compounds like 4-tert-butylpyridine (4-TBP) and pyridine analogs of the N-alkylbenzimidazole derivatives are purposely used to improve the V_{oc} . Lastly, the organic solvents and ionic liquids are primarily selected as the solvents for the liquid electrolyte. The organic solvents like acetonitrile (ACN), ethylene carbonate (EC), 3-methoxypropionitrile (MPN), propylene carbonate (PC), N-methylpyrrolidone (NMP) and water have been widely investigated for liquid electrolyte-based DSSCs. The ACN is the first choice organic solvent in considering of the solar-to-electricity conversion efficiency of DSSC, due to its low viscosity (0.34 cp at 25°C) and good solubility to dissolve salts and organic components. However, the encapsulation of volatile organic solvents is a critical issue owing to their high vapor pressures. Therefore, the quasi-solid-state electrolyte and solid-state electrolyte were used to enhance the encapsulation of the DSSCs.

The quasi-solid-state electrolyte is consisted of a polymer network swollen with liquid electrolytes or ionic liquid electrolytes. The quasi-solid-state electrolyte possesses both cohesive property of solid and diffusive transport property of liquid, and therefore

the quasi-solid-state electrolytes offer better long-term stability than that of the liquid electrolytes. The quasi-solid-state electrolytes can be made by different methods and being classified into various sorts, for example, composite polymer electrolytes, quasi-solid ionic liquid electrolytes, and thermosetting polymer electrolytes. Table 5 lists the used sensitizers and the photovoltaic parameters for the DSSCs based on the three types of quasi-solid-state electrolytes mentioned above.

The solid-state DSSC applied the hole transport materials (HTMs) or the solid-state electrolyte containing I^-/I_3^- redox couple as the medium to solve the solvent leakage and corrosion issues. Major research interests focus on the organic hole conductor, 2,2',7,7'-tetrakis(*N,N*-di-*p*-methoxyphenyl-amine)-9,9'-spiro-bifluorene (spiro-MeOTAD), which was originated in 1998 by Bach *et al.* (1998). To enhance the cell performance of the solid-state DSSC, Kojima *et al.* used two organolead halide perovskite

nanocrystals, CH₃NH₃PbBr₃ and CH₃NH₃PbI₃ to sensitize TiO₂ for the visible-light conversion, and a η value of 3.8% was achieved for the photoelectrochemical cell (Kojima *et al.*, 2009). Afterwards, another type of the solid-state TiO₂ solar cell, the lead iodide perovskite (CH₃NH₃PbX₃) solar cell, was proposed to have promising photovoltaic performance. A recorded η value of 23% was attained for the perovskite solar cell in the year of 2016 by Chen *et al.* (2016).

Counter electrodes

The CE plays a role of transferring electrons from the external circuit to the electrolyte to reduce the oxidized redox couple used as a mediator in regenerating the sensitizer after electron injection, so as to generate the photocurrent. High electrocatalytic activity, excellent electrical and thermal conductivities, high corrosion resistance and large electrochemical surface area, as well as high exchange current densities and low charge transfer resistances are important requirements for a CE of DSSCs.

Platinum is the most commonly used catalyst in the CE, due to the high conductivity, high stability, and high catalytic activity toward I₃[−] reduction. Pt can be deposited on the transparent conductive oxide (TCO) glasses by various methods, for example, spin-coating, screen-printing or sputtering. Modifying the structural characteristics and facets of Pt were verified to be useful in enhancing its catalytic activity. The high surface area and therefore the high amount of active sites available for reducing I₃ can be obtained by varying the morphology of Pt, like the Pt nanoflowers as shown in Fig. 10. The catalytic and photovoltaic behavior of the CE toward the I₃[−] reduction also varied with different facets of Pt (Zhang *et al.*, 2013). However, since Pt is one of the expensive and rare metals in the earth, it is not suitable for the commercial production of DSSCs. Developing alternative materials to Pt as the catalyst on the CE of DSSCs is expected to decrease the cost of DSSCs.

Other cheaper materials were proposed to reduce the production cost of the cells. Conducting polymers like poly(3,4-ethylenedioxythiophene) (PEDOT), PEDOT doped with poly(4-styrene sulfonate) (PEDOT:PSS), polypyrrole (PPy), polyaniline (PANI), and poly(3,4-propylenedioxythiophene) (PProDOT) have been used as the catalyst on the CE of

DSSCs, due to their unique properties such as high conductivity, low cost, good stability, and high catalytic activity for I_3^- reduction. Among the conducting polymers, PANI has been one of the most intensively studied conducting polymers due to its easy synthesis, high conductivity, good environmental stability, and interesting redox properties in recent years. The performance of the conducting polymer can be enhanced by designing the morphology to achieve optimized surface roughness or doping foreign anions such as SO_4^{2-} , ClO_4^- , BF_4^- , Cl^- , and $tosyl^-$ into the conducting polymer film to increase the conductivity. However, the major problem of the conducting polymer is that the thick layer is required to achieve sufficient catalytic activities.

On the other hand, carbon materials like glassy carbon, graphene, and carbon nanotubes (CNT), are interesting low-cost alternatives to Pt. Carbonaceous materials have the advantages of high heat resistance, high electronic conductivity, high electrocatalytic activity toward I_3^- reduction, and high corrosion resistance. The power conversion efficiency and the fill factor of DSSCs are strongly dependent on the thickness of the carbon layer, which can be increased up to 10 μm to improve the fill factor of DSSCs. However, the main drawback of carbon-based CE is the requirement of large dosage to attain the targeted catalytic activity and the poor connection between the carbon film and the substrate. The photovoltaic parameters for the DSSCs using different catalysts on the CE are shown in Table 6.

Future Prospects

DSSCs have emerged as one of the cheap alternatives to the traditional silicon solar cells for harnessing the immense solar energy. Great progresses have been made for DSSCs since it was originated in 1972. The major aims are to enhance its solar-to-electricity

conversion efficiency and long-term durability. Developing efficient and novel sensitizers for converting light with broader wavelength especially in the near IR region into multiple electrons, constructing well-defined structures of semiconductors for providing more dye-adsorbed sites and the enhancing charge transfer among the photoanode, and designing suitable catalysts on the CE for accelerating the redox reactions in the electrolyte are necessary to achieve a highly efficient DSSC. Also, gel-type or solid-state electrolytes are needed to exploit for enhancing the long-term operating stability. Eventually, the detailed studies on the charge transfer resistance at the interfaces and the electron lifetime in the electrodes should be understood for selecting more effective routes to improve the performance of DSSCs.

Organic Inorganic Hybrid Perovskite Materials and Devices

Yihua Chen, Ning Zhou, and Huanping Zhou, Peking University, Beijing, P.R. China

© 2018 Elsevier Ltd. All rights reserved.

Introduction

Organic–inorganic hybrid halide perovskites have received increasing attention in the photovoltaic research community due to its remarkable optoelectronic properties, such as high carrier mobility, tunable band gap, long diffusion lengths and long lifetime. The efficiency record of perovskite solar cells has experienced a dramatic progress from 3.8% in 2009 to more than 20%, which makes perovskite one of the most competitive and promising candidate materials for solar cells. Besides, the perovskite materials have also proven to be feasible in a large variety of other optoelectronic applications, for example, light emitting diode, laser, detector, and transistors as well. In this section, the perovskite materials and the corresponding devices are reviewed regarding the progress in the crystal structure, optoelectronic property, and device working mechanism.

Crystal Structure

Organic–inorganic hybrid halide perovskite is a category of materials with the chemical formula of ABX_3 , where A and B sites are often occupied with two different cations with different ionic radii. A site occupant is generally methylammonium ($CH_3NH_3^+$), formamidinium ($NH_2CH=NH_2^+$) or cation cesium (Cs^+), rubidium (Rb^+), and X is halide anion, such as I^- , Br^- and Cl^- (Green *et al.*, 2014). The crystal structure of perovskites is depicted in Fig. 1(a). Their crystallographic structure and pertaining stability can be guided by a tolerance factor t proposed by Goldschmidt and an octahedral factor μ . In theory, $t = (R_A + R_X) / \{\sqrt{2} (R_B + R_X)\}$ (Yin *et al.*, 2015) where R_A , R_B and R_X are the ionic radii of the corresponding ions, and μ is defined as the ratio R_B/R_X . To achieve stable halide perovskite, it typically requires $0.81 < t < 1.11$ and $0.44 < \mu < 0.90$. If t is lower, it is intended to form the less symmetric structures such as tetragonal (β phase) or orthorhombic (γ phase) perovskite (Lu *et al.*, 2016). In contrast, larger t ($t > 1$) could result in destabilized three dimensional (3D) B–X framework, leading to a two-dimensional (2D) layered structure (Yin *et al.*, 2015). μ is directly correlated to the BX_6 octahedral structure. When $\mu > 0.442$, we often observe BX_6 octahedron in a stable assembly. However, lower μ value will destabilize BX_6 octahedral assembly (Li *et al.*, 2008). A summary of both calculated tolerance factors and octahedral factors for commonly seen halide perovskites are provided in Fig. 1(b) (Chen *et al.*, 2015). Along with different ions and structural stabilities, different perovskites possess different transition temperatures. As the archetypal halide perovskite of $CH_3NH_3PbI_3$, the α to β , and β to γ phase transitions occur at around 330 and 160K, respectively (Ball *et al.*, 2013). Some relevant crystallographic data of different perovskite materials with phases in high, intermediate or low temperatures (e.g., α , β , and γ phases, respectively), are summarized in Table 1 (Chen *et al.*, 2015).

It is generally believed that the cation at A site has shown no apparent effects on the electronic configurations and thus the band structure of the resultant materials, but plays the role of making charge compensation within the lattice. The A cation has been observed to influence the optical properties of perovskite by deforming the MX_6^{4-} octahedron framework when intercalating into the crystal structures. A larger (smaller) A cation can cause the entire lattice to expand (contract), and lead to the change of B–X bond lengths, which has been demonstrated to be important in determining the bandgap (Borriello *et al.*, 2008; Kulkarni *et al.*, 2014). For example, the use of formamidinium ($HC(NH_2)_2^+$) instead of $CH_3NH_3^+$ as A cation of the perovskite can shift the band

Fig. 1 (a) Cubic perovskite crystal structure; (b) calculated octahedral and tolerance factors for various combinations of commonly employed organic and inorganic hybrid perovskite components.

Table 1 Structural phase transformations for commonly employed hybrid perovskites

PVSK	Phase	Temperature (K)	Structure	Space group	Lattice parameters(Å)	Volume (Å ³)
MAPbI ₃	α	400	Tetragonal	P4mm	$a=6.3115; b=6.3115; c=6.3161$	251.6

gap from 1.55 to 1.45 eV (Eperon *et al.*, 2014). Following FA⁺, the ions such as Cs⁺, Rb⁺ with smaller ion radii have also been reported to be the applicable substitution for MA⁺ at A site, which results in the tailored bandgap and carrier behavior in the resultant materials (Choi *et al.*, 2014; Saliba *et al.*, 2016).

The most widely reported B cations ever reported in hybrid perovskite are Pb²⁺ and Sn²⁺, and the most efficient devices have been obtained always using Pb²⁺ based perovskite absorber. However, the toxicity of Pb²⁺ is seriously concerned which hinders the development of large-scale industrialization. To address this issue, the replacement of this heavy metal cation by an environmental friendly metal is under intense research, whereas Sn²⁺ or Ge²⁺ are investigated to be used as absorber without significant detriment to the device performance. Although CH₃NH₃SnX₃ possesses a more optimal band gap (1.2–1.4 eV) than CH₃NH₃PbX₃ (1.6–1.8 eV) does, the devices based on Sn perovskite do not appear comparable power conversion efficiency (PCE). It is mainly because the Sn based perovskite has shown a poor stability in air compared with the Pb based perovskite due to the oxidation of Sn²⁺ to Sn⁴⁺, which destroys the crystal structure and thus deteriorates the device performance (Kumar *et al.*, 2014).

The halide anion exhibit the substantial influence to the optoelectronic properties in the resultant hybrid perovskites. It has been widely reported the halogen elements I, Cl and Br, and their combinations affects the performance of the perovskite solar cells significantly. The Br[−] introduction into the perovskite lattice to replace I[−] will produce a higher absorption coefficient in the visible range of the spectrum, and upshift the conduction band to result in a wider bandgap perovskite suitable for tandem perovskite solar cells (Noh *et al.*, 2013). However, the Br[−] incorporation in MAPbI₃ often causes significant phase segregation upon illumination, which causes the instability issue. Introduction of Cl[−] into the perovskite can extend the charge diffusion length without changing the spectrum response, but only a small percentage of Cl atoms can be tolerated in the perovskite lattice (Chen *et al.*, 2015).

Optoelectronic Properties

Hybrid perovskites demonstrate strong optical absorption, adjustable band gap, long diffusion length, high carrier mobility, ambipolar charge transport and a high tolerance of defects. We thus provide a thorough discussion regarding the origin of the above excellent optoelectronic properties in the hybrid perovskites.

Hybrid perovskites exhibit large optical density with absorption coefficient of 10⁴–10⁵ cm^{−1}, which allows for a reduced film thickness as the absorber in solar cells to facilitate the light harvest efficiently. Devices based on less than 500 nm perovskite film can absorb sufficient sunlight and achieve high efficiency over 15%. In comparison, the commercially available crystalline Si or other inorganic thin film GaAs or CdTe photovoltaic technology are based on the absorber with thickness of few to hundreds of μm, much thicker than those of hybrid perovskites ones. The schematic illustration for optical transition over the bandedge that contributes to the optical absorption in Si, GaAs and perovskite materials are depicted in Fig. 2(a). The direct bandgaps of the halide perovskite (e.g., CH₃NH₃PbI₃) often exhibit optical absorption much stronger than that of silicon which possess an indirect bandgap. Compared with the GaAs semiconductor, the CB edge of the CH₃NH₃PbI₃ is mainly composed of degenerate Pb p orbitals. The atomic p orbital is less dispersive than s orbitals. Additionally, the edge transition in CH₃NH₃PbI₃ is mainly contributed from mixed-(Pb s, I p) to Pb p orbitals. It is generally believed the probability of intra-atomic Pb s to Pb p transition is high, which makes the VBM–CBM transition probability of CH₃NH₃PbI₃ comparable to that of GaAs. As is observed, halide perovskites show stronger optical absorption than GaAs in the visible range (Yin *et al.*, 2015). The calculated optical absorption coefficients of CH₃NH₃PbI₃ and GaAs are shown in Fig. 2(b) (Yin *et al.*, 2014).

Fig. 2 (a) The schematic optical absorption of the three kinds of solar cell absorber. (b) The optical absorptions of $\text{CH}_3\text{NH}_3\text{PbI}_3$, CsSnI_3 and GaAs.

Table 2 DFT–PBE calculated effective masses for electrons and holes

	Electron effective mass	Hole effective mass
$\text{CH}_3\text{NH}_3\text{PbI}_3$	0.35, 0.32	0.31, 0.36
$\text{CH}_3\text{NH}_3\text{PbI}_3$ (SOC)	0.18, 0.23	0.21, 0.29
CsSnI_3	0.19	0.09
CsSnI_3 (SOC)	0.16	0.07
Silicon	0.26	0.29
GaAs	0.07	0.34
CuInSe_2	0.09	0.75
$\text{Cu}_2\text{ZnSnSe}_4$	0.1	0.26
CdTe	0.09	0.28

The electronic structure of $\text{CH}_3\text{NH}_3\text{PbI}_3$ is different from the conventional III–V (p–s) semiconductors. Its CBM is derived from Pb p orbitals, and the VBM is a combination of Pb s and I p orbitals. Even though the CBM comes from p orbitals, the p orbital of Pb^{2+} has a much higher energy level than anion p orbitals, as is usually observed in III–V (p–s) semiconductors. It leads to a more dispersive conduction band of $\text{CH}_3\text{NH}_3\text{PbI}_3$ which is lower than that of the p–s semiconductors with a higher valence band. Furthermore, the valence band of $\text{CH}_3\text{NH}_3\text{PbI}_3$ is dispersive due to strong s–p coupling over the VBM. The calculated electron and hole effective masses of $\text{CH}_3\text{NH}_3\text{PbI}_3$ via DFT–PBE, are compared with typical first and second-generation solar cell absorbers, which are listed in Table 2. The hole effective mass of $\text{CH}_3\text{NH}_3\text{PbI}_3$ is close to the electron effective mass, leading to ambipolar conductivity in perovskites, which facilitates to construct the p–i–n junction solar cells with versatile architectures (Yin *et al.*, 2015; Giorgi *et al.*, 2013). The carrier diffusion lengths of $\text{CH}_3\text{NH}_3\text{PbI}_3$ is up to 100 nm for both electrons and holes, and exceeding 1 μm in the mixed halide $\text{MAPbI}_{3-x}\text{Cl}_x$ have been reported via transient photoluminescence (TRPL) measurements (Xing *et al.*, 2013; Stranks *et al.*, 2013). Through the formation of hybrid perovskite single crystal, it demonstrated diffusion lengths over 175 μm in single crystals of $\text{CH}_3\text{NH}_3\text{PbI}_3$ under 1 sun illumination, owing to the reduced density of defects in the single crystal (Dong *et al.*, 2015). The defects with the relatively low formation energies are Pb^{2+} vacancies and interstitial MA^+ . Consequently, both of them are able to create shallow charge-carrier trap states near the perovskite band edges as shown in Fig. 3 (Yin *et al.*, 2014). Fortunately, the shallow defects are not responsible to nonradiative recombination centers that hampers the carrier diffusion length, which has been experimentally observed (Duan *et al.*, 2015).

Device Structures of Perovskite Solar Cell

The unprecedented rise in power conversion efficiency of perovskite solar cell, combined with the potential of cost-effective fabrication technique have stimulated the further understanding of perovskite devices (Green *et al.*, 2014; Stranks and Snaith, 2015; Park *et al.*, 2016). Two commonly employed structures for perovskite photovoltaic devices are shown in Figs. 4(a) and (b). Both device architectures consist of a perovskite layer as the light absorber layer which is sandwiched between electron transport layer (ETL) and hole transport layer (HTL). The main difference between the two configurations is whether there is mesoporous scaffold layer or not, and accordingly they were categorized as mesoporous PSC and planar heterojunction PSC. The first adoption

Fig. 3 The transition energy levels of (a) intrinsic acceptors and (b) intrinsic donors in $\text{CH}_3\text{NH}_3\text{PbI}_3$.

Fig. 4 The device structures of (a) mesoporous perovskite solar cell, (b) planar heterojunction perovskite solar cell, and (c) dye sensitized solar cell. (d) The n-i-p and p-i-n cell architectures.

of perovskite absorber $\text{CH}_3\text{NH}_3\text{PbI}_3$ (MAPbI_3) in photovoltaic device was to replace conventional dye in dye sensitized solar cell (DSSC) (Kojima *et al.*, 2009), whose structure was shown in Fig. 4(c). Generally, it is considered as the archetype of mesoporous PSC. The presence of TiO_2 mesoporous scaffold layer as ETL greatly increase the contact area between perovskite and TiO_2 material, giving rise to the faster and more efficient electron transport. Further investigation has demonstrated that perovskite absorbers exhibit superior ambipolar transport ability (both electron and hole, which means that mesoporous scaffold is not necessary for perovskite photovoltaic devices, leading to the emergence of planar heterojunction PSC (Leijtens *et al.*, 2014). Compared to the mesoporous PSC, the fabrication of planar structured PSC possessed the added advantage of more simple and low-temperature processing that are attractive for mass production and flexibility. Additionally, a great deal of excellent carrier conducting layers including inorganic materials, as well as organic materials have been successfully demonstrated in the efficient planar heterojunction PSC. Depending on the relative position of the electron/hole conducting layer and incident sunlight, the planar heterojunction PSC can be simply divided into n-i-p structure devices (regular configurations) and p-i-n structure devices (inverted configurations), as shown in Fig. 4(d).

To this day, the highest PCE of perovskite solar cell have reached a certified 22.1%, which is reported from National Renewable Energy Laboratory (NREL), but the detailed device structures and experiment process have not come forward yet. Moreover, Grätzel and his coworkers have realized the mesoporous PSCs with good reproducibility showing a certified PCE of 21.02% and a champion PCE of up to 21.6% under standard test condition (Bi *et al.*, 2016). The typical mesoporous PSCs device structure is FTO/compact TiO₂/mesoporous TiO₂/perovskite/spiro-OMeTAD/Au. And recently, Sargent and his coworkers reported top-performing planar heterojunction PSC using chlorine-capped TiO₂ colloidal nanocrystal film. The optimized planar photovoltaic devices have been demonstrated a certified PCE of 20.1%, which is the highest efficiency of planar heterojunction devices for now (Tan *et al.*, 2017). The reported device structure is ITO/TiO₂-Cl/Perovskite/Sprio-OMeTAD/Au.

Working Mechanism of Perovskite Solar Cell

When two types of semiconductors contact, the majority carriers in the material bulk will diffuse to each other. The movement of majority carriers will leave positive ion cores in the n-type semiconductor and negative ion cores in the p-type semiconductor, respectively, resulting in a charge depletion region with a built-in electric field, which is usually defined as a junction. When the sunlight incidence happens, the photogenerated carriers are created and the equilibrium is broken in the semiconductor absorber and in the contact region. During the subsequent diffusion process, part of the photogenerated carriers will recombine via direct recombination, Shockley-Read-Hall recombination or Auger recombination. The others will eventually diffuse to the junction and get separated assisted by the built-in electric field. The carriers will then be extracted selectively through the carrier-transport layers and reach the external circuit to generate photocurrent. When a photovoltaic devices is illuminated under sunlight, the key processes are shown in Fig. 5, including that (1) the incident photo with energy higher than the bandgap of light absorber layer can be absorbed in perovskite layer to generate holes and electrons, (2) the electrons transfer from perovskite to ETL, (3) the holes transfer from perovskite to HTL, which is equivalent to that of electron, (4) the electrons are recombined with photogenerated holes, (5) and (6) back charge carriers transport may occur at the interface of ETL and HTL with perovskite, (7) the electrons and holes recombine between ETL and HTL, which may occur if the quality of perovskite film is inferior so that many pinholes exist. In order to pursue high performance, process (4)–(7) must be restrained as strictly as possible, to ensure sufficient charge generation and extraction in operated perovskite photovoltaic devices.

Charge Carriers Transport Materials

Apart from the perovskite absorber, charge carriers transport layers, including ETL and HTL, also play a significant role in perovskite photovoltaic devices (Fan *et al.*, 2016; Hossain *et al.*, 2015; Zhang *et al.*, 2017; Ke *et al.*, 2015). The relative position of the valence band maximum (VBM) and conductive band minimum (CBM) of the charge carriers transport materials and perovskite provides the intrinsic motivation force for carrier separation and extraction at charge carriers transport layers/perovskite junction, which also determines the device's built-in potential of cell operation at equilibrium upon illumination. The design principles for choosing charge carriers transport materials must take two into account of two aspects. On one hand, the VBM and CBM of charge carriers transport materials are critical for appropriate energy level alignment between perovskite and charge carriers transport layers, which is essential for efficient charge carrier separation, extraction and transport to minimize open-circuit voltage loss (Cha *et al.*, 2016). On the other hand, the processibility of each functional layers should also be taken into consideration. For instance, the substrate wetting characteristics and chemical compatibility of carrier transport layers, particularly the deposition of subsequent layer upon perovskite. It has been widely reported that the processing approach can directly influence the film quality

Fig. 5 Schematic of electron-transfer processes in an operated perovskite solar cell.

of perovskite solar cell, in terms of the grain size, morphology, crystallinity, surface coverage, *etc* (Song *et al.*, 2015). Therefore, rational design of carrier selective layers and the relevant processing methods determines the performance for photovoltaic devices, which has been carefully investigated in the research community.

Holes Transport Materials

Originated from the other third generation photovoltaic technologies, such as organic photovoltaics (OPV) and DSSC, 2,2',7,7'-Tetrakis[N,N-di(4-methoxyphenyl)amino]-9,9'-spirobifluorene (spiro-OMeTAD) and Poly(3,4-ethylenedioxythiophene):poly(styrene sulfonate) (PEDOT:PSS) have become two of the most popular hole transport materials (HTM) in perovskite photovoltaic devices, whose molecular structures are shown in Fig. 6(a). Owing to the excellent hole carriers mobility and appropriate VBM, CBM and Fermi energy level (Fig. 6(b)), both spiro-OMeTAD and PEDOT:PSS based PSC exhibit fascinating power conversion efficiency (Tan *et al.*, 2017; Meng *et al.*, 2016). However, neither of them is perfect, and they are facing a few critical challenges in way of commercialization of PSCs. Spiro-OMeTAD is too expensive to use on a large scale. In addition, it is reported pure spiro-OMeTAD exhibits weak electric conductivity, whereas chemical doping has been employed to greatly improve the carrier concentration and conductivity of the materials. However, the additive induced for chemical doping will damage the perovskite film in the solar cells. PEDOT:PSS shows acidic characteristics, which is not compatible to the perovskite film in devices and leads to long-term stability issues. Apart from that, both materials are organic species which are sensitive to moisture and oxygen. Therefore, lots of efforts are invested by research community aiming at feasible substitutions to address the current concern of inferior long-term stability in PSC devices (Bella *et al.*, 2016; Saliba *et al.*, 2016). Recently, lots of attention have been attracted to a variety of inorganic new candidates, such as NiOx, Cu₂O, CuSCN, CuI, and some cheaper or more stable organic HTM, whose energy level structures are shown in Fig. 6(b) (Hossain *et al.*, 2015). Taken as the example, NiOx is now under the spotlight as an inorganic p-type metal oxide hole transport material for PSCs. With the regard of valence band edge, it is demonstrated that NiOx can match with MAPbI₃ absorber (−5.4 eV) better than that of PEDOT:PSS (5.26 eV) or spiro-OMeTAD (5.22 eV), which leads to greater open-circuit voltage and more efficient hole carriers separation and extraction. Moreover, its intrinsic stability and low-cost processing has brought forth to apparent advantages of NiOx among other potential HTM candidate material (Xu *et al.*, 2015).

Fig. 7 (a) The left curves is the relationship of $(\alpha h\nu)^2$ vs. energy for perovskite, SnO_2 and TiO_2 , respectively. The bandgap of materials can be determined by the linear extrapolation of the leading edges of the $(\alpha h\nu)^2$ curve to the base lines. The right curves are ultraviolet photoelectron spectroscopy (UPS) cutoff edges of SnO_2 , TiO_2 and perovskite layer. (b) The molecular structures of PCBM. (c) The scan electron micrographs of three kinds of typical perovskite solar cells.

Electrons Transport Materials

Regarding electron transport materials (ETM), TiO_2 is the most popular choice as the electrode buffer to transfer electron from the absorber to electrode often employed in both mesoporous and planar heterojunction architectures (Tan *et al.*, 2017). This is mainly attributed to its well-aligned energy level to the perovskite absorber, as well as its well spread in DSSC/OPV. However, both compact and mesoporous TiO_2 suffer from low electron mobility and relatively high density of electronic trap states, giving rise to a high electron recombination rates. Moreover, it is reported that the TiO_2 layer is sensitive to ultraviolet exposure and oxygen, and its catalytic effects to decompose perovskite absorber is still under investigation, which may severely restrict the long-term application of perovskite photovoltaic devices. Right now, tin dioxide (SnO_2) is the most promising candidate to replace TiO_2 as electron transport material in planar heterojunction PSC with superiority of the much higher electron mobility and wider band gap than TiO_2 (Fig. 7(a)) (Jiang *et al.*, 2016). So with a wider bandgap of the SnO_2 as ETL, it can greatly minimize the photocurrent loss. SnO_2 also exhibits considerable stability upon ultraviolet illumination, which satisfies the requirements for commercialization. Besides these inorganic ETM, [6,6]-phenyl-C61-butyric acid methyl ester (PCBM, the molecular structure is shown in Fig. 7(b)) is one of the most popular ETM usually used in inverted planar heterojunction PSC to deliver outstanding performance due to its good mobility, Fermi energy level, and particularly, the electron extraction capability. What attracts researchers most for PCBM-based perovskite devices is its negligible J-V hysteresis behavior during cell efficiency measurement.

Based on various charge carriers transport materials mentioned above, the typical devices structure of mesoporous PSC is FTO/compact TiO_2 /mesoporous TiO_2 /perovskite/spiro-OMeTAD/Au. As shown in Fig. 7(c) (Bi *et al.*, 2016), the device contains a FTO glass substrate covered by a compact TiO_2 ETL (~ 30 nm). A mesoporous TiO_2 scaffold (~ 150 nm) is deposited on the top of compact TiO_2 layer, followed with the perovskite absorber (~ 450 nm). Subsequently, a ~ 200 nm thick spiro-OMeTAD as HTL is deposited by spin-coating. Finally, a thin layer of gold (~ 100 nm) is generally evaporated as the top electrode. As the counterpart, the typical devices structures of regular planar PSC indium tin oxide (ITO)/compact TiO_2 /MAPbI₃/spiro-OMeTAD/Au (Zhou *et al.*, 2014), And inverted planar PSC often adopt the configuration of ITO/PEDOT:PSS/ MAPbI₃/PCBM/Ag (Heo *et al.*, 2015), which are shown in Fig. 7(c). Moreover, the devices performance of PSC using various HTLs and ETLs are summarized in Table 3.

Tandem Solar Cell

For a single-junction solar cell, it achieves the limited power conversion efficiency due to the thermalization and transmission losses according to the Shockley–Queisser theory, leaving the maximum achievable efficiency close to 31% (Meillaud *et al.*, 2006).

**Fig. 8** Schematics of four terminal tandem solar cell and two terminal tandem solar cell.**Fig. 9** (a) Schematic of a four-terminal tandem cell on silicon. (Inset) Optical distribution of absorbed sunlight (AM1.5G) through the complete tandem cell. (b) Scanning electron micrograph of the two terminal perovskite-perovskite tandem solar cell.

Different absorbers with different bandgaps will meet different theoretical PCE limits. So far, the traditional silicon solar cells are approaching their theoretical efficiency limit of $\sim 25\%$. To further improve the PCE of solar cells, tandem solar cells that consists of multiple absorbers stacked in a horizontal fashion have attracted many researchers' interests. The simplest tandem solar cell, that two sub-cells are working together, can be divided into "Four terminal device" and "Two terminal device" depending on how the power output is extracted. As shown in Fig. 8, in a four terminal device, the photocurrents extracted from the two sub-cells are collected independently. In a two terminal device however, the two sub-cells are connected in series for power output (Chen *et al.*, 2015). When the incident sunlight photons reach the tandem devices, the top cell will absorb short-wavelength photons with energy higher than its bandgap E_{g1} , and the bottom cell will utilize the remaining long-wavelength photos with energy higher than its bandgap E_{g2} . In this scenario, a smart tandem design is expected to include the top photo-active layer and junction layer with

negligible absorption for long-wavelength photons to reduce the parasitic absorption as much as possible. This is essential for tandem solar cell to achieve higher efficiency. The perovskite materials are reported to exhibit negligible mid-band-gap states, which is evidenced by its low Urbach energy. Therefore, the hybrid perovskites not only exhibit very high absorption in short-wavelength spectrum range, but also display excellent transmittance over the long-wavelength spectrum range, indicating the promising potential of perovskite materials in tandem cells.

Another challenge for light activated materials in tandem solar cells application is their bandgaps. According to the theoretical calculation, the silicon-perovskite tandem solar cell can achieve an efficiency over 35%, only when the absorber with an optimized bandgap of 1.7 eV is employed in the front cell, as shown in Fig. 9(a) (Lal *et al.*, 2014). For this reason, the perovskite materials with tunable bandgap from 1.48 to 2.3 eV are carefully investigated, regarded as the excellent candidate as the top absorber materials. Moreover, perovskite-perovskite tandem solar cells are born sequentially and reported 20.3% efficiency for four terminal tandem cells, 17.0% efficiency for two terminal tandem cells, whose device structure is shown in Fig. 9(b) (Eperon *et al.*, 2016). It is believed the perovskite/c-silicon solar cell is one of the most potential technical approach toward commercialization by capitalization the well-developed crystalline silicon industry.

Summary

In summary, organic–inorganic hybrid perovskite materials as the star candidate employed in photovoltaics have made tremendous progress in decade years thanks to the intrinsic characteristics, such as high absorption coefficients, ambipolar carrier transport, long carrier lifetimes and diffusion lengths and shallow defect levels. However, there is still a long way for practical use of perovskites in photovoltaic market. In this article, we briefly review optical and electrical property for perovskite, and present the fundamental device structure and working mechanism of perovskite solar cell, whereas the relevant charge carriers transport materials are also included. Moreover, the perovskite-based tandem solar cell as a promising developing direction have been concisely discussed. Substantial efforts and researches toward the further development of perovskites photovoltaics are in progress. We confidently believe that low-cost, high performance, long-term stable and environmental friendly perovskite photovoltaic technology will be achieved in the coming years.

Light Harvesting in Organic Solar cells

Introduction

Considerable interest has evolved in the development of technologies to address the complex fabrication process and high cost of solar cells. Organic solar cells (OSCs) belong to a class of photovoltaic technology that are fabricated with organic, carbon-based semiconductors as the light absorbing active layer. OSCs offer a competitive path to realize cost-effective as well as environmentally friendly solar cells for future photovoltaic applications. They have the potential to be ultra-low cost, ultrathin, light weight and flexible (Krebs, 2009). They also offer the promise of high performance with opportunities not only in photovoltaics, but also in electronics and lighting applications. The ultrathin nature of OSC makes it transparent and allows it to be integrated into window glass or used as design elements for lighting installations. The polymers used in OSC can be easily printed and can be made in different colors.

The working principle of an organic solar cell has been discussed in the previous articles. However, to bring the need for light harvesting to context, it is important to understand that the exciton diffusion length L_D (the distance charge carriers can travel before recombining) is very short in organic semiconductors. Furthermore, L_D is significantly less than the absorption length $1/\alpha$ (distance into a material where the light intensity has dropped to $1/e$ or 36% of its original incident flux) for an organic solar cell. This means there is an inherent trade-off between the absorption in the organic absorber layer and the exciton diffusion length, thus forming an exciton diffusion bottleneck whereby the excitons cannot reach the donor–acceptor interface prior to dissociation into free carriers. This limits the thickness of the absorber layer d used to ~ 100 nm so that more charge carriers can be successfully extracted before recombination occurs (Yu *et al.*, 1995; Ma *et al.*, 2005) and significantly affects the cell efficiency. The absorption efficiency within the absorber layer $\eta_A = 1 - e^{-\alpha d}$ and the exciton diffusion efficiency can be calculated as $\eta_{ED} = e_D^{-d/L_D}$. Fig. 1 shows the dependence of the exciton diffusion bottleneck and the ratio of the layer thickness d to the exciton diffusion length L_D (Forrest, 2005).

The low efficiencies of OPV have hindered the commercial success of this technology. While different strategies are in place to improve either the absorption length or the diffusion length by design variations, blending polymers or improved material properties (Vezie *et al.*, 2016), this article will briefly discuss light harvesting schemes that have demonstrated or could potentially be used for increased light absorption through optical means. Conventional light trapping in silicon (Si) solar cells make use of surface textures that are on the micron scale (wavelength of light) to increase the optical pathlength. However, this is not feasible on very thin absorber layers like OSC. Moreover, texturing can induce roughness which increases the density of surface and bulk defect states, with the potential of degrading the electrical performance of cells. Hence, alternate light harnessing schemes need to be employed. They include antireflection (AR) schemes that direct more light into the absorber layer or light trapping schemes that aid the light to bounce back and forth in the active layer, thus increasing the optical path length thereby providing multiple opportunities for the light to be absorbed in the process. Other techniques include resonance/light concentration/near-field effects

Fig. 1 Plot showing the dependence of the “exciton diffusion bottleneck” on the ratio of layer thickness d to exciton diffusion length L_D . Here α is the optical absorption coefficient within a particular layer. Taken from Forrest, S.R., 2005. The limits to organic photovoltaic cell efficiency. MRS Bulletin 30 (1), 28–32.

Fig. 2 Different ways of harnessing light (a) antireflection (AR) to maximize absorption, (b) light trapping where random scattering increase the path length, and (c) coherent light trapping where diffraction or electric field concentration is exploited. Taken from Mallick, S.B., Sergeant, N.P., Agrawal, M., Lee, J.-Y., Peumans, P., 2011. Coherent light trapping in thin-film photovoltaics. *MRS Bulletin* 36 (6), 453–460.

that can increase the optical density of states or confine the light in the absorber layer where photovoltaic conversion occurs. Approaches include graded index structures, substrate texturing, plasmonics, diffraction grating, photonic crystals, microcavities (Chen *et al.*, 2014a,b; Sergeant *et al.*, 2013) which makes use of one or more schemes. A schematic of the different light harnessing schemes is shown in Fig. 2. These light harvesting schemes are targeted for optical enhancement, however, some designs like plasmonics can benefit from both optical and electronic enhancement. Other approaches involve manipulating the light spectrum to be absorbed in different layers such as tandem configurations. In this work, we will discuss each of these approaches in more detail.

AR Effects

The realization of an efficient cell comes with minimization of optical losses. Since OSCs consist of stacks of different layers, the chances of reflective losses at each of the interfaces have to be eliminated to maximize in-coupling of incident light in the active layer. Hence the mitigation of optical losses has to start at the first point of incidence, which is at the front interface. This ensures that all the light that reaches the cell can be harvested in some way.

One way to achieve broadband AR properties is by using techniques seen in nature. For instance, the moth eye structures consist of nanostructured hexagonal cone shaped patterns that can substantially suppress the reflections of light at an interface of light over a broad spectral range (Bernhard, 1967) thereby increasing transmittance into the absorbing substrate over a wide angle of incidence (Huang *et al.*, 2007). Photonic structures are fabricated by mimicking moth eyes where the sub-wavelength features in the moth eye provide an effective refractive index that gradually varies and can suppress the reflection of light. The effective refractive index depends on the refractive indices of the nanostructured material and incident medium, and the angle of incidence. By tweaking these parameters the photonic structures can be optimized. Large scale fabrication of such structures is possible by interference lithography deeming it suitable for large scale production in solar cells.

Moth eye AR structures have been successfully incorporated to improve the performance of OSCs with an increase in the peak EQE by 3.5% along with making it angularly independent to oblique light (Forberich *et al.*, 2008). Another study achieved hydrophobic surfaces that enable self-cleaning properties for solar cells using a polydimethylsiloxane (PDMS) film as the AR layer on glass substrate with an encapsulated poly[(4,8-bis-(2-ethylhexyloxy)-benzo[1,2-b:4,5-b']dithiophene)-2,6-diyl-alt-(4-(2-ethylhexanoyl)-thieno[3,4-b]thiophene)-2,6-diyl]:[6,6]-phenyl-C61 butyric acid methyl ester (PBDTTT-C:PCBM) cell increasing photocurrent efficiency. An improvement of 6.19% was reported where the nanostructures were fabricated by soft imprint lithography and the patterns formed by laser interference lithography and dry etching (Leem *et al.*, 2014). Another study using such dual-side bio-inspired nanostructures fabricated using nanoimprint lithography improved the light in-coupling efficiency of OSCs by 20%, yielding an enhanced power conversion efficiency of 9.33% (Zhou *et al.*, 2014).

Another light harnessing inspired by nature is called “flower power” that makes use of the epidermal structures of plants. Plants living in low light intensity regions make use of nanostructured surfaces need to harness light for metabolism or flowers for color saturation. These structures can not only reduce reflections like the moth eye structures, but also, in addition, can redirect incoming photons to induce light focussing effects thereby facilitating efficient light collection as well as light trapping (Hünig *et al.*, 2016). The densely packed combination of microstructures increase the chance of reflected light to bounce onto the neighboring feature especially at large angles of incidences and show only minor dependence to wavelengths. These structures also act as an imperfect lens diverging the incoupled light thereby increasing the optical path length resulting in light trapping. This double contribution has increased the power conversion efficiency of OSCs by 13% at normal incidence and 44% at an angle of incidence of 80 degree (Hünig *et al.*, 2016). The structures were fabricated by transferring the features directly from the rose petals to a PDMS stamp and then imprinting it to the cells as shown in the inset of Fig. 3(a) and (b) shows the smoothening of the Fabry–Perot resonances and reduction in the reflection on employing the rose structure on a ZnO:Al layer.

Nanowire (NW) arrays are another type of structure which has demonstrated AR and light trapping effects (Muskens *et al.*, 2008). Like in moth eye and flower structures they also exhibit broadband and omnidirectional AR properties due to the gradual

Fig. 3 (a) Scanning electron microscope (SEM) images of moth eye structures on a Si master that can be transferred to the substrate by soft imprint lithography to form inverted moth-eye structures (Reproduced from Leem, J.W., Kim, S., Lee, S.H., *et al.*, 2014. Efficiency enhancement of organic solar cells using hydrophobic antireflective inverted moth-eye nanopatterned PDMS films. *Advanced Energy Materials* 4 (8), 1301315) and (b) reduction in reflection and smoothening interference upon employing the “flower structure.” Inset shows a 55 degree tilted SEM picture of one such structure. Taken from Hünig, R., Mertens, A., Stephan, M., *et al.*, 2016. Flower power: Exploiting plants’ epidermal structures for enhanced light harvesting in thin-film solar cells. *Advanced Optical Materials* 4 (10), 1487–1493.

index profile. The tapered shape of the nanorod arrays leads to impedance matching between absorber and air through a gradual reduction of the effective refractive index away from the surface, resulting in low reflection particularly at longer wavelengths and eliminating interference fringes through roughening of the top interface (Lee *et al.*, 2008). Following its success on Si solar cells, ZnO NWs grown using metalorganic chemical vapor deposition have been applied on OSCs following its success on Si solar cells resulting in a 36% boost in optical absorption compared to planar devices (Hiralal *et al.*, 2014). These AR structures are particularly interesting due to the fact that the AR effect becomes more pronounced at large angles of incidence and they can exhibit self-cleaning properties due to the hydrophobic surfaces created through relevant surface treatment.

Light Trapping

While optical losses in cells can be reduced by proper choice of materials and good AR layers, inefficient light absorption in thin OSCs is a critical issue that limits cell efficiency. Traditional light trapping in solar cells consist of surface textures such as pyramids which allows randomized light paths in the cell, thus enhancing the optical path length and providing more opportunities for the light to be absorbed. However, the fragile nature and small physical dimensions of OSCs preclude such trapping schemes used in inorganic solar cells like Si which makes low cost fabrication challenging. Hence light trapping schemes have to be modified in OSCs using coherent light trapping approaches that make use of wave nature of light to make significant contributions. A good discussion on coherent light trapping can be found in Mallick *et al.* (2011).

The fundamental light trapping limit of light is $4n^2$ where n is the refractive index of the thick absorber layer. This was proposed by Yablonovitch and is known as the ray-optics limit (Yablonovitch, 1982) where the light scattered is considered to be ergodic, i.e., light will be coupled equally to all available modes. However, for thin layers where the thickness of the absorber layer is smaller or comparable to the wavelength of light, this limit does not apply as the number of modes available reduces to a set of discrete modes. Based on a rigorous electromagnetic wave approach, Yu *et al.* proposed that the standard limit can be surpassed to an absorption enhancement factor of $12 \times 4n^2$ using nanophotonic light trapping approaches (Yu *et al.*, 2011). Two such nanophotonic structures were proposed by Yu *et al.*, (2011) and (Green, 2011) where both proposed low index absorber layer sandwiched between high index layers that is ideal for OSCs. In both cases the index contrast between the cladding layer and the absorber layer provides strong nanoscale field confinement in the absorber layer with the potential to improve cell performance dramatically. Yu’s structure considered a 5-nm absorber layer sandwiched between a 60 nm thick high refractive index cladding layer and a mirror. An 80-nm scattering layer consisting of groove patterns was used to couple light into the guided modes from all

Fig. 4 (left) Schematic of a nanophotonic light trapping structure with an 80 nm thick scattering layer comprising square lattice of air grooves of periodicity 1200 nm, 60 nm cladding layer and 5 nm active layer on a mirror; (right) electric field intensity profile of the fundamental waveguide mode. Taken from Yu, Z., Raman, A., Fan, S., 2011. Nanophotonic light-trapping theory for solar cells. *Applied Physics A*. doi: 10.1007/s00339-011-6617-4.

angles. Green's work used a similar sandwiched structure but with the absorber layer between two high index cladding layers leading to an enhanced field in the absorber layer due to tunneling evanescent waves. While organic materials with low index are suitable and could highly benefit with active layers in these two configurations, it is crucial to identify high index cladding materials with low parasitic absorption. **Fig. 4** shows nanophotonic light trapping structure along with the electric-field intensity for the waveguide mode that is strongly confined to the active layer.

Light trapping by scattering and randomizing of light in such a way that light travels more in the plane of the absorber is difficult to realize in OSCs as the feature sizes should be larger or comparable to the thickness of the organic layer (which is the order of wavelength of light). Moreover, as mentioned earlier, nano-textures can degrade the performance of the device due to recombination losses. Hence different engineering solutions to trap light have been investigated without increasing the surface recombination. One such case is where the scattering layer is isolated from the absorber layer. The structure comprises of low absorption micro-lenses on top of reflecting mirrors with small transmitting openings for the focused light to be incident onto an OSC absorber as shown in **Fig. 5(a)**. The lens/mirror combination collimates the incident light in the forward direction and is highly reflective to both collimated and scattered light in the opposite direction. The light in this case bounces back and forth between the mirror and the back electrode increasing the probability of light absorption. More chances of photon recycling exist where absorption is weak with these light trapping elements enhancing photocurrent by as much as 25% (Tvingstedt *et al.*, 2008). One drawback of such structures is the need for accurate focusing as it is angle sensitive which may otherwise result in shading when the holes are not properly aligned.

Micro-lens array of closely packed hemispherical shape has been fabricated earlier using soft lithographic molding technique as shown in **Fig. 5(b)** (Myers *et al.*, 2012). Both AR and light trapping resulted in a 15–60% relative increase in efficiency. This structure did not have any mirrors, unlike the patterned mirror-and-lens light trap structure in **Fig. 5(a)**, hence a more economical structure considering that it is attached to the outer layer of glass without affecting the surface morphology of the active layer. Similar enhancements and 2.5 times longer pathlength using pyramidal rear reflectors fabricated on glass for semitransparent OSC have also been reported (Cao *et al.*, 2011).

Attempts have also been made to realize surface textures that are on a length scale much larger than the active layer thickness and that requires no modification of the device structure. The active layer and reflective metal electrode are deposited on a V or W-shaped transparent substrate coated with a transparent electrode such as indium tin oxide (ITO) (**Fig. 5(c)**) that increases photocurrent efficiency for all angles of incidence (Rim *et al.*, 2007). A 52% increase in power conversion efficiency was demonstrated using poly(3-hexylthiophene-2,5-diyl):[6,6]-phenyl-C61 butyric acid methyl ester (P3HT:PCBM) polymer blend cells that occupied the complete V shaped area. The viability of the V-shaped trap depends on the balance of the added cost of the structure and increase in active material with the reduction in installation cost of modules with high efficiencies. **Fig. 5(d)** shows a photo of the V and W-geometry cell taken from Zhou *et al.* (2008).

A photonic crystal structure is another method used for light management in OSCs. They comprise of dielectric or metallic structures that can manipulate the flow of photons. A variation to the micro-lens structure consist of polymer micro-lens on the exterior glass coupled with a photonic-plasmonic crystal at the metal cathode on the back of the cell but without mirrors (Peer and Biswas, 2014) (plasmonic structures are metal-based nanostructures with the potential to manipulate the flow of light in the adjoining absorber layer and will be discussed in more detail in a separate section). These micro-lens arrays focus and diffract light within the OSC which then is coupled to a periodically patterned organic layer facilitated by the periodically patterned metal cathode. Strong diffraction, waveguide modes and plasmonic light concentration effects contribute to the performance enhancement. This work demonstrated experimentally realizable solar cell structures with simulations predicting a photocurrent enhancement of ~58% relative to a flat cell. The absorption approached the Lambertian limit with enhanced absorption at longer wavelengths.

Multifolded polymer solar cells on flexible substrates. *Applied Physics Letters* 93 (3), 033302. ITO, indium tin oxide; PEDOT:PSS, poly (3,4-ethylenedioxythiophene):polystyrene sulfonate).

A photonic substrate texturing technique, making use of folds and wrinkles, has shown to significantly enhance the incoupling of the light in OSCs (Gregg and van de Lagemaat, 2012) taking inspiration from the structure of leaves which has high light-harvesting efficiency. Fig. 6(a)–(e) shows the scanning electron microscope (SEM) image of the wrinkles developing into folds. Here an optically curable adhesive layer on the substrate is subject to compressive stress with a sequence of ultraviolet pulses and subsequent plasma treatment creating folds and wrinkles (Kim *et al.*, 2012). The entire folded layer was then coated with gold (Au) (anode) followed by the organic polymer P3HT:PCBM as shown in the inset of Fig. 6(e). These combination of wrinkles and deep folds act as photonic structures; they increase light coupling into and trapping light by waveguiding effects. In this work although there was a 79% increase in the external quantum efficiency (EQE) in the visible region compared to devices on flat surfaces, the EQE of the polymer material was interestingly improved by more than 600% in the near-infrared (where absorption is weak), where the useful range of solar energy conversion is extended by more than 200 nm (beyond the absorption edge of P3HT:PCBM > 650 nm). Fig. 6(e) and (f) show the IV and EQE of the cells with the wrinkles and wrinkle and fold combination compared to a reference cell.

Metal Nanostructures (Plasmonics)

Metal nanostructures in the form of metal nanoparticles (NPs), NWs or nanogratings have attracted a lot of attention as a means of light trapping in solar cells. Metal nanostructures in the nanoscale support plasmons which are collective oscillations of conduction electrons at a metal–dielectric interface. They support resonances that can be tuned by changing the geometry (size, shape, aspect ratio), the choice of metal or the dielectric environment around it (Raether, 1988). An entirely new field called Plasmonics is credited to the unique properties of these metallic nanostructures that can scatter, concentrate or manipulate the flow of light. Inside the device, the scattered light effectively increases the optical path length, while the near-field effect increases the electric field in the vicinity of the plasmons through the excitation of localized surface plasmon resonance (LSPR). Both effects enhance

absorption of light in the active absorber layer in a solar cell (Pillai and Green, 2010). Structured metal interfaces can also help couple the light using surface plasmon polaritons (SPP) that are propagating plasmons at a metal dielectric interface. Fig. 7 shows a schematic of the various plasmonic effects contributing to enhanced power conversion efficiency.

Among the metal NPs used to improve light absorption, silver (Ag) and Au are traditionally the focus of research, even though other metals also exhibit plasmonic properties (Pillai and Green 2010). In particular, aluminum (Al) NPs have been known to effectively reduce reflection losses due to their higher resonant frequency, and hence have limited metal absorption (Green and Pillai 2012). While an interband absorption in Al at 800 nm limits its use in Si solar cells (Temple and Bagnall, 2011), potential applications in organic photovoltaics (OPV) devices can be considered due to the larger bandgap of organic semiconductors.

Various plasmonic device architectures have been proposed to take advantage of the improved optical properties when plasmonic nanostructures are integrated into OSCs (Gan *et al.*, 2013; Chou and Chen, 2014; Stratakis and Kymakis, 2013) as shown in Fig. 8. The device structure can incorporate NPs, nanorods (NRs), nanoplatelets, nanoprisms, NWs, or nanogratings, which can be located in the active layer, the transport layers, buffer layer or at the interface between two layers (Chou and Chen, 2014). The improved optical properties in these metal nanostructures can manifest in the near field or far field, with various effects observed depending on the configuration of the plasmonic organic solar cell. A common methodology for fabricating plasmonic OSCs involves integration of plasmonic NPs (or discrete particles such as NRs) in one of the charge transport layer of the device as shown in Fig. 7(a).

Rand *et al.* (2004) reported one of the earliest device architectures incorporating plasmonic nanostructures, where enhanced optical field intensity in the near-field was observed when Ag nanoclusters were utilized in OSCs. This broadband enhanced field allowed increased light absorption up to 10 nm from the clusters. More recently, Au NPs and NRs were incorporated into the poly (3,4-ethylenedioxythiophene):polystyrene sulfonate (PEDOT:PSS) layer of an organic solar cell to trigger various LSPR bands. Improvements in light absorption due to an enhanced LSPR-induced local field resulted in an increase in the device efficiency by up to 24% (Hsiao *et al.*, 2012). Transmission electron microscopy (TEM) images of the plasmonic nanostructures and the improved EQE in the 450–600 nm wavelength range are shown in Fig. 9. Another example of near field enhancement can be seen

Fig. 9 (a)–(f) Transmission electron microscopy (TEM) images of different size/shape Au nanoparticle (NPs) with tunable localized surface plasmon resonance (LSPR) and (g) external quantum efficiency (EQE) spectra of poly(3,4-ethylenedioxythiophene) polystyrene sulfonate (PEDOT:PSS) layers incorporating the Au NPs at 100 mW/cm² illumination and EQE of devices containing various plasmonic nanostructures. when Ag NPs are incorporated into the PEDOT:PSS using a pulse-current electrodeposition technique (Kim *et al.*, 2008). It was found that stronger light absorption is due to the high electromagnetic field strength in the vicinity of excited surface plasmons. While NPs can affect device performance when inadvertently contacting the active layer, there have been successful demonstrations of plasmonic nanostructures integrated in the active layer as represented in Fig. 7(b). In one report, Au NPs embedded into the active layer of the polymer solar cells showed improved performance both experimentally and theoretically due to excitation of LSPR (Wang *et al.*, 2012). The strong lateral distribution of the near field in this case is cited as the reason for enhancement as shown in the results in Fig. 10. Plasmonic nanostructures have also been used in a dual plasmon configuration. Liu *et al.* demonstrated increased J_{sc} from a device containing Au nano-dots and Au NPs in a blend with PEDOT:PSS respectively at each interface of the active layer (Liu *et al.*, 2013). The effective optical path length was increased due to the light scattering and LSPR effects of the Au NPs. It was also reported that increased light absorption from the Au nanodots was mainly derived from near-field

ITO, indium tin oxide; PTB7:PC₇₀BM, poly[[4,8-bis[(2-ethylhexyl)oxy]-benzo[1,2-b:4,5-b']dithiophene-2,6-diyl][3-fluoro-2-[(2-ethylhexyl)-carbonyl]thieno[3,4-b]thiophenediyl]]:[6,6]-phenyl-C70-butyric acid methyl ester. Taken from Lu, L., Luo, Z., Xu, T., Yu, L., 2013. Cooperative plasmonic effect of Ag and Au nanoparticles on enhancing performance of polymer solar cells. *Nano Letters* 13 (1), 59–64.

effects. Cooperative plasmonic effect using Au and Ag NP of ~ 40 – 50 nm diameter size embedded in the anode buffer layer PEDOT resulted in an 8.67% bulk heterojunction polymer cell accounting for 20% enhancement (Lu *et al.*, 2013). The observed effects were greater than any one type of the single NPs alone and were attributed to the dual resonance peaks of the two different NPs. The IV curve and the EQE of the comparative performance of poly[[4,8-bis[(2-ethylhexyl)oxy]-benzo[1,2-b:4,5-b']dithiophene-2,6-diyl][3-fluoro-2-[(2-ethylhexyl)-carbonyl]thieno[3,4-b]thiophenediyl]] (PTB7) and [6,6]-Phenyl-C70-butyric acid methyl ester (PC₇₀BM) blend polymer cell is shown in Fig. 11(a) and (b), respectively, along with a schematic and TEM images of the NPs in Fig. 11(c). In this work, it was concluded that the LSPR-induced local field not only helped to improve light absorption, but also aided the electrical properties like charge separation and transport thereby improving carrier density and lifetime.

There have been many observations of the near-field in plasmonic OSCs, however, far-field effects or light scattering can also significantly contribute to improved device performances. By varying the size of Ag NPs in PEDOT:PSS, a plasmonic forward scattering effect was demonstrated in PCDTBT:PC₇₀BM and PTB7:PC₇₀BM OSCs (Baek *et al.*, 2013). Enhanced light absorption due to plasmonic scattering by the Ag NPs led to improved EQE. Near-field scanning optical microscopy was used to probe the higher degree of light scattering in plasmonic devices. Simulations with these Ag NPs also found a high ratio of forward light scattering to total scattering, which indicates minimum backward scattered power loss.

Advanced plasmonic nanostructures, such as NWs, nanogratings and nanocomposites, have also been successfully integrated into OSCs. Kang *et al.* (2010) used a Ag NW electrode configuration to enhance power conversion efficiency by SPR and waveguide effects. Further improvements can be made to raise the efficiency by adjusting the period of the Ag grating such that the enhanced spectral range matches the peak absorption in organic semiconductors, thus demonstrating the flexibility and potential when integrating plasmonic nanostructures. Improvements in device performance extends to the application of Ag nanogratings and Au NPs in a dual plasmonic nanostructured device, which revealed broadband absorption enhancement (Li *et al.*, 2012). The improved broadband light absorption was ascribed to the simultaneous effects of LSPR (Au NPs) and hybridized SPR (Ag nanogratings).

As discussed previously, far-field effects also exist when these advanced plasmonic nanostructures are incorporated into OSCs. In one study, hole-mask colloidal lithography was used to pattern the Ag rear electrode and MoO_x hole transport layer (Niesen *et al.*, 2013). The resultant nanostructured Ag electrode as shown in Fig. 12(a) was tuned by varying the size of the protrusions in the MoO_x layer to maximize light scattering due to the dipole LSPR at the red absorption tail of the poly(3-hexylthiophene-2,5-diyl):indene-C60 bisadduct (P3HT:ICBA) active layer. Systematic optimization of the optical interference pattern, when changing the dimensions of the optical spacer and plasmonic nanostructure, were essential in achieving the observed enhanced absorption

Fig. 12 (a) Scanning electron microscope (SEM) image of a nano-textured rear Ag electrode showing the different layers. Inset is the field profile in the active layer overlaid onto a section of the active layer and (b) I-V characteristics of flat reference devices with a 5-nm-thick MoO_x layer and the nanostructured device with a total MoO_x layer thickness of 135 nm with the increase attributed to light scattering.

(Fig. 12(b)). Importantly, it was noted that the near-field enhancement exists mainly within the MoO_x layer and, in that case, was not the cause of enhanced light absorption, rather the enhancement was the result of light scattering.

In general, it is often important to isolate the plasmonic nanostructures from the active layer. This is to avoid any metal assisted recombination or defects impacting the electrical properties of the cell. Another important consideration is also to avoid any parasitic losses in the metal that could compromise useful absorption. Plasmonic applications that rely on the near-field effect would need to address the trade-off between proximity of plasmon to the active absorber layer and electric field strength caused by SPR. The trade-off arises because it is advantageous to physically separate plasmonic nanostructures from the active layer to decrease surface recombination. However, the electric field enhancement provided by the plasmons decays exponentially with distance. Hence, there is an optimal physical separation to achieve high efficiency devices, which usually is ~ 20 nm in the vicinity of the particle. A systematic study of the near-field interaction between excitons and plasmonic metal NPs in OSCs found that far-field light scattering was not a significant consideration for the Ag NPs used in their study (Niesen *et al.*, 2012). As expected, the enhanced absorption from the near-field rapidly decreased when a spacer layer was introduced between the active layer and the NPs. In another experiment, Morfa *et al.* (2008) found that varying Ag film thickness affects the average J_{sc} and V_{oc} . It was suggested that the film thickness of the PEDOT:PSS layer should be limited as the electric field decays with distance.

Recent efforts in utilizing core-shell NPs have found promising results that both preserves the near-field and reduce surface recombination effects (Chen *et al.*, 2013; Janković *et al.*, 2013). A unique device structure for plasmonic OPV devices, that used large sized Au@SiO₂ NPs (50 nm SiO₂ shell and 70 nm Au core) which penetrated into all layers in the device had been successfully demonstrated (Chen *et al.*, 2013). The main contribution of the Au@SiO₂ NPs was reported to be LSPR effects from the Au NP core. Au-SiO₂ core-shell NRs can also be blended within the active layer to improve performance in poly[2,6-(4,4-bis-(2-ethylhexyl)-4H-cyclopenta [2,1-b;3,4-b']dithiophene)-alt-4,7(2,1,3-benzothia-diazole)]:[6,6]-phenyl-C70-butyric acid methyl ester (PCPDTBT:PC₇₀BM) OPV devices (Xu *et al.*, 2013).

The challenges of having the metal nanostructures incorporated into the device and the extent of understanding the physical mechanisms behind these effects have prompted many simulation studies. The studies attributed enhanced performance in plasmonic device to light concentration and redistribution of plasmons (Zhu *et al.*, 2012; Dunbar *et al.*, 2012), which can be further categorized depending on the positioning of plasmonic nanostructures: NPs dispersed in the active layer, nanostructured metallic electrode and in-scattering NPs. Simulations can be used to model light absorption and compared to a reference flat solar cell. The presence of the NPs provided an overall increase in absorption despite the reduction in absorption due to the omitted parts of the active layer. It is predicted that both scattering and near-field enhancement due to SPR are responsible for the broadband enhancement in light absorption. A simulation study has also analyzed the trade-off between absorption in the active layer as opposed to parasitic absorption in the near-field of the metal for the case of embedded spheres (Lee and Peumans 2010). The study showed that enhanced optical absorption results from strong scattering by a 10 nm Ag metal nanoparticle which locally enhances the optical electric fields. The enhancement extends to wavelengths longer than the plasmon resonance wavelength for which the losses in the metallic particles become insignificant.

A three-dimensional finite-difference time domain (FDTD) model is also commonly employed for simulation purposes. Using FDTD software, changes in metal NPs scattering cross-section, emission efficiency and far-field scattering pattern can be investigated by varying properties of a thin dielectric film around the NPs (Powell *et al.*, 2013). It is also imperative that the refractive indexes of materials within the device be considered when integrating metal NPs into OSCs. In particular, transparent conducting oxides, that frequently form the front contact in OPV devices, typically have large refractive indexes compared to the active layer. Hence, losses around the dipolar peak are expected due to the preferential light scattering into the higher index front contact.

Discussions on the progress in incorporating metallic nanostructures in OSCs and categorization of the physical mechanisms that led to improvements can be found in the literature (Choy, 2014). These improvements were found to originate from modifications of the optical or electrical properties in the OPV device. Changes in electrical properties, such as exciton dissociation,

charge carrier transport and charge extraction can also contribute to enhanced performance in plasmonic OSCs as mentioned earlier. Further discussions on the electrical effects of plasmonic OSCs can be found in the literature (Choy and Xingang, 2016; Chan *et al.*, 2016) and will not be discussed here.

Spacer Layer and Cavity Effects

Light harvesting by manipulating and optimizing the optical field can also be achieved via cavity effects or optical spacers. OSCs consist of many thin layers, each with a unique refractive index and thickness. (Burkhard *et al.*, 2010). Fig. 13 provides a schematic device structure, which includes a glass substrate, conducting oxide ITO electrode, thin electron transport layer (e.g., TiO_2), organic active layer (like P3HT:PCBM), a hole transport layer (e.g., MoO_3) and a reflective metal electrode (Ag).

As shown in Fig. 13, light enters the device through the glass substrate. Ideally, all the light would be absorbed in the active layer, however, in practice, this is not the case as mentioned before due to various losses. The light passes through the transparent electrode, some light is absorbed in the active layer, however, some light passes through and is reflected by the back electrode. Interference between the incoming and reflected light causes the optical field to go to zero at the reflective electrode. This leads to the formation of an optical field standing wave, of which the maximum and minimum will lie somewhere in the device. The nature of this optical field is determined by the refractive index and thickness of each layer.

It seems intuitive to simply increase the thickness of the active layer to maximize the absorption, however, the nature of the organic semiconductors places limitations on the film thickness. The optimum active layer film thickness is usually very thin, on the order of 100 nm, limited by the diffusion length of the excitons. Due to the limited film thickness, it is crucial to understand and optimize this optical interference effect.

As the maximum in the optical field is governed by the thickness and refractive index of the layers, it is possible to control the position of the maximum field by altering the device architecture. Including an additional layer to redistribute the optical field is called an optical spacer (Kim *et al.*, 2006). Fig. 14 describes the influence of an optical spacer. As shown, the insertion of a thin layer can shift the absorption maximum to better align with the active layer. It was shown that the insertion of a TiO_2 optical

Fig. 13 Schematic diagram of a device structure showing the many layers involved. ETL, electron transport layer; HTL, hole transport layer; ITO, indium tin oxide.

Fig. 14 Schematic representation of the optical field in an organic solar cell with and without an optical spacer. ITO, indium tin oxide; PEDOT, poly(3,4-ethylenedioxythiophene). Taken from Kim, J.Y., Kim, S.H., Lee, H.H., *et al.*, 2006. New architecture for high-efficiency polymer photovoltaic cells using solution-based titanium oxide as an optical spacer. *Advanced Materials* 18 (5), 572–576.

Fig. 15 Calculated short circuit current density (I_{sc}) as a function of active layer thickness for varying ZnO thicknesses. An assumption of 100% internal quantum efficiency (IQE) for all wavelengths was used. Reproduced from Gilot, J., Barbu, I., Wienk, M.M., Janssen, R.A.J., 2007. The use of ZnO as optical spacer in polymer solar cells: Theoretical and experimental study. *Applied Physics Letters* 91 (11), 113520.

spacer caused the power conversion efficiency to increase by 50% (relative) (Kim *et al.*, 2006). It is important to note that the optical spacer material must also serve a purpose electronically, as well as optically. For example, due to the spacer layer being part of the device, the photocatalytic property of TiO_2 under ultraviolet light can result in the breakdown of organic molecules limiting the lifetime of the device (Hiralal *et al.*, 2014). Hence the choice of the materials becomes important.

Gilot *et al.* (2007) used a ZnO layer as an optical spacer. They used transfer matrix modeling to calculate the optimum ZnO thickness, which would most effectively shift the optical field maximum into the active layer. They also calculated the maximum generated photocurrent (I_{sc}) as a function of active layer thickness, for varying ZnO layer thickness. This is displayed in Fig. 15. This clearly shows that the I_{sc} is not directly proportional to active layer thickness. The oscillations, causing maxima and minima, are due to the interference effects. By incorporating the ZnO optical spacer, the maxima are shifted to lower thicknesses. This positive influence of the optical spacer is more pronounced for thinner active layers.

Betancur *et al.* extend on this argument. They suggest that the position of the optical field maximum is dependent on the thickness of all layers in the device stack, not just the optical spacer (Betancur *et al.*, 2012). The device architecture, meaning the types of buffer layers used, which determines the direction of current flow, may also influence the optical field distribution. In another study it was suggested that an optical spacer will have much less impact on the photon absorption in an inverted structure device, when compared to conventional structure devices, which contain a PEDOT:PSS hole selective contact (Ameri *et al.*, 2008). In a study using ITO as spacer layer, it was found that although the degree of light absorption in inverted OPVs was not increased in such inverted structures, the favorable distribution of photogenerated excitons is expected to have decreased the level of exciton quenching near the electrodes (Chen *et al.*, 2010). Their results indicate that the inverted OPVs could still benefit from such optical effects when they had a sufficiently thick active layer. Subsequently there were studies that completely dismissed the idea of using spacer layer for increasing efficiency although the potential for increase was not ruled out for suboptimal thicknesses (Andersson *et al.*, 2009).

The nature of the interference effects also plays a role in the correct determination of the internal quantum efficiency (IQE) of an organic solar cell (Burkhard *et al.*, 2010). The IQE represents the wavelength dependent solar response for photons which are absorbed by the active layer; this parameter should be independent of the absorption profiles. Armin *et al.* showed that due to the nature of OSCs, optical interference and parasitic absorption in non-active layers must be considered to accurately determine the IQE (Armin *et al.*, 2014).

Another strategy adopted to help enhance the absorption in the thin photoactive layer is to incorporate a microcavity array into the device architecture. The concept of a microcavity design involves a resonator structure which consists of a spacer layer sandwiched between two reflectors (Chen *et al.*, 2014a,b). This allows for optical confinement due to the multiple reflections, significantly increasing the absorption path length of light with resonant frequencies. A normal OPV cell has a reflective back electrode; however, the front electrode is required to be transparent to allow light in. Such a structure behaves as an inefficient microcavity device, due to the limited reflection from the transparent electrode, which is most commonly ITO. This is made more complex as the two sandwiching layers must play a role in the electronic operation of the device, not only the optical confinement. To successfully harness this optical confinement technique, a precise trade-off between the transmission and reflection of the bottom electrode, to allow for light to enter the active layer and to enhance the multi-reflection optical confinement, respectively, must be understood.

To do so, the ITO layer was replaced. Studies have demonstrated an efficient device containing a microcavity structure by replacing the ITO with an ultrathin metal film (UTMF) and a capping layer which acted as an optical spacer (Chen *et al.*, 2014a,b; Sergeant *et al.*, 2013). The UTMF behaves as a semitransparent mirror enhancing lateral conductivity and reduce sheet resistance. One such modified device structure is shown schematically in Fig. 16. As shown, the light shines through the top, semitransparent

Fig. 16 Schematic depiction of (a) the traditional device structure, containing indium tin oxide (ITO), and (b) the microcavity configuration containing an ultrathin metal film (UTMF) and capping layer to increase the incoupling of light. In this device structure, the light is illuminated through the top electrode. ITO, indium tin oxide; PEDOT:PSS, poly(3,4-ethylenedioxythiophene):polystyrene sulfonate, PIDTT-DFBT, poly[(indacenodithieno[3,2-b]thiophene)-alt-difluorobenzothiadiazole]. Reproduced from Chen, K.-S., Yip, H.-L., Salinas, J.-F., *et al.*, 2014b. Strong photocurrent enhancements in highly efficient flexible organic solar cells by adopting a microcavity configuration. *Advanced Materials* 26 (20), 3349–3354.

electrode. The device contained an Ag UTMF and a TeO₂ capping layer. Compared to the reference, with an ITO electrode, the average efficiency increased from 7.21 to 8.47%, which was due mainly to the J_{sc} increase. This was attributed to the increased intensity in the EQE curve, caused by the resonance effect. In addition, a device employing a variation to this architecture was fabricated using a flexible PET substrate, with an efficiency of 8.37%, only slightly lower than that for the glass substrate. Huang *et al.* achieved higher performance by coupling a microcavity structure with a high performance bulk heterojunction (BHJ) blend of poly({4,8-bis[(2-ethylhexyl)oxy]benzo[1,2-b:4,5-b']dithiophene-2,6-diyl}{3-fluoro-2-[(2-ethylhexyl)-carbonyl]-thieno[3,4-b]thiophenediyl}) (PBDDT-F-TT):PC₇₁BM (Huang *et al.*, 2015). They also used an UTMF with a TeO₂ buffer layer to achieve the microcavity resonance. The best performing device achieved an efficiency of 10.4%. The enhancement mechanism was similar to that in reference (Chen *et al.*, 2014a,b), a broadband improvement in the EQE profile correlated with improved J_{sc} . The structure was also tested on large area devices. An efficiency of more than 7% was achieved for large area devices, due to a novel semitransparent electrode containing the UTMF. This electrode was shown to be much more applicable to large device areas, when compared with ITO. Additionally, it is advantageous to replace the ITO layer, as it represents the highest cost and embodied energy in thin film solar cells.

Other Approaches for Light Harvesting

The narrow absorption band of OPV limits the use of the wider solar spectrum for energy conversion. One way to circumvent this issue is the use of multijunction or tandem solar cells in stacks with each of the cells absorbing different parts of the spectrum. The concept of tandem cells was proposed as a third generation solar cell alternative to increase light harvesting for solar applications (Green, 2001). The structure consists of a high bandgap top cell absorbing the high energy photons and thereby transmitting the low energy photons to the subsequent bottom solar cells which is arranged in the order of decreasing bandgap through a transparent interconnecting layer. For series connected cells (i.e., contact is made between the top and bottom cell), the open circuit voltage (V_{oc}) of the tandem cell is the sum of V_{oc} of the subcells, while the overall current is limited by the subcell with the smaller current. This means that the cells need to be current matched. Another approach is a three (Sista *et al.*, 2010a,b) or four terminal configuration in a two cell stack that allows separate connections, which does not require current matching. In this device configuration the two subcells are connected in parallel through a common/separate semitransparent interlayer. Hence tandem cell approach allows light harvesting of a much wider spectrum of the solar radiation than what would be possible by a single junction solar cell.

With this strategy, tremendous efforts have been devoted to the development of desirable device configurations. The lack of high performance low bandgap polymer materials along with good interconnection layer has limited the performance of tandem cells (Kim *et al.*, 2007; You *et al.*, 2013; Sista *et al.*, 2010a,b). The interconnection layers mostly used semitransparent metal layers

that added to the complexity of device fabrication and caused undesirable parasitic absorption. One of the earlier reports was that of 6.5% performance conversion efficiency at 200 W/cm^2 from fully solution processed tandem cells comprising a transparent TiO_x layer between the front and bottom cell. It made use of an inverted structure with the low bandgap polymer-fullerene composite as the charge-separating layer in the front cell and the high band-gap polymer composite as the back cell (Kim *et al.*, 2007). While tandem solar cells benefit from complementary absorption spectra by utilizing different polymer materials for the sub cells, more recently an efficiency of 6.7% was reported from identical subcells based on P2F-DO:N2200, which the authors claim is among the highest efficiencies for an all polymer tandem solar cell and attributed to the enhanced absorption of the tandem cell (Yuan *et al.*, 2016).

More understanding and development of the technology has made further improvements possible with a power conversion efficiencies exceeding 11% for a triple junction solar cell (see Fig. 17(a) and (b)) (Chen *et al.*, 2014a,b) which was greater than the first certified efficiency of 10.6% from a double junction tandem from the same group (You *et al.*, 2013).

Tremendous efforts have been devoted to the development of desirable device configurations using the tandem strategy. One such structure, unlike the sequential deposited layers, consists of a folded V-structure, like the one previously mentioned for light trapping (Rim *et al.*, 2007). It also allows an alternative solution to the problem of assembling tandem and multiple junction solar cells in the micron to centimeter range. Here the single cells are reflecting the non-absorbed light upon another adjacent cell and by folding the cells spectrally toward each other like in Fig. 5(c) wherein spectral broadening and light trapping are combined (Tvingstedt *et al.*, 2007).

Photon absorption and reemission in a quantum dot (QD) layer is another scattering technique capable of light harnessing in a polymer layer. Whilst only in its conceptual stage, this method has the potential to increase absorption by 28% (Xu and Munday, 2014). Here high luminescence QDs are used to absorb photons and reemit to the waveguide modes, thereby changing the directionality of the incident photons to improve coupling in the active layer. Another method of light harnessing is when

Fig. 17 (a) Layers of a triple junction organic tandem solar cell arranged in decreasing order of bandgap (light incident from glass side), (b) measured external quantum efficiency (EQE) of device in (a) showing a wider use of the solar spectrum, (c) schematic of a luminescent concentrator with cells placed either on the side or on the bottom of the concentrator plate, (d) absorbance (dashed) and photoluminescence (solid) spectra of the concentrator plate. PEDOT:PSS, poly(3,4-ethylenedioxythiophene) polystyrene sulfonate; ITO, indium tin oxide; LBG:PC₇₁BM, low band gap:phenyl-C61-butyric acid methyl ester; P3HT:ICBA, poly(3-hexylthiophene-2,5-diyl):indene-C60 bisadduct. Images (a) and (b) taken from Chen, C.C., Chang, W.H., Yoshimura, K., *et al.*, 2014a. An efficient triple-junction polymer solar cell having a power conversion efficiency exceeding 11%. *Advanced Materials* 26, 5670–5677; (c) and (d) from Koeppel, R., Sariciftci, N.S., Büchtemann, A., 2007. Enhancing photon harvesting in organic solar cells with luminescent concentrators. *Applied Physics Letters* 90 (18), 181126.

luminescence concentrators are optically coupled to OSCs as shown in Fig. 17(c) where the solar cell can be placed either on the side or bottom of the concentrator plate. Luminescence concentrators use organic dyes with high photoluminescence quantum yields that concentrate and red shift the incident light (also called down conversion) and couples it to a waveguide. OSCs fabricated using zinc-phthalocyanine and C_{60} with the absorption in the 600–800 nm range, demonstrated photocurrent density increase from 8.5 to 10 mA/cm² by spectrally shifting the blue and green light (below 600 nm) toward the red when using such concentrators fixed to the cell (Koeppel *et al.*, 2007). Here the luminescence spectrum of the dye must overlap with the maximum in the conversion efficiency of the solar cell for optimum performance. The absorbance and emission spectrum of the concentrator plate used in the study in (Koeppel *et al.*, 2007) is shown in Fig. 17(d).

The wider implementation of low-cost OSCs relies on increasing the efficiency of this technology through material improvements and optical gains. With myriad promising opportunities available for light harvesting for OSCs, the challenge is in optimizing one or more techniques into the cell without compromising on the electrical gains and at the same time keeping the fabrication cost low. In depth understanding the physical mechanisms for each of these techniques along with its dependence on the material properties is hence critical. For metal-based structures the optical properties should always be considered along with its electrical properties of OSCs. The ultimate goal of light harnessing structures should be to increase the absolute absorption in the thin film layers and not necessarily approaching the efficiency limits (Tang *et al.*, 2014). More detailed light harnessing reviews are available for those interested in further reading (Tang *et al.*, 2014; Ou *et al.*, 2016; Wang *et al.*, 2014; Fei Guo *et al.*, 2014).

Conclusion

OSCs, due to the exciton diffusion bottleneck that limits charge carrier transport in such cells, are severely limited by the thickness of the active layer. This comes with challenges in absorption of light and hence requires efficient light harvesting schemes to minimize optical losses. Different light harnessing schemes were discussed that includes AR coatings, light trapping using dielectric and metallic structures, light concentration using plasmonics, cavity effects and also the tandem structures that make use of different parts of the solar spectrum using cell stacks of different bandgaps. While the poor absorption efficiency in such cells have limited this technology to be a major player in the photovoltaics market compared to Si and other emerging thin film technologies, OSCs that can offer cheap, light weight and pliable cells may see a bright future as technology improves. It is expected that this technology may not need to be a replacement technology to Si but has the potential to find its own niche market for example, on windows or electric vehicles which require light weight structures. However, irrespective of the application, efficiency improvements will be key and it can be foreseen that light harnessing will play a major role in the development of OSCs given the potential for remarkable improvements possible as discussed in this article.

Gain coefficient α ($\exp(\alpha z)$) [cm^{-1}]

Intensity/power density [kW cm^{-2}]

Optical gain [dB cm^{-1}]

Stimulated emission cross section [cm^2]

Waveguide propagation loss coefficient

γ ($\exp(-\gamma z)$) [cm^{-1}]

Wavelength [nm]

Conjugated Polymers

Plastics are widely used in low-cost optical components such as lenses, diffraction gratings, optical fibers, and adhesives. Their common use derives from a combination of qualities: good optical transmission, a wide range of mechanical properties and simple fabrication via molding, extrusion, or solution processing. Functional optical polymers, including liquid crystals and photorefractives, have also been widely applied to polarization control and for nonlinear- and electro-optics. Conjugated polymers are a remarkable class of functional plastics that exhibit some quite unusual properties. Firstly, they are plastics that can conduct electricity; and in fact are electrically semiconducting. Secondly, they are plastics that can be stimulated either optically or electrically to emit visible light.

These two unusual properties derive from a particular chemical structure specific to this family of plastics. In all conjugated polymers, the backbone of the molecule is a chain of carbon atoms joined by alternating single and double covalent bonds. The simplest example is illustrated in Fig. 1(a), which shows the chemical structure of the polymer poly(acetylene). Structural integrity of the polymer is provided by a string of single σ -bonds between adjacent carbon atoms. The additional bonding electrons in the double bonds are located in π -orbitals oriented perpendicular to the polymer chain. Adjacent π -orbitals overlap, and their electrons can be widely delocalized along the polymer backbone. The delocalized electrons can move relatively freely along the chain, giving the electronic properties of the material. The π -orbitals can be transformed between bonding and anti-bonding states by the absorption or emission of light, leading to strong optical transitions. While poly(acetylene) is a very inefficient light emitter, other conjugated polymers, notably those that include phenyl rings in the backbone (Fig. 1(b)–(d)), can be highly emissive. Photoluminescence quantum efficiencies approaching unity in solution and as high as 60% in the semiconducting solid state have been realised.

Organic Semiconductor Lasers

While organic dye lasers have been widely used since the mid-1960s, the history of organic semiconductor lasers is much more recent. Other than a few early observations of lasing in molecular crystals in the 1970s by Karl and others, the field of organic

Fig. 1 Chemical structures of several conjugated polymers: (a) poly[acetylene]; (b) poly[2-methoxy-5-(2'-ethylhexyloxy)-1,4-phenylene vinylene] (MEH-PPV); (c) ladder-type poly[1,4-phenylene] (MeLPPP); (d) poly[9,9-dioctylfluorene] (PFO).

Fig. 2 Photoluminescence spectra of three common conjugated polymers. With chemical structures inset.

semiconductor lasers began in earnest following the related discovery in 1990 by Burroughes *et al.* of electroluminescence in a conjugated polymer. In 1992, Moses demonstrated lasing for the first time in a solution of the conjugated polymer poly[2-methoxy-5-(2'-ethylhexyloxy)-1,4-phenylene vinylene] (MEH-PPV) (**Fig. 1(b)**). However, it was another 4 years – once material synthesis had been sufficiently refined – before stimulated emission and then true laser action were observed in polymers in the semiconducting solid state. In the following year the first demonstrations were made of dye-doped small molecular semiconductor lasers. Since that time, there has been a great growth in interest in the field with an average of ~ 30 research papers per year. Further details of the development of the field of organic semiconductor lasers can be found in the bibliography.

So, what are the particular properties of conjugated polymers that have stimulated interest in developing organic semiconductor lasers? Firstly these materials are broadband visible emitters. Through appropriate chemical design, their emission can be tuned throughout the visible spectrum, from 400 to 700 nm (**Fig. 2**). The polymers exhibit large optical gain coefficients, because the optical transitions are dipole-allowed. Compared with small molecular dyes, polymers exhibit a relatively low degree of self-absorption of the emitted light, and much reduced quenching of the luminescence with increased concentration. This means that it is possible to work with much higher chromophore densities than conventional laser dyes, which is advantageous for achieving very low threshold lasing in extremely compact resonators. Furthermore, because these materials are semiconducting, they have the potential for direct electrical excitation. This could lead to semiconductor diode lasers operating throughout the visible spectrum and, in particular, in the blue and green spectral bands where currently there are few commercially-viable inorganic semiconductor sources. Finally, these materials are plastics and so are amenable to simple processing, and can be shaped and structured into complex feedback resonators.

Organic Semiconductor Gain Materials

A great advantage of organic laser media is that a very wide range of materials can be readily synthesized, and through minor changes in the molecular structure one can relatively simply tune the emission properties of the material. Many different organic semiconductors have been applied as lasers, though they fall into three major categories. These are conjugated polymers, dye-doped small molecular semiconductors and molecular single crystals. Conjugated polymers make up the most diverse materials set, most notably including derivatives of poly(paraphenylene-vinylene), poly(paraphenylene) and poly(fluorene) (**Fig. 1(b)–(d)**). The second category comprises small molecular semiconductors that are co-evaporated under vacuum with a dopant laser dye. In this blend of materials, the organic semiconductor functions simply as an energy transfer host for the emitting dye molecules. In the third category are organic single crystals, including materials, such as polyacenes and thiophene oligomers. These materials have the advantage of having the highest electrical mobilities of any organic semiconductors, which is important for electrical excitation. However, they can be demanding to grow into high quality single crystals, and so lack the key processing advantages of the other families of organic semiconductors.

Fig. 3(a) shows a typical energy level structure of a semiconducting polymer. Similar to a conventional laser dye, the energy levels comprise a manifold of singlet states and a manifold of triplet states, each with vibrational sublevels. The laser transition occurs from the bottom of the first excited singlet state S_1 to the vibronic overtones of the ground state S_0 , so forming a classic 4-level laser system. The optical transition is dipole-allowed and so has a high oscillator strength. As a result conjugated polymers typically exhibit simulated emission cross sections in the range 10^{-16} – 10^{-15} cm², while the population inversion lifetime is as short as a few hundred picoseconds.

There are, however, several other transitions that can compete with the stimulated emission process. There can be excited-state absorption from the S_1 singlet state into higher lying singlet states. Additionally intersystem crossing from the S_1 state to the lowest excited triplet state T_1 can subsequently lead to excited triplet absorption. Other processes in the polymer can also impede the

Fig. 3 (a) Generic energy level structure and optical transitions of a conjugated polymer. S_N refers to the N th singlet state, T_N refers to the N th triplet state; (b) absorption and photoluminescence spectra of the polymer poly[2-methoxy-5-(2'-ethylhexyloxy)-1,4-phenylene vinylene] (MEH-PPV). ISC, intersystem crossing.

stimulated emission. Firstly, charged excitations can exhibit absorption bands that overlap with the emission. Secondly, at high excitation densities, exciton-exciton annihilation can significantly deplete the excited states available for stimulated emission. Ultimately, singlet-singlet annihilation is the limiting factor for the maximum excitation density possible, and while polymer films can have a repeat-unit density of $\sim 10^{21} \text{ cm}^{-3}$ the excited state density is typically limited to around 10^{18} cm^{-3} . In many materials this is not restrictive on achieving optical gain because stimulated emission can occur at densities of 10^{17} cm^{-3} and below.

An important factor that distinguishes the photo-physics of semiconducting polymers from conventional laser dyes is an internal process of exciton migration between the absorption and emission of a photon. Excitations are confined to short straight sections of the polymer between kinks or twists in the chain. These straight sections, or "sites," are typically of a few repeat units in length, though there is a statistical spread of site lengths in any given material. When formed, excitons tend to hop to the longest, lowest energy, sites before emitting a photon. The exciton migration process has two effects. Firstly it means the emission takes place from a subset of the chain segments, resulting in a lower degree of inhomogeneous broadening of the emission spectrum (vibronic peaks are better resolved than in absorption – see Fig. 3(b)). Secondly the peaks of the absorption and emission spectra tend to be widely separated in wavelength, reducing the level of self-absorption at the lasing wavelength.

As mentioned before, blending materials is a particularly attractive approach toward further reducing self-absorption in organic semiconductor lasers. In such systems, a narrow band-gap dopant chromophore is blended with a concentration of 1–2% in a wider band-gap semiconducting host. Emission from the host is strongly quenched via nonradiative Förster energy transfer to the guest molecule. The blended material exhibits an absorption profile that is dominated by the host absorption, while the emission profile is almost completely that of the guest dopant. By strongly separating the emission peak from the absorption edge of the host it is possible to achieve a substantially reduced (by perhaps an order of magnitude or more) residual absorption coefficient at the lasing wavelength. In doing so, the combined material acts much more like an ideal 4-level laser medium and can thereby have substantially lower pump thresholds for stimulated emission.

Measuring Gain

The dynamics of the excited state population in semiconducting polymers have been widely studied using femtosecond transient absorption experiments. This is a pump-probe technique in which the transmission of the broadband probe pulse is compared in the presence and absence of a pump pulse that excites molecules into the first excited state. Such measurements have the time resolution of the pump pulses used and so can typically be ~ 100 fs. By systematically delaying the arrival of the broadband probe pulse it is possible to map out the evolution of the gain dynamics across the emission spectrum of the material with very high time resolution.

Fig. 4 shows a series of snapshots of the absorption induced by a pumping pulse in a poly(thiophene) derivative. This figure shows the changing absorption of the sample between 200 fs and 400 ps after excitation. Within the absorption band of the material, one finds that the level of absorption is slightly reduced because the pump pulse has partly depleted the ground state. In the emission band there is also a reduction in the absorption that mimics in shape the photoluminescence spectrum of the polymer. This negative absorption- or optical-gain shows direct evidence for stimulated emission through much of the emission band. In the low energy tail of the emission, however, there is an increase in absorption that arises due to the excited-state absorption process mentioned earlier. Clearly, for a good laser material, the spectra of excited-state and charge-induced absorptions should overlap as little as possible with the photoluminescence.

Many other investigations of gain in semiconducting polymer films have used a phenomenon known as spectral line narrowing to explore indirectly the amplifying properties of the medium. The experimental procedure for such studies is as follows. A thin

film of the semiconducting material, of typically 100 nm thickness, is excited by a pulsed pump laser focused to a stripe of dimensions $\sim 100 \mu\text{m}$ wide by a few millimeters in length. A significant fraction of the light emitted by the material is trapped in the film by total internal reflection at the polymer–air and polymer–substrate interfaces, and is thereby waveguided along the length of the excitation stripe. This waveguided spontaneous emission can be amplified by stimulated emission before being emitted out the edge of the film.

One finds that, above a particular threshold of pump energy, there is a superlinear increase in the output energy with pump intensity. Associated with this is a dramatic narrowing of the broad emission spectrum to a linewidth of typically less than 10 nm, as illustrated in **Fig. 5**. These two features are signatures of gain narrowing via the process of amplified spontaneous emission. The line-narrowed feature usually appears at the first vibronic overtone, of the optical transition, where the gain exceeds the losses in the material by the greatest amount. This particular wavelength experiences the greatest amplification and, above a particular pumping density, undergoes a runaway effect in which most of the light is stimulated to emit at that wavelength at the expense of the rest of the spectrum.

In the case of amplified spontaneous emission or mirrorless lasing as it is also known, the spontaneous emission guided along the length of the stripe acts as the “probe pulse.” In these experiments it is therefore necessary to extract information indirectly about the net gain in the material. By integrating the spontaneous and stimulated emission along the length of the stripe one finds that the wavelength-dependent output intensity $I(\lambda)$ of the spectral line narrowed light is given by the relationship

$$I(\lambda) \propto \frac{1}{g(\lambda)} [\exp[g(\lambda)l] - 1]$$

where I_p is pumping intensity, l is the length of the stripe, and $g(\lambda)$ is the net gain coefficient. Therefore, by monitoring the intensity of the line-narrowed emission as a function of the length of the pump stripe, one can extract the value of the net gain for the material. Similarly, by progressively moving the stripe further and further away from the edge of the film, it is possible to evaluate the waveguide losses of light propagating through an unpumped region of the waveguide. Waveguide losses in conjugated polymers typically lie in the range of 3–50 cm⁻¹. Net gains can be as high as 60 cm⁻¹ or 260 dB cm⁻¹ at modest pumping densities of 4 kW cm⁻². These substantial gains in very small propagation lengths therefore highlight the attraction of waveguide-based resonators for polymer lasers. In the next section we will discuss the most commonly used feedback structures that have been used for polymer lasers.

Polymer Laser Resonators

The first demonstration of cavity lasing in a conjugated polymer was made by Moses in 1992. The resonator consisted simply of Fresnel reflections from the walls of the glass cuvette containing the polymer in solution. Lasing occurred at the peak wavelength of the gain profile. Subsequent developments in solid-state polymer lasers have involved more sophisticated resonators that exploit the capacity of these materials for very simple processing. For example, solution-processing methods such as spin-casting or dip-coating, make it possible to fabricate very high quality optical waveguides. Wavelength-scale microstructures can also be readily formed allowing the straightforward fabrication of laser microresonators.

Many different resonators have been explored for solid-state polymer lasers. Some of the key types are shown in Fig. 6, including different geometries of both microcavities and distributed feedback (DFB) structures. The first resonator used, by Tessler *et al.*, was a planar microcavity (Fig. 6(a)) in which the polymer film was sandwiched between two mirrors. The structure supported standing-wave resonances perpendicular to the plane of the film, at three wavelengths in the emission band of the polymer. Above laser threshold, light was preferentially stimulated into only one of these modes. Microcavities of other geometries have also been studied, including annular and spherical microresonators (Fig. 6(b) and (c)) in which the optical field is confined in waveguide modes, whispering gallery modes, or a superposition of the two. Such structures provide a longer interaction length in the gain medium for stimulated emission; though tend to lase on many longitudinal modes and have no directional output beam.

The final key group of resonators are DFB structures, which researchers have progressively favoured to attain the low pump threshold densities that will be required to realize electrically pumped lasing. Fig. 6(d) shows a typical DFB laser structure. The device is based on a thin polymer film that is typically 100 nm in thickness deposited on top of a silica substrate. The silica–polymer–air structure forms an asymmetric slab waveguide that supports only the lowest order transverse electric mode TE₀. To provide the feedback, the substrate is modulated with a wavelength-scale periodic grating structure. These corrugations give rise to Bragg scattering of the waveguide mode. Through careful selection of the grating period one may arrange that optical wavelengths close to the peak of the polymer gain will be Bragg scattered from the propagating TE₀ mode to the counter-propagating TE₀ mode. This is achieved when Bragg equation

$$2n_{\text{eff}}\Lambda = m\lambda_B,$$

is satisfied, where Λ is the grating period, n_{eff} is the effective refractive index of the waveguide, m is an integer and λ_B is Bragg wavelength. In so doing one may arrange that two counter-propagating waveguide modes can be coupled together thereby providing the distributed resonant feedback for the laser process. Commonly in semiconducting polymer lasers, a second order (i.e., $m=2$) Bragg grating has been favoured to provide the feedback for the laser, so that the first order scattering provides a surface-emitted output coupling, perpendicular to the plane of the guide. This surface-emitting geometry is particularly attractive in polymer lasers because it is relatively difficult to achieve a high optical quality edge to the waveguide. DFB lasers have the

Fig. 6 Resonators used for conjugated polymer lasers. (a) Planar microcavity; (b) annular microcavity; (c) spherical microcavity; (d) distributed feedback (DFB) resonator; (e) 2-D DFB/photonic crystal resonator; (f) random laser.

advantage over simple microcavity resonators in that they can combine long interaction lengths, limited by the scattering length of Bragg grating, with excellent wavelength selection, which is controlled by the grating period.

In addition to conventional 1-D DFB gratings, a number of more exotic 2-D and 3-D DFB, and photonic crystal resonators have been explored in semiconducting polymers. Even randomly located scattering sites in a polymer film have been used to provide a weak closed-loop cavity feedback. Examples of 2-D gratings are given in **Fig. 7**, which shows atomic force micrographs of an eggbox structure, formed from two orthogonal gratings, and a circular DFB grating. Such 2-D DFB structures can significantly improve the operation of surface-emitting polymer lasers compared with 1-D gratings. Improved feedback yields lower oscillation thresholds, combined with higher slope efficiencies and significantly improved beam quality. Indeed such surface emitting DFB lasers can produce nearly diffraction limited laser beams.

Typical operating characteristics of an egg-box DFB polymer laser are shown in **Fig. 8**. This laser, which is based on the material MEH-PPV, is transversely pumped with a pulsed pump laser focussed onto a small region of the waveguide; up to 90% of the incident pump light is absorbed in the 100 nm thick film. The laser has a threshold pump energy of 4 nJ and an external slope efficiency of $> 7\%$, and operates on a single frequency close to Bragg wavelength of the periodic waveguide. Lasing does not occur exactly at Bragg wavelength because at this wavelength the propagation of light is suppressed by the periodic structure. This leads to a photonic stopband within which the emission is reduced. At the edges of this stopband the microstructure can support standing wave electric field patterns of the same spatial period. At these wavelengths there can be a strong interaction between the electric field and excited states in the gain medium, which leads to low threshold band edge lasing as observed in the figure.

Although DFB resonators have advantages over microcavity devices, the complicated lithographic and etching steps involved in their fabrication can detract from the key material advantage of simple processing. To address this issue several different techniques for simply replicating the complicated microstructures have been explored. These include UV embossing of flexible plastic substrates, and hot embossing and micromoulding of the active polymer itself. Such techniques can very readily reproduce structures with feature sizes as small as 100 nm and could allow future mass production of photonic microstructures in these materials.

Towards Plastic Diode Lasers

A typical experimental configuration for characterising optically pumped polymer lasers is shown in **Fig. 9**. The laser is mounted in a vacuum chamber in order to isolate the polymer from oxygen and water. A pulsed visible or ultraviolet pump laser is attenuated and then focussed onto the waveguide to transversely pump the polymer laser. The emission is collected using a charge-coupled device (CCD) spectrograph for spectral measurements and energy meter and beam profilers for other characteristics. Typical pulsed pump lasers which have been used include nitrogen laser pumped dye lasers, and spectral harmonics of regeneratively amplified Ti^{3+} -sapphire lasers or flashlamp pumped Nd^{3+} :YAG lasers. Recent advances have shown the thresholds to be low enough to be successfully pumped with a modest Nd^{3+} pulsed microchip laser.

So while optically pumped polymer lasers are now proving to be compact, functional light sources, a major motivation for research in this field remains the prospect of electrically driven plastic diode lasers. Such lasers could be very low cost, flexible light sources that would access any wavelength throughout the visible spectrum. In particular, there are exciting prospects of producing blue and green diode lasers in spectral regions currently difficult to access with inorganic semiconductors. The lowest threshold densities reported for optically pumped organic semiconductor lasers are of the order of 100 W cm^{-2} . To achieve similar excitation densities electrically, one requires pump current densities of $\sim 200 \text{ A cm}^{-2}$. This is substantially more than the few milliampere per square centimeter commonly used in polymer light-emitting diodes (LEDs) for display applications. Presently, such high current densities are infeasible with continuous excitation, but can be exceeded with short current pulses of a few tens of nanoseconds duration.

Fig. 9 Schematic of a typical experimental configuration for characterising polymer lasers. CCD, charge-coupled device.

Electroluminescence in conjugated polymers was first achieved in 1990 by Burroughes and coworkers. Since that time there has been remarkable progress made in the science and technology of organic LEDs. Commercial products are now on the market, and the feasibility of both flexible and full color light emitting displays, in which the individual pixels have been ink-jet printed, have been demonstrated in the laboratory. Despite such rapid progress in the field of organic LEDs, there have been no successful demonstrations to date of electrically pumped lasing in any organic semiconductor. In this section we highlight some of the challenges that must be faced if electrically pumped lasing is to be achieved. To understand the problems associated with electrical driving of organic semiconductor lasers it is useful first to review the generic structure of organic light emitting diodes.

A generic organic LED structure is shown in **Fig. 10**. The device consists of one or more organic layers sandwiched between two electrical contacts. Usually a transparent anode is used, commonly made from indium tin oxide (ITO), which allows light to be emitted from the front face of the LED. A low work-function metal such as calcium or aluminum is used as the cathode. The

Fig. 10 Schematic structure of a generic organic light emitting diode.

organic part of the device may consist of several layers. These include one or more charge transport layers, plus a light-emitting layer in which the electrons and holes combine to form excitons before emitting light. Typically, the combined thickness of these organic layers is as little as 100 nm. Such thin devices are necessary to keep operating voltages low, to overcome potential barriers for injection and because charge mobilities in organic semiconductors are very low (10^{-5} – 10^{-2} cm² V⁻¹ s⁻¹).

The inclusion of electrical contacts into organic semiconductor laser structures can be problematic since they need to be situated very close to the emitting region. Metallic contacts can quench the luminescence and introduce losses to the waveguide mode, thereby increasing the oscillation thresholds. Furthermore, the ITO anode has a high refractive index and so can reduce the spatial overlap of the guided mode with the active medium. Such issues indicate that the design of organic LEDs needs to be somewhat modified for achieving electrically pumped lasing. In particular, there needs to be a trade-off between the optimum electronic and photonic designs. To address these issues various device structures have been proposed that distance the optical mode from metallic contacts, while reducing the thickness of the ITO layer to optimize the mode confinement in the active material.

A more demanding obstacle to electrically pumped lasing is the additional excited state absorption associated with the electrical pumping scheme. As many as three quarters of the generated excitons in an organic LED are formed in the triplet state which is non-emissive and can lead to excited-state absorption, albeit principally at lower energies than the lasing wavelength. Additionally, injected charges that have not yet formed excitons exhibit strong absorption, which overlaps significantly with the peak of the material gain. Indeed, this charge-induced absorption has so far prevented the demonstration of injection lasing in conjugated polymers, even in optimized device structures mentioned above. A possible alternative route for efficient pumping of polymer lasers could be through indirect electrical pumping. For example, an inorganic diode laser or LED, or even an organic LED, could be used as an electrically efficient optical pump for the semiconducting polymer laser. Recent advances in GaN-based LEDs and lasers provide interesting prospects for such alternative systems.

Research on semiconducting polymer lasers keenly continues, both to reduce the excitation densities needed for threshold and to investigate new material systems that could overcome the obstacle of charge-induced absorption. By building on recent developments in resonator geometries, material blends and compact pumping schemes, semiconducting polymer laser systems, whether optically or electrically pumped, should soon become practical, visible light sources for a range of applications.

Organic Photodetectors

Jaehoon Jeong, Hwajeong Kim, and Youngkyoo Kim, Kyungpook National University, Daegu, Republic of Korea

© 2018 Elsevier Ltd. All rights reserved.

Introduction

Organic photodetector is an optoelectronic device that can sense light with organic semiconducting materials, which typically feature pi-conjugated molecular structures, and convert it to electrical signals. The sensing range of organic photodetectors is basically dependent on the optical absorption spectra of organic semiconducting materials. Various organic semiconducting materials including small molecules and polymers can be used as a light-sensing layer in organic photodetectors.

Two types of device structures, diode and transistor, are generally employed for the fabrication of organic photodetectors. It is noted that transistors here mean “field-effect transistors.” The diode structure leading to organic photodiodes has organic sensing layers (OSLs) between two electrodes, while the transistor structure leading to organic phototransistors includes additional electrode for gate control in the presence of organic layers and two counter electrodes. Therefore, organic photodiodes are in principle much simpler than organic phototransistors in terms of device structure and fabrication process. In contrast to organic photodiodes, however, organic phototransistors benefit signal amplifications by adjusting the gate voltage and enable active-matrix sensor arrays for two-dimensional images.

Organic photodetectors, both organic photodiodes and organic phototransistors, can be fabricated using wet-coating processes such as ink-jet printing, screen printing, gravure printing, spray coating, slot-die coating, etc. at low temperatures. In addition, flexible plastic films, such as poly(ethylene naphthalate) (PEN) and poly(ethylene terephthalate) (PET), can be applied as a substrate for the fabrication of organic photodetectors. These benefits enable organic photodetectors to be manufactured with continuous roll-to-roll processes leading to low-cost advantages.

Device Structure and Mechanism

Organic Photodiodes

Organic photodiodes consist of two electrodes and OSLs between the two electrodes (Fig. 1(a)). As shown in Fig. 1(b), the charges (holes and electrons) generated by incoming photons transport to corresponding electrodes due to the built-in potential made at short circuit condition. The OSLs can be composed of single materials, either p-type or n-type organic semiconductors,

Fig. 1 (a) Typical device structures for organic photodiodes consisting of (left) single organic sensing layer (OSL) between anode and cathode and (right) with additional hole-collecting buffer layer (HCBL) and electron-collecting buffer layer (ECBL). (b) Simplified energy band diagrams for the sensing mechanism in organic photodiodes with single OSL (refer to the left structure in (a)).

(b) Energy band diagram for organic phototransistors (p-type): (left) no electric field condition in the dark, (middle) under a field-effect condition in the dark (ϕ_h : hole injection barrier), (right) light illumination under a field-effect condition. V_{GS} and V_{DS} denote gate voltage and drain voltage, respectively.

as shown in Fig. 2(a). However, p–n junction structures are required in order to enhance the photosensitivity of devices. The simple bilayer structure can be easily prepared by employing multilayer coatings even though orthogonal solvents are essential for preparing solutions for each layer in the case of wet-coating processes (Fig. 2(b)). Considering the contact area between p-type and n-type organic semiconducting layers, the simple bilayer structure has an intrinsic limitation in the number of p–n junctions. As shown in Fig. 2(c), an interdigitated bilayer structure is expected to provide ideal p–n junctions. Unfortunately, however, the interdigitated bilayer structure on a scale of a few nanometers cannot be easily fabricated with current coating technology. Alternatively, bulk heterojunction structures are considered to deliver high photosensitivity because numerous p–n junctions are made intimately in the mixture (blend) of p-type and n-type organic semiconducting materials (Fig. 2(d)).

Organic Phototransistors

Organic phototransistors are different from organic photodiodes in the point that gate electrodes are required for the control of devices (Fig. 3(a)). Four types of organic phototransistors can be fabricated according to the position of electrodes. In general, the source and drain electrodes exist in parallel with the film plane of organic sensing channel layers. As shown in Fig. 3(b), very low charge transport (current flow) in the dark are measured when voltages (biases) are applied between source and drain electrodes in the absence of applying voltages between source and gate electrodes. Applying voltages to the gate electrodes creates field-effect charges in organic channel layers, which contributes to the increased charge transport between source and drain electrodes. Here, when light shines to the channel part of organic sensing channel layers, photons generate excitons that in turn dissociate into individual charges (electrons and holes). Therefore, the photo-generated charges are added to the field-effect charges, which are measured at the same time.

Fig. 4 Illustration for the cross-sections of organic phototransistors: (a) single sensing layer (either p-type or n-type organic semiconductors) and (b) bulk heterojunction layer (mixture of p-type and n-type organic semiconductors). GIL, gate-insulating layer.

Fig. 6 Output (top) and transfer (bottom) curves for representative organic phototransistors with p-type organic sensing layers (OSLs) according to the incident light intensity (P_{IN}).

In terms of organic sensing channel layers, a variety of material combinations are possible but a single layer structure is basically applied as used for typical organic transistors. The single sensing channel layer is typically composed of one kind of organic semiconducting materials (either p-type or n-type). However, as explained for organic photodiodes, bulk heterojunction-type sensing channel layers can deliver enhanced photosensitivity because of the benefit of bulk heterojunctions leading to efficient charge separation. In addition, the bulk heterojunction-type sensing channel layers can take further advantages in tuning the sensing wavelengths by controlling the composition of p-type and n-type organic semiconducting materials with different absorption spectral ranges (Fig. 4).

Photosensitivity (Responsivity) of Organic Photodetectors

The photosensitivity (or responsivity, R) of organic photodetectors is defined by the ratio of net photocurrent density (J_P) to incident light intensity (P_{IN}), as given by Eq. (1). The net photocurrent density is obtained by subtracting the dark current density (J_D) from the whole current density under light (J_L) (see Fig. 5). It is noted that the unit of current density and incident light intensity is typically expressed as milliamperere per square centimeter and watt per square centimeter, respectively. Thus the unit of responsivity becomes A/W.

$$R = \frac{J_P}{P_{IN}} [\text{A/W}] \quad (1)$$

In addition, signal-to-noise (S/N) ratios are frequently used to understand the effect of background noises made in photodetectors. The S/N ratio is defined by the ratio of photocurrent density to dark current density. Further detailed approach is to

employ specific detectivity (D^*) that represents a figure of merit for photodetectors. As shown in Eq. (2), the specific detectivity is expressed by the ratio of responsivity (R and active area (A)) to noise spectral density (S_n).

$$D^* = \frac{R \cdot \sqrt{A}}{S_n} \text{ [Jones]} \quad (2)$$

The responsivity of organic photodiodes can be simply calculated using Eq. (1) from current density–voltage (J – V) curves as illustrated in Fig. 5. However, organic phototransistors provide two types of current–voltage curves, output and transfer curves, as shown in Fig. 6. Output curves are useful to get responsivity depending on drain voltage at a fixed gate voltage, while transfer curves can be employed to calculate the gate voltage-dependent responsivity at a fixed drain voltage. A particular attention needs to be paid for the measurement of photocurrent because the active area is too small to block with a shadow mask if the incident light comes directly to the sensing channel layers but the source/drain electrodes are unable to block the incident light owing to their positions.

Organic Photodiodes With Small Molecules

Organic Layer – Single Material

Various types of small molecules have been used for the fabrication of organic photodiodes with OSLs composed of single material. As shown in Fig. 7, pentacene and phthalocyanines were used as a p-type small molecule, while fullerene (C_{60}) and perylene derivatives were employed as an n-type small molecule. Most of small molecules have been deposited by thermal evaporation in vacuum, but soluble small molecules such as [6,6]-phenyl- C_{61} -butyric acid methyl ester ($PC_{61}BM$) can be coated from solutions. Lee *et al.* (2004) reported pentacene photodiodes (Schottky type) that could measure spectral photoresponses from 325 to 650 nm at zero bias condition. Voz *et al.* (2007) demonstrated fullerene devices of which the rectifying behavior could

Fig. 7 p-type and n-type small molecules used for organic sensing layers (OSLs) in organic photodiodes: pentacene, 3,4,9,10-perylenetetracarboxylic bisbenzimidazole (PTCBI), fullerene (C_{60}), [6,6]-phenyl- C_{61} -butyric acid methyl ester ($PC_{61}BM$), copper phthalocyanine (CuPc), and lead phthalocyanine (PbPc).

Fig. 8 (a) (top) Device structure and materials used for the fabrication of organic photodiodes with the EHTPPD-MT:PC₆₁BM (1:2) BHJ layers, (bottom) flat energy band diagram for the device (note that minus “-” sign and “eV” unit were omitted for clarity). (b) Corrected responsivity (R_c) as a function of the incident light intensity (P_{IN}) under illumination with near UV (405 nm), green (532 nm), and red (650 nm) lights. (Copyright 2015 Royal Society of Chemistry).

be improved by inserting a conducting polymer interlayer. The performance of organic photodiodes was noticeably improved by employing small molecular p–n junction structures. Peumans *et al.* (2000) reported bilayer-type organic photodiodes using copper phthalocyanine (CuPc) and 3,4,9,10-perylene-tetracarboxylic bisbenzimidazole (PTCBI) as a p-type and an n-type small molecule, respectively. However, the bilayer-type devices have a limitation in improving the device performances because of short exciton diffusion lengths in organic layers.

Organic Layer – Bulk Heterojunction

In this regard, organic bulk heterojunction structures were suggested as an alternative approach. Peumans *et al.* (2003) reported organic photodiodes based on CuPc:PTCBI bulk heterojunction layers, which showed controllable device performances by applying thermal annealing treatment leading to internal crystallization in bulk heterojunction films. Sullivan *et al.* (2004) demonstrated organic photodiodes based on CuPc:C₆₀ bulk heterojunction films in which exciton dissociations could be improved due to the intermolecular mixing between p-type (CuPc) and n-type (C₆₀) molecules. Panchromatic organic photodiodes based on the bulk heterojunction films of lead phthalocyanine (PbPc) and fullerene (C₇₀), which can detect broadband lights from 300 to 1000 nm, have been reported by Su *et al.* (2015). As shown in Fig. 8, Lee *et al.* (2015) reported solution-processed all-small molecular organic photodiodes, using solutions of 2,5-bis(2-ethylhexyl)-3,6-bis(4'-methyl-[2,2'-bithiophen]-5-yl)pyrrolo[3,4-c]pyrrole-1,4(2H,5H)-dione (EHTPPD-MT) and PC₆₁BM, which could sense near ultraviolet (UV, 405 nm) and broad visible light (up to 650 nm).

Organic Photodiodes With Polymers

Organic Layer – Single Material

Semiconducting polymers have been more extensively studied than small molecules because of their potentials for real plastic photodetectors with tough and rugged characteristics. Harrison *et al.* (1997) studied the thickness-dependent photo-generation characteristics for organic photodiodes with poly[2-methoxy-5-(2-ethylhexyloxy)-1,4-phenylenevinylene] (MEH-PPV) films.

Polymer nanowire photodiodes with poly[(9,9-dioctylfluorenyl-2,7-diyl)-*co*-(bi-thiophene)] (F8T2) films have been reported by O'Brien *et al.* (2006); Ray *et al.* (2015) tried to fabricate organic photodiodes with poly(3-hexylthiophene) (P3HT) films and tried to explain the collection-limited theory for extraordinary responses.

Organic Layer – Bulk Heterojunction

Nalwa *et al.* (2010) reported organic photodiodes based on the P3HT:PC₆₁BM bulk heterojunction films and applied for chemical sensors that could sense gas-phase oxygen and glucose. The similar P3HT:PC₆₁BM photodiodes, which were fabricated by Liu *et al.* (2015) who applied transparent conductive electrodes composed of graphene/PEDOT:PSS hybrid inks, exhibited excellent sensitivity in the wavelength range between 300 and 650 nm (see Fig. 9). Saracco *et al.* (2013) reported organic photodiodes with the bulk heterojunction layers of poly[(4,8-bis-(2-ethylhexyloxy)-benzo[1,2-b:4,5-b']dithiophene)-2,6-diyl-*alt*-(4-(2-ethylhexanoyl)-thieno[3,4-b]thiophene)-2,6-diyl] (PBDTTT-C) and PC₇₁BM, which exhibited the effective role of very thin polymeric interfacial layer for achieving homogenous interfaces leading to considerably low dark current by preventing undesired charge injection from cathodes in the devices. Armin *et al.* (2015) proposed new concept called charge collection narrowing (CCN)

Fig. 10 Semiconducting (conjugated) polymers used for organic photodiodes: poly[2-methoxy-5-(2-ethylhexyloxy)-1,4-phenylenevinylene] (MEH-PPV), poly(3-hexylthiophene) (P3HT), poly[(4,8-bis-(2-ethylhexyloxy)-benzo[1,2-b:4,5-b']dithiophene)-2,6-diyl-*alt*-(4-(2-ethylhexanoyl)-thieno[3,4-b]thiophene)-2,6-diyl] (PBDTTT-C), poly[2,5-bis(2-octyldodecyl)-3,6-diketopyrrolopyrrole-*alt*-5,5'-(2,5-di(thien-2-yl)thieno[3,2-b]thiophene)] (DPP-DTT), and poly[N-9'-heptadecanyl-2,7-carbazole-*alt*-5,5'-(4',7'-di-2-thienyl-2',1',3'-benzothiadiazole)] (PCDTBT).

in organic photodiodes fabricated with the bulk heterojunction layers of poly[2,5-(2-octyldodecyl)-3,6-diketopyrrolopyrrole-*alt*-5,5'-(2,5-di(thien-2-yl)thieno[3,2-b]thiophene)] (DPP-DTT) or poly[*N*-9'-heptadecanyl-2,7-carbazole-*alt*-5,5'-(4',7'-di-2-thienyl-2',1',3'-benzothiadiazole)] (PCDTBT) and PC₇₁BM. Some examples of semiconducting (conjugated) polymers for organic photodiodes are listed in Fig. 10.

Organic Phototransistors With Small Molecules

Organic Layer – Single Material

Organic phototransistors with two types of organic thin-films (pentacene and tetracene), which exhibited photoresponses in both UV and visible ranges, were reported by Choi *et al.* (2006); Qi *et al.* (2013) showed n-type organic phototransistors using core expanded naphthalene diimides fused with two 2-(1,3-dithiol-2-ylidene)malononitrile moieties (NDI-DTYM2) bears one N-alkyl chain and one aromatic phenyl group, (NDI(2OD)(4tBuPh)-DTYM2). Organic phototransistors with highly aligned crystalline 2,7-dioctyl[1]benzothieno[3,2-b][1]benzothiophene (C8-BTBT) films, which exhibited strong responses under weak UV

Fig. 11 Small molecules used for organic phototransistors: tetracene, 2,7-dioctyl[1]benzothieno[3,2-b][1]benzothiophene (C8-BTBT), dinaphtho[2,3-b:2',3'-f]thieno[3,2-b]thiophene (DNTT), perylene-3,4,9,10-tetracarboxylic dianhydride (PTCDA), core-expanded naphthalene diimides fused with two 2-(1,3-dithiol-2-ylidene)malononitrile moieties (NDI-DTYM2) bears one N-alkyl chain and one aromatic phenyl group, (NDI(2OD)(4tBuPh)-DTYM2), and 3,6-Bis(5-(benzofuran-2-yl)thiophen-2-yl)-2,5-bis(2-ethylhexyl)pyrrolo[3,4-c]pyrrole-1,4(2H,5H)-dione (DPP(TBFu)₂).

illumination, were reported by Yuan and Huang (2016); Chu *et al.* (2016) demonstrated high photosensitivity from flexible organic phototransistors using dinaphtho[2,3-b:2',3'-f]thieno[3,2-b]thiophene (DNTT) as an organic sensing channel layer. Fig. 11 shows various small molecules used for organic phototransistors.

Organic Layer – Bulk Heterojunction

Peng *et al.* (2013) reported organic phototransistors with the bulk heterojunction layers of PbPc and PTCDA, which showed superior performances compared to single component-based devices and high photo-responsivity in the near infrared region. Zhang *et al.* (2013) demonstrated organic phototransistors with solution-processable bulk heterojunction layers of 3,6-Bis(5-(benzofuran-2-yl)thiophen-2-yl)-2,5-bis(2-ethylhexyl)pyrrolo[3,4-c]pyrrole-1,4(2H,5H)-dione (DPP(TBFu)₂) and PC₇₁BM and studied field-assisted charge separation in small molecular bulk heterojunction structure. It has been also reported by Xu *et al.* (2015) that solution-processed ambipolar organic phototransistors can be fabricated with microphase-separated bulk heterojunction films from solutions of p-type (silylthynylated pentacene) and n-type (silylthynylated tetraazapentacene). This study was demonstrated that photo-effects were associated with a shift of threshold voltage because of photoinduced charge carriers.

Organic Phototransistors With Polymers

Organic Layer – Single Material

Narayan and Kumar (2001) demonstrated polymer-based phototransistors with regioregular poly(3-octylthiophene-2,5-diyl) (P3OT) films for a low intensity optical detection, while wavelength-selective phototransistors with dye-doped P3HT films were also reported by Meixner *et al.* (2006); Li *et al.* (2014) showed that organic phototransistors can be fabricated by employing a

Fig. 12 Conjugated polymers used for organic phototransistors: PQBOC8 that was synthesized by Suzuki coupling reaction between 2,9-diboronic ester-N,N'-di(2-octyldodecyl)quinacridone and 4,7-bis(5-bromothiophen-2-yl)-5,6-bis(octyloxy)-benzothiadiazole, PBIBDF-BT that contains electron-rich bithiophene (BT) and electron deficient bis(2-oxindolin-3-ylidene)-benzodifuran-dione (BIBDF), and poly(3,3'-didodecylquaterthiophene) (PQT-12).

Fig. 13 (a) Materials and device structure for all-polymer phototransistors with the P3HT:THBT-ht layer. (b) Optical density (OD) as a function of wavelength (λ) for the pristine polymer and bulk heterojunction (P3HT:THBT-ht) layers. (c) Comparison of HOMO and LUMO levels for P3HT and THBT-ht. (Copyright 2016 IEEE).

simple self-assembly process in a large area at chloroform/water interface using ultrathin crystalline p-type semiconductor (PQBOC8) that was synthesized by Suzuki coupling reactions between 2,9-diboronate ester- N,N' -di(2-octyldodecyl)quinacridone and 4,7-bis(5-bromothiophen-2-yl)-5,6-bis(octyloxy)-benzothiadiazole. Lee *et al.* (2016) reported organic phototransistors with highly flexible nanofiber based on poly(3,3-didodecylquaterthiophene) (PQT-12) and poly(ethylene oxide) (PEO) as a semi-conducting polymer and a processing aid component, respectively. A couple of conjugated polymers for organic phototransistors are shown in Figs. 12 and 13.

Organic Layer – Bulk Heterojunction

Hwang *et al.* (2011) demonstrated organic phototransistors with the nanoscale phase-separated polymer:polymer bulk heterojunction films of p-type P3HT and n-type poly(9,9-dioctylfluorene-*co*-benzothiadiazole) (F8BT). Han *et al.* (2015)

Fig. 14 (a) (left) Device structure for organic phototransistor with all-polymer bulk heterojunction (P3HT:PEHTPPD-BT) layer and (right) optical absorption spectra for the indium tin oxide (ITO) glass substrate and the P3HT:PEHTPPD-BT layer-coated ITO-glass substrate (see the photograph “2” compared with the photograph “1” of the P3HT layer-coated ITO-glass substrate). (b) Photographs for flexible plastic organic phototransistors with the P3HT:PEHTPPD-BT layers, which are bended at an angle of ~ 30 degree for the measurement of phototransistor performances (note that the green light was roughly illuminated as a guide for the channel part). (c) Low-voltage operation (upon bending at 30 degree) of the optimized flexible plastic organic phototransistors under illumination with near-infrared (NIR) (1000 nm) lights: (left) output curves and (right) repeated on/off modulation. (Copyright 2015 Nature Publishing Group).

demonstrated that all-polymer phototransistors, which were fabricated with the nanostructured bulk heterojunction layers of P3HT and poly[$\{2,5\text{-bis-(2-ethylhexyl)-3,6-bis-(thien-2-yl)-pyrrolo[3,4-c]pyrrole-1,4-diyl}\}-\text{co-}\{2,2'-(2,1,3\text{-benzothiadiazole})\}-5,5'\text{-diyl}\}$] (PEHTPPD-BT), can sense a broadband light from visible to near infrared region (see Fig. 14). Han *et al.* (2016) reported all-polymer phototransistors with the polymer:polymer bulk heterojunction layers of p-type P3HT and n-type hexylthiophene-end capped poly(3-hexylthiophene-co-benzothiadiazole) (THBT-ht) (see Fig. 13). All-polymer phototransistors with P3HT and poly[$\{4,8\text{-bis(2-ethylhexyloxy)-benzo[1,2-b:4,5-b']\text{-dithiophene}-2,6\text{-diyl-alt-(N-2-ethylhexylthieno[3,4-c]pyrrole-4,6-dione)-2,6\text{-diyl}\}$] (PBDITPD) were also demonstrated by Nam *et al.* (2016). These reports support that all-polymer (polymer:polymer) bulk heterojunctions play an efficient role in improving the photosensitivity of organic phototransistors (Fig. 15).
